Robust Positive Consensus for Heterogeneous Multi-agent Systems

Ruonan Li, Yutao Tang, and Shurong Li *

Abstract: This paper investigates a robust positive consensus problem for a class of heterogeneous highorder multi-agent systems subject to external inputs. Compared with existing multi-agent consensus results, the most distinct feature of the formulated problem is that the state variables of all heterogeneous agents are confined in the positive orthant. To solve this problem, we present a two-step design procedure. By constructing an auxiliary multi-agent system as positive local reference generators, we incorporate the reference generator into some applicable decentralized robust tracking controller for each agent. The proposed distributed algorithm is proven to ensure a robust consensus fulfilling certain prescribed pattern for the multi-agent system under switching topology in the sense of finite-gain stability with respect to the external inputs. A simulation example is finally given to illustrate the effectiveness of our design.

Keywords: positive consensus, distributed control, multi-agent systems, switching topology.

1 Introduction

Over the past decades, there has been a tremendous expansion of the research on the multi-agent coordination problem due to its wide applications in sensor networks, robotics, and power systems. Particularly, the fundamental consensus problem has been intensively studied and generalized for various kinds of agent dynamics from integrators to general linear systems and also typical classes of nonlinear ones under different communication topologies, to name a few, [1–11].

In practical applications arising in the areas of chemical process industry, electronic circuit design, communication networks, and biology, we may face an important class of multi-agent systems composed of a group of positive subsystems. Different from standard multi-agent systems, the state variables of positive agents are confined to the positive orthant. Although we might view the whole positive multi-agent systems as a single but large-scale positive systems, the coordination of positive multi-agent systems suffers from at least two extra difficulties compared with conventional designs for a single positive plant [12–16]. First, the controller for each agent (as an individual input channel) is not allowed to use the full state of the whole multi-input multi-output systems and the information flow among the agents should be compatible with some prior (time-varying) structure. Second, we have to ensure the positivity of the state variables of each agent, which might have different dimensions and be affected by others. These two aspects together make the coordination problem of multiple positive systems much more challenging. As a consequence, compared with the intensive research for conventional standard multi-agent systems, distributed coordination results for general positive multi-agent systems are relatively few.

Ruonan Li, Yutao Tang, and Shurong Li are all with the School of Artificial Intelligence, Beijing University of Posts and Telecommunications, Beijing, China (e-mails: nanruoliy@163.com, yttang@bupt.edu.cn, lishurong@bupt.edu.cn).

Meanwhile, integrators are typical positive systems. Thus, the classical integrator-type multi-agent systems are naturally interconnected positive multi-agent systems. Although the positive constraint is not required in designing rules for single-integrator multi-agent systems, the fundamental consensus dynamics are indeed positive. In [17], such a positive constraint was explicitly discussed in the consensus problem for some positive linear multi-agent systems. Necessary and sufficient conditions for the consensusability of all agents were derived under the positive constraint. Note that the positive consensus in this work was achieved via solving a positive static output feedback stabilization problem for the whole multi-agent system. Further efforts along this technical line have been made in [18–20] using state feedback. Moreover, some authors considered dynamic rules to relax the required conditions, e.g., [21–23]. However, all these positive consensus results are only derived for homogeneous multi-agent systems where all agents share the identical dynamics. Noticing the various kinds of conventional consensus results for different classes of multi-agent systems, it is natural for us to ask whether and how the positive consensus problem can be solved for heterogeneous multi-agent systems.

On the other hand, the agents' dynamics may not be perfectly known due to various uncertainties from either inaccurate modeling or environmental disturbances. Note that the controllers designed for nominal dynamics might fail to ensure the same performance for physical plants and probably cause some instability issues. Thus, it is crucial to take the robustness of controllers into account when solving the multi-agent coordination problems. Although many interesting results have been delivered for single positive systems in the literature, e.g., [24–26], it is not clear how to extend these results to positive multi-agent systems for a robust consensus.

Based on the aforementioned observations, we will focus on a group of heterogeneous positive linear multi-agent systems where the agent dynamics are allowed to be different from each other in both system matrices and the dimension of state spaces. Moreover, we assume the agents are subject to external inputs in the dynamics. We aim at distributed rules for these positive agents to reach an output consensus corresponding to some predefined pattern with their state variables being positive. Since the agents' dynamics are high-order and subject to external inputs, we expect that an exact output consensus can be asymptotically ensured for the nominal multi-agent systems while such performance is robust with respect to these external inputs. Note that we have to achieve the expected robust consensus goal and ensure the positive constraints for each agent simultaneously. Hence the considered robust positive consensus problem for these heterogeneous positive agents has some exclusive challenges in contrast to existing (robust) consensus results for standard linear multi-agent systems or positive consensus for homogeneous multi-agent systems.

To overcome the difficulties brought by the positive constraint and heterogeneous uncertain agent dynamics, we constructively present a two-step procedure. First, we construct an auxiliary multi-agent system as a positive local reference generator for each agent. Then, we design an effective robust tracking controller and bring the two parts together with rigor solvability analysis to solve the robust positive consensus problem. The contributions of this paper can be summarized as follows:

- A robust positive consensus problem is formulated for a group of high-order positive multi-agent systems subject to external inputs. Our problem is an extended version of existing positive consensus results with exactly known agent dynamics [18, 20, 23].
- Compared with existing positive consensus results for homogeneous multi-agent systems, both state and output feedback controllers are provided to remove the identical agent dynamics requirement and allow the consensus trajectory to meet some prespecified pattern including the finite constant as special cases.

The rest of this paper is organized as follows. We first introduce some preliminaries on our notations and positive system in Section 2. Then we present the formulated robust positive consensus problem in Section 3. The main results are given in Section 4. We also provide a simulation example to illustrate the effectiveness of our algorithms in Section 5 along with conclusions in Section 6.

2 Preliminary

In this section, we introduce some preliminaries on our notations and positive systems.

Let \mathbb{R}^n be the *n*-dimensional real space. Denote by $\mathbb{R}^{n \times m}$ the set of all $n \times m$ matrices with entries in \mathbb{R} . Let \mathbb{I}_n be the *n*-dimensional identity matrix. **1** (or **0**) denotes an all-one (or all-zero) matrix or vector with proper dimensions. $\operatorname{col}(a_1, \ldots, a_n) = [a_1^\top, \ldots, a_n^\top]^\top$ for column vectors a_i $(i = 1, \ldots, n)$ with compatible dimensions. Let $\operatorname{diag}(b_1, \ldots, b_n)$ represent an $n \times n$ diagonal matrix with diagonal elements b_1, \ldots, b_n . For matrices B_1, \ldots, B_n , blkdiag (B_1, \ldots, B_n) represents the block diagonal matrix with diagonal blocks B_1, \ldots, B_n . For a vector x (or matrix A), ||x|| (or ||A||) denotes its Euclidean (or spectral) norm.

Let \mathbb{R}^n_+ be the nonnegative orthant. Denote the set of all $m \times n$ matrices with each entry in \mathbb{R}_+ by $\mathbb{R}^{m \times n}_+$. We say such matrices are nonnegative and adopt the notation $A \ge \mathbf{0}$. If, in addition, A has at least one positive entry, we say A is positive $(A > \mathbf{0})$. If all the entries are positive, we say A is strictly positive $(A \gg \mathbf{0})$. $A < \mathbf{0}$ (or $\leq \mathbf{0}$) if $-A > \mathbf{0} (\geq \mathbf{0})$. The nonnegativity, positivity, and strict positivity of vectors can be defined likewise. For a square matrix $A, A \in \mathbb{H}$ means A is Hurwitz, i.e., its eigenvalues have negative real parts. A is Metzler if the off-diagonal entries are nonnegative, which is equivalent to $A \in \mathbb{M}$. $P \succ (\prec) 0$ means P is a positive (negative) definite matrix, i.e. $x^\top Px > (<) 0$ for every $x \neq \mathbf{0}$.

Consider the following (time-varying) linear system:

$$y(t) = C(t)x(t), \quad \dot{x}(t) = A(t)x(t) + B(t)u(t)$$
 (1)

where x(t) is the *n*-dimensional state vector, u(t) is the *p*-dimensional control input, y(t) is the *l*dimensional output vector. Here, A(t), B(t), C(t) are system matrices with compatible dimensions. We say this system is (internally) positive if for any nonnegative initial condition $x(0) \ge \mathbf{0}$ and $u(t) \ge \mathbf{0}$, it holds that $x(t) \ge \mathbf{0}$ and $y(t) \ge \mathbf{0}$ for $t \ge 0$. It is said to be a Metzler system if A(t) is Metzler and B(t), $C(t) \ge \mathbf{0}$ for almost all $t \ge 0$.

Here is a lemma modified from [27].

Lemma 1 If (1) is a Metzler system then it is positive. Conversely, if (1) is positive and A(t), B(t), C(t) are continuous, then (1) is a Metzler system.

3 Problem Formulation

In this paper, we consider a multi-agent system consisting of N high-order dynamic agents of the following form:

$$y_i(t) = C_i x_i(t), \, \dot{x}_i(t) = A_i x_i(t) + B_i u_i(t) + D_i d(t)$$
(2)

where $x_i(t) \in \mathbb{R}^{n_i}$, $u_i(t) \in \mathbb{R}^{m_i}$, and $y_i(t) \in \mathbb{R}^l$ are the state, input, and output of agent $i = 1, \ldots, N$, while $d(t) \ge \mathbf{0} \in \mathbb{R}^q$ represents some unmodeled time-varying external input (or disturbance) acting on agent *i*. Here the external inputs are considered to be identical for each agent without loss of generality. Otherwise, we can lump all local external inputs together and redefine the associated input matrix D_i for the same form (2). Moreover, we assume matrix A_i is Metzler, B_i , C_i , D_i are nonnegative, and the disturbance d(t) is locally essentially bounded.

We aim at effective controllers for the agents such that this multi-agent system can reach a positive output consensus specified by the following pattern:

$$y_0(t) = C_0 x_0(t), \, \dot{x}_0(t) = A_0 x_0(t) \tag{3}$$

with internal state $x_0(t) \in \mathbb{R}^{n_0}$ and output $y_0(t) \in \mathbb{R}^l$. In other words, the output trajectory of each agent is expected to reach some solution to this differential equation simultaneously. Since the agent is subject to external inputs, we expect that the patterned consensus error converges to zero when $d(t) \equiv \mathbf{0}$ while the influence of external inputs is attenuated to certain level when it is nonzero.

Moreover, we are interested in distributed designs for this problem and assume the agents can share their own information with others. For this purpose, we utilize an undirected graph $\mathcal{G} = \{\mathcal{N}, \mathcal{E}, \mathcal{A}\}$ to represent the allowed information flow among them with node set $\mathcal{N} = \{1, \ldots, N\}$, edge set $\mathcal{E} \subset \mathcal{N} \times \mathcal{N}$, and the symmetric adjacency matrix $\mathcal{A} = [a_{ij}]_{N \times N}$ ([28]). When agents *i* and *j* can exchange information, there is an edge between them in this graph \mathcal{G} . For simplicity, we assume $a_{ij} = a_{ji} = 1$ in this case and $a_{ij} = 0$ otherwise. Node *i*'s neighbor set is defined as $\mathcal{N}_i = \{j \mid (j, i) \in \mathcal{E}\}$. We denote $\mathcal{N}_i^0 = \mathcal{N}_i \cup \{i\}$. Moreover, we consider the case when the communication topology may be time-varying. To describe the communication constraint precisely, we denote all possible communication graphs among these agents by $\{\mathcal{G}_1, \ldots, \mathcal{G}_p\}$ with $\mathcal{P} = \{1, 2, \ldots, p\}$. Consider a strictly increasing sequence of positive constants $\{t_i\}$ with $t_0 = 0$ and $\lim_{\iota \to \infty} t_{\iota} = \infty$. We suppose $t_{\iota+1} - t_{\iota} \geq \tau > 0$ for any $\iota = 0, 1, \ldots$ as that in [2, 3]. This sequence divides $[0, \infty)$ into some contiguous time intervals $[t_{\iota}, t_{\iota+1})$. Define a switching signal $\sigma(t): [0, \infty) \to \mathcal{P}$. It is time-dependent and piece-wise constant. During each $[t_{\iota}, t_{\iota+1})$, all the agents can share their information according to graph $\mathcal{G}_{\sigma(t)}$.

The considered robust positive consensus problem can be formulated as follows.

Problem 1 Given a multi-agent system (2), graph \mathcal{G}_p , the consensus pattern (3), and a constant $\gamma > 0$, find distributed controllers of the following form:

$$u_{i} = f_{i}(t, x_{j}, \eta_{j}), \, \dot{\eta}_{i} = g_{i}(t, x_{j}, \eta_{j}), \, j \in \mathcal{N}_{i}^{0}(t)$$
(4)

with proper smooth functions f_i , g_i and a compensator $\eta_i \in \mathbb{R}^{n_{\eta_i}}$ such that, for any initial point $x_i(0) \ge \mathbf{0}$, the closed-loop system (2) and (4) satisfies the following properties.

- 1) The trajectory of $x_i(t)$ is always nonnegative, i.e., $x_i(t) \ge 0$ for any $t \ge 0$.
- 2) It internally achieves a patterned consensus specified by system (3). That is, there exists a positive constant $x_{00} \in \mathbb{R}^{n_0}_+$ such that, $e_i(t) \triangleq y_i(t) y_0(t)$ converges to **0** as $t \to \infty$ with $y_0(t) = C_0 x_0(t)$ and $x_0(t)$ the corresponding trajectory of (3) starting from $x_0(0) = x_{00}$.
- 3) The influence of external inputs is attenuated such that the following inequality

$$\int_0^\infty \|e_i(s)\|^2 \mathrm{d}s \le \gamma^2 \int_0^\infty \|d(s)\|^2 \mathrm{d}s + \kappa$$

holds for some positive constant κ .

The formulated problem has been partially discussed in the literature for standard nonpositive multiagent systems under the name of output consensus or synchronization in [1, 29, 30]. Some recent attempts have been made in extending them to positive multi-agent systems assuming $A_0 = \mathbf{0}$ [17, 18, 20, 23]. However, the obtained positive consensus results often require all agents share an identical high-order

Figure 1: Illustration of two-step design scheme.

dynamics. Here, we consider heterogeneous agent dynamics subject to external inputs and aim to ensure a nontrivial pattern consensus and states' positivity simultaneously.

Before the main results, we make several extra assumptions to ensure the solvability of our problem as follows.

Assumption 1 Matrix A_0 is Metzler with no eigenvalues having negative real parts.

Assumption 2 Each graph \mathcal{G}_p is connected.

Assumption 3 For each i = 1, 2, ..., N, there exist constant matrices $X_i \in \mathbb{R}^{n_i \times n_0}_+$ and $U_i \in \mathbb{R}^{1 \times n_i}_+$ such that

$$A_i X_i + B_i U_i - X_i A_0 = \mathbf{0}$$

$$C_i X_i - C_0 = \mathbf{0}$$
(5)

Since the agents are positive, we assume the consensus pattern is also positive with nontrivial modes as stated in Assumption 1. Assumption 2 is made to ensure the connectivity of the communication graphs. Under this assumption, the potential number of digraphs are finite and the Laplacian L_p of each graph \mathcal{G}_p is positive semidefinite with a simple zero eigenvalue. Assumption 3 is known as the solvability of regulator equations for plant (2) with an exosystem (3) in the terminology of output regulation [31]. Similar conditions have been widely used in the multi-agent literature, e.g., [4, 6, 32].

4 Main Result

This section is devoted to the design of effective distributed controllers for each agent to solve our problem.

4.1 Two-step design scheme

To hurdle the corresponding difficulties from agent dynamics and positive constraints, we present a twostep design to solve our problem. The basic layered structure is shown in Fig. 1. We will first construct an auxiliary multi-agent system as local reference generators for each agent to meet the consensus pattern. After that, we will focus on the resultant tracking problem for the original agents. In this way, the full controller for each agent consists of a reference generator and an effective tracking controller.

According to our two-step scheme, we first present the following auxiliary multi-agent system with the same system matrix in pattern dynamics (3):

$$\dot{w}_i = A_0 w_i + \mathbb{I}_{n_0} v_i \tag{6}$$

where $w_i \in \mathbb{R}^{n_0}$ is the virtual state and v_i the virtual input. Consider the typical distributed controller for agent (6) as $v_i = \mu \sum_{j=1}^{N} a_{ij}(t)(w_j - w_i)$. The resultant reference generator is thus given as

$$\dot{w}_i = A_0 w_i + \mu \sum_{j=1}^N a_{ij}(t)(w_j - w_i), \quad i \in \mathcal{N}$$
(7)

Let $w_{av}(t) = \frac{\sum_{i=1}^{N} w_i(t)}{N}$, $\tilde{w}_i(t) = w_i(t) - w_{av}(t)$, and $\tilde{w} = \operatorname{col}(\tilde{w}_1, \ldots, \tilde{w}_N)$. It can be verified that

$$\dot{w}_{\rm av} = A_0 w_{\rm av} \tag{8}$$

with an initial point $w_{av}(0) = \frac{\sum_{i=1}^{N} w_i(0)}{N}$. That is, the trajectory $w_{av}(t)$ is an admissible solution to the expected pattern dynamics (3).

Since there are a finite number of graphs fulfilling Assumption 2, $\underline{\lambda} \triangleq \min_{p \in \mathcal{P}} \{\lambda_2(L_p)\}$ is well-defined and strictly greater than 0. Here is a key lemma on the performance of virtual positive multi-agent system (7).

Lemma 2 Suppose Assumptions 1-2 holds. Let $\mu \geq \frac{\|A_0\|}{\underline{\lambda}} + 1$. Then, along the trajectory of system (7), it holds that $w_i(t) \geq \mathbf{0}$ and $\|\tilde{w}_i(t)\| \leq \|\tilde{w}(0)\| e^{-\underline{\lambda}t}$ for any initial condition $w_i(0) \geq \mathbf{0}$.

Proof. We first put (6) into a compact form:

$$\dot{w} = (\mathbb{I}_N \otimes A_0 - \mu L_{\sigma(t)} \otimes \mathbb{I}_{n_0})w$$

where $w = \operatorname{col}(w_1, \ldots, w_N)$. Since A_0 and $-L_p$ are Metzler for any $p \in \mathcal{P}$, $(\mathbb{I}_N \otimes A_0 - \mu L_p \otimes \mathbb{I}_{n_0})$ is also Metzler for any $\mu > 0$. Then, we can conclude that the positivity of w(t) for $t \ge 0$ by Lemma 1 from any $w_i(0) \ge \mathbf{0}$.

Next, we prove the positive consensus of $w_i(t)$. Recalling equation (8), it is sufficient to prove the exponential stability of the following error system at the origin:

$$\dot{\tilde{w}} = (\mathbb{I}_N \otimes A_0 - \mu L_{\sigma(t)} \otimes \mathbb{I}_{n_0})\tilde{w}$$
(9)

For this purpose, we introduce two matrices $M_1 \in \mathbb{R}^{N \times 1}$ and $M_2 \in \mathbb{R}^{N \times (N-1)}$. Here, $M_1 = \frac{1}{\sqrt{N}}$ and M_2 be a matrix such that $M_1^{\top} M_2 = \mathbf{0}$, $M_2^{\top} M_2 = \mathbb{I}_{N-1}$, and $M_1 M_1^{\top} + M_2 M_2^{\top} = \mathbb{I}_N$. Let $\check{w}_1 = (M_1^{\top} \otimes \mathbb{I}_{n_0}) \tilde{w}$ and $\check{w}_2 = (M_2^{\top} \otimes \mathbb{I}_{n_0}) \tilde{w}$. It can be verified that $\dot{\check{w}}_1 = (M_1^{\top} \otimes A_0) \tilde{w} = \mathbf{0}$ and $\check{w}_1(t) \equiv \mathbf{0}$ by the definition of $w_{av}(t)$ and the property $\mathbf{1}^{\top} L_p = \mathbf{0}$ under Assumption 2. This further implies that

$$\dot{\check{w}}_2 = [\mathbb{I}_{N-1} \otimes A_0 - \mu(M_2^\top L_{\sigma(t)} M_2) \otimes \mathbb{I}_{n_0}] \check{w}_2$$

It can be verified that the matrix $M_2^{\top} L_{\sigma(t)} M_2$ is positive definite with only real eigenvalues $0 < \lambda_2(L_{\sigma(t)}) \le \cdots \le \lambda_N(L_{\sigma(t)})$ under Assumption 2.

Let us choose a candidate of common Lyapunov function $V_{\tilde{w}} = \frac{1}{2}\tilde{w}^{\top}\tilde{w}$ for the switched positive linear system (9). It can be found that $V_{\tilde{w}} = \frac{1}{2}\check{w}_1^{\top}\check{w}_1 + \frac{1}{2}\check{w}_2^{\top}\check{w}_2 = \frac{1}{2}\check{w}_2^{\top}\check{w}_2$ along the trajectory of system (9). We assume $\sigma(t) = p$ during $[t_k, t_{k+1})$. Since $M_2^{\top}L_pM_2$ is positive definite, there must be a unitary matrix $U_p \in \mathbb{R}^{(N-1)\times(N-1)}$ such that $U_p^{\top}[M_2^{\top}L_{\sigma(t)}M_2]U_p = D_p$ where D_p is a diagonal matrix with the eigenvalues $\lambda_2(L_p), \ldots, \lambda_N(L_p)$ on the diagonal. Let $\tilde{\check{w}}_2 = (U_p^{\top} \otimes \mathbb{I}_{n_0})\check{w}_2$. During this time interval, we have

$$\bar{\check{w}}_2 = (\mathbb{I}_{N-1} \otimes A_0 - \mu D_P \otimes \mathbb{I}_{n_0}) \bar{\check{w}}_2$$

Note that $\mathbb{I}_{N-1} \otimes A_0 - \mu D_P \otimes \mathbb{I}_{n_0}$ is a block diagonal matrix with diagonal blocks of the form $A_0 - \mu \lambda_i(L_p)\mathbb{I}_{n_0}$ for i = 2, ..., N. Jointly using the fact that $\check{w}_2^{\top}\check{w}_2 = \check{w}_2^{\top}\check{w}_2$, we set μ as in the theorem condition and obtain

$$\dot{V}_{\tilde{w}} = \bar{w}_{2}^{\top} (\mathbb{I}_{N-1} \otimes A_{0} - \mu D_{P} \otimes \mathbb{I}_{n_{0}}) \bar{w}_{2}$$
$$\leq (\|A_{0}\| - \mu \lambda_{2}(L_{p})) \|\tilde{w}_{2}\|^{2} \leq -2\underline{\lambda} V_{\tilde{w}}$$

It is verified that this inequality holds for any $p \in \mathcal{P}$ and thus holds over $[0, \infty)$. According to Theorem 3.1 in [14], $\tilde{w}_i(t)$ exponentially converges to zero as $t \to \infty$. Solving this inequality gives $V_{\tilde{w}}(t) \leq V_{\tilde{w}}(0)e^{-2\underline{\lambda}t}$. It follows then

$$\|\tilde{w}_i(t)\| \le \|\tilde{w}(t)\| = \sqrt{2V_{\tilde{w}}(t)} \le \|\tilde{w}(0)\|e^{-\underline{\lambda}t}$$

The proof is thus completed.

Lemma 2 is motivated by the observer-based designs in [4, 6]. With this lemma, we will embed the auxiliary generator into some reference tracking controller for agent (2) to solve the formulated positive patterned consensus problem in the next subsection.

4.2 Algorithm design and solvability analysis

In this subsection, we combine the reference generator (7) with a robust tracking controller towards the final distributed controller for multi-agent system (2).

Since each agent has positive linear dynamics, we consider distributed controllers of the following form:

$$u_{i} = K_{1i}x_{i} + K_{2i}w_{i}$$

$$\dot{w}_{i} = A_{0}w_{i} + \mu \sum_{j=1}^{N} a_{ij}(t)(w_{j} - w_{i}), \quad i \in \mathcal{N}$$
(10)

where μ is chosen as above and K_{1i} , K_{i2} are matrices to be specified later.

Here is the main result of this paper.

Theorem 1 Suppose Assumptions 1–3 hold. The formulated robust positive consensus problem with a given pattern (3) and performance level $\gamma > 0$ is solved by a distributed controller of the form (10) if there exist diagonal matrices $Q_1 \ldots, Q_N > \mathbf{0}$ and a scalar $\delta > 0$ such that the following inequalities hold:

$$A_i Q_i - B_i B_i^{\top} + \delta Q_i > \mathbf{0}$$

$$Q_i A_i^{\top} + A_i Q_i - 2B_i B_i^{\top} + \frac{1}{\gamma^2} D_i D_i^{\top} + Q_i C_i^{\top} C_i Q_i \prec \mathbf{0}$$

$$(11)$$

Proof. We attach the controller (10) to agent (2) and obtain the following composite system:

$$\dot{x}_{i} = (A_{i} + B_{i}K_{1i})x_{i} + B_{i}K_{2i}w_{i} + D_{i}d(t)$$

$$\dot{w}_{i} = A_{0}w_{i} + \mu \sum_{j=1}^{N} a_{ij}(t)(w_{j} - w_{i})$$

$$y_{i} = C_{i}x_{i}, \quad i \in \mathcal{N}$$

(12)

To ensure the solvability of our problem, we choose $K_{1i} = -B_i^{\top}Q_i^{-1}$ and $K_{2i} = U_i - K_{1i}X_i$ with Q_i, U_i , and X_i defined as above. We are going to verify the three required properties in the formulation section.

We first show the closed-loop system is indeed positive. In fact, according to (11), the matrix $\bar{A}_i = A_i + B_i K_{1i}$ is Metzler by definition. Meanwhile, the matrices $-K_{1i}$ and K_{2i} can be found to be nonnegative.

Hence, by Lemma 1, the x_i -subsystem is positive with w_i and d(t) as its input. Since $w_i(t) > 0$ by Lemma 2, we have that from any $x_i(0) > 0$, $x_i(t) > 0$ holds for any $t \ge 0$.

Next, we verify the second property in our formulation. We suppose $d(t) \equiv \mathbf{0}$ and show that there exists some $x_{00} \geq \mathbf{0}$ such that $e_i(t)$ converges to zero as $t \to \infty$ in this case. That is, the patterned consensus is indeed reached under this controller (10). To this end, we can verify that

$$Q_i \bar{A}_i^\top + \bar{A}_i Q_i = Q_i (A_i - B_i B_i^\top Q_i^{-1})^\top + (A_i - B_i B_i^\top Q_i^{-1}) Q_i$$
$$= Q_i A^\top + A_i Q_i - 2B_i B_i^\top \prec \mathbf{0}$$

Thus \bar{A}_i is Hurwitz. Moreover, one can further determine some $c_0 > 0$ such that $Q_i \bar{A}_i^\top + \bar{A}_i Q_i \prec -c_0 Q_i^2$ holds for any *i*. By our two-step design procedure and Lemma 2, we set $x_{00} = w_{av}(0)$. Then, $e_i(t) = C_i x_i(t) - C_0 w_{av}(t)$. Performing the coordinate transformation $\tilde{x}_i = x_i - X_i w_{av}$, we have

$$\dot{\tilde{x}}_{i} = (A_{i} + B_{i}K_{1i})\tilde{x}_{i} + B_{i}K_{2i}\tilde{w}_{i}$$

$$\dot{\tilde{w}} = (\mathbb{I}_{N} \otimes A_{0} - \mu L_{\sigma(t)} \otimes \mathbb{I}_{n_{0}})\tilde{w}$$

$$e_{i} = C_{i}\tilde{x}_{i}$$
(13)

Choose $V_i(t) = \tilde{x}_i^{\top}(t)Q_i^{-1}\tilde{x}_i(t) + \iota_i V_{\tilde{w}}(t)$ with a constant $\iota_i > 0$ to be determined later. It is positive definite in $[\tilde{x}_i^{\top}(t), \tilde{w}(t)^{\top}]^{\top}$. Recalling the proofs in Lemma 2, we take its time derivative along the trajectory of (13) and obtain

$$\begin{split} \dot{V}_{i}(t) &= 2\tilde{x}_{i}^{\top}Q_{i}^{-1}[(A_{i}+B_{i}K_{1i})\tilde{x}_{i}+B_{i}K_{2i}\tilde{w}_{i}] + \iota_{i}\dot{V}_{\tilde{w}} \\ &\leq 2\tilde{x}_{i}^{\top}Q_{i}^{-1}(A_{i}Q_{i}-B_{i}B_{i}^{\top})Q_{i}^{-1}\tilde{x}_{i} \\ &+ 2\tilde{x}_{i}^{\top}Q_{i}^{-1}B_{i}K_{2i}\tilde{w}_{i} - 2\iota_{i}\underline{\lambda}V_{\tilde{w}} \\ &\leq -c_{0}\|\tilde{x}_{i}\|^{2} + 2\|Q_{i}^{-1}B_{i}K_{2i}\|\|\tilde{x}_{i}\|\|\tilde{w}_{i}\| - 2\iota_{i}\underline{\lambda}V_{\tilde{w}} \end{split}$$

We complete the square and have

$$\dot{V}_i(t) \le -\frac{c_0}{2} \|\tilde{x}_i\|^2 - (\iota_i \underline{\lambda} - \frac{2}{c_0} \|Q_i^{-1} B_i K_{2i}\|^2) \|\tilde{w}\|^2$$

Letting $\iota_i \geq \frac{2}{\underline{\lambda}} \max\{\frac{2}{c_0} \|Q_i^{-1} B_i K_{2i}\|^2, 1\}$ implies

$$\dot{V}_i(t) \le -\frac{c_0}{2} \|\tilde{x}_i\|^2 - \|\tilde{w}\|^2$$

According to Theorem 3.1 in [14], $V_i(t)$ and $\tilde{x}_i(t)$ both exponentially converge to 0 as $t \to \infty$. As a result, the tracking error $e_i(t) = C_i \tilde{x}_i(t)$ also converges to **0** exponentially fast. This means that the agent outputs indeed reach a positive consensus and the consensus confirms the pattern specified by (3) when the external input d(t) vanishes.

To confirm the third property, we use the same Lyapunov function V_i and take its time derivative along the trajectory of system (13). It follows then

$$\begin{split} \dot{V}_{i} &= 2\tilde{x}_{i}^{\top}Q_{i}^{-1}[(A_{i}+B_{i}K_{1i})\tilde{x}_{i}+B_{i}K_{2i}\tilde{w}_{i}+E_{i}d(t)] + \iota_{i}\dot{V}_{\tilde{w}} \\ &\leq 2\tilde{x}_{i}^{\top}Q_{i}^{-1}(A_{i}Q_{i}-B_{i}B_{i}^{\top})Q_{i}^{-1}\tilde{x}_{i} \\ &+ 2\tilde{x}_{i}^{\top}Q_{i}^{-1}B_{i}K_{2i}\tilde{w}_{i} + 2\tilde{x}_{i}^{\top}Q_{i}^{-1}E_{i}d(t) - 2\iota_{i}\underline{\lambda}V_{\tilde{w}} \end{split}$$

Under the theorem conditions, there exists some small constant $\tilde{c}_0 > 0$ such that the following inequality holds:

$$Q_i A_i^\top + A_i Q_i - 2B_i B_i^\top + \frac{1}{\gamma^2} E_i E_i^\top + Q_i C_i^\top C_i Q_i \prec -\tilde{c}_0 Q_i^2$$

With this inequality, we further have

$$\begin{split} \dot{V}_{i}(t) &\leq -\tilde{c}_{0} \|\tilde{x}_{i}\|^{2} - \tilde{x}_{i}^{\top} Q_{i}^{-1} (\frac{1}{\gamma^{2}} E_{i} E_{i}^{\top} + Q_{i} C_{i}^{\top} C_{i} Q_{i}) Q_{i}^{-1} \tilde{x}_{i} \\ &+ 2\tilde{x}_{i}^{\top} Q_{i}^{-1} B_{i} K_{2i} \tilde{w}_{i} + 2\tilde{x}_{i}^{\top} Q_{i}^{-1} E_{i} d(t) - 2\iota_{i} \underline{\lambda} V_{\tilde{w}} \\ &\leq -\frac{\tilde{c}_{0}}{2} \|\tilde{x}_{i}\|^{2} - (\iota_{i} \underline{\lambda} - \frac{2}{\tilde{c}_{0}} \|Q_{i}^{-1} B_{i} K_{2i}\|^{2}) \|\tilde{w}\|^{2} \\ &+ \gamma^{2} \|d(t)\| - \|e_{i}\|^{2} \end{split}$$

By letting $\iota_i \geq \frac{2}{\underline{\lambda}} \max\{\frac{2}{\overline{c_0}} \|Q_i^{-1}B_iK_{2i}\|^2, 1\}$, we have

$$\dot{V}_i(t) \le -\frac{\tilde{c}_0}{2} \|\tilde{x}_i\|^2 - \|\tilde{w}\|^2 + \gamma^2 \|d(t)\| - \|e_i\|^2$$

Integrating this inequality from 0 to ∞ yields that

$$V_i(\infty) - V_i(0) \le \int_0^\infty \gamma^2 ||d(s)||^2 \mathrm{d}s - \int_0^\infty ||e_i(s)||^2 \mathrm{d}s$$

Using the fact that $V_i(t) \ge 0$ for any t, we have

$$\int_0^\infty \|e_i(s)\|^2 \mathrm{d}s \le \int_0^\infty \gamma^2 \|d(s)\|^2 \mathrm{d}s + V_i(0)$$

The proof is thus complete.

When $d(t) \equiv 0$, condition (11) can be further relaxed as follows to ensure a patterned positive consensus:

$$A_i Q_i - B_i B_i^\top + \delta Q_i > 0$$

$$Q_i A^\top + A_i Q_i - 2B_i B_i^\top \prec 0$$
(14)

We summarize the result as follows.

Corollary 1 Suppose Assumptions 1–3 hold and there exist diagonal matrices $Q_1 \ldots, Q_N > \mathbf{0}$ and a scalar $\delta > 0$ fulfilling (14). Then, under the following controller

$$u_{i} = -B_{i}^{\top}Q_{i}^{-1}x_{i} + [U_{i} + B_{i}^{\top}Q_{i}^{-1}X_{i}]w_{i}$$

$$\dot{w}_{i} = A_{0}w_{i} + \mu \sum_{j=1}^{N} a_{ij}(t)(w_{j} - w_{i}), \quad i \in \mathcal{N}$$
(15)

the trajectory of $x_i(t)$ is always nonnegative and the multi-agent system (2) internally achieves a patterned consensus specified by (3).

In many circumstances, the state x_i may not be available for us. Here we present an output feedback extension for (10) as follows to solve our problem:

$$u_{i} = K_{1i}\xi_{i} + K_{2i}w_{i}$$

$$\dot{\xi}_{i} = (A_{i} - K_{3i}C_{i})\xi_{i} + B_{i}u_{i} + K_{3i}y_{i}$$

$$\dot{w}_{i} = A_{0}w_{i} + \mu \sum_{j=1}^{N} a_{ij}(t)(w_{j} - w_{i}), \quad i \in \mathcal{N}$$
(16)

where $K_{3i} \in \mathbb{R}^{n_i \times l}$ is a chosen gain matrix to be specified later. To meet the positivity requirement, we set $w_i(0) = \mathbf{0}$ for i = 1, ..., N as in [33].

Theorem 2 Suppose Assumptions 1–3 hold. The formulated robust positive consensus problem with a given pattern (3) and performance level $\gamma > 0$ is solved by a distributed controller of the form (16) if there exist diagonal matrices P_i , $Q_i > \mathbf{0}$ and a scalar $\delta > 0$ such that the following inequalities hold:

$$P_{i}A_{i} - C_{i}^{\top}C_{i} + \delta P_{i} > \mathbf{0}$$

$$A_{i}^{\top}P_{i} + P_{i}A_{i} - 2C_{i}^{\top}C_{i} \prec \mathbf{0}$$

$$A_{i}Q_{i} - B_{i}B_{i}^{\top} + \delta Q_{i} > \mathbf{0}$$

$$Q_{i}A_{i}^{\top} + A_{i}Q_{i} - 2B_{i}B_{i}^{\top} + \frac{1}{\gamma^{2}}D_{i}D_{i}^{\top} + Q_{i}C_{i}^{\top}C_{i}Q_{i} \prec \mathbf{0}$$

Proof. The proof is analogous to that of Theorem 1 and we only give a sketch to save space. Let $K_{3i} = P_i^{-1} C_i^{\top}$. It is verified that $A_i - K_{3i} C_i$ is Hurwitz and Metzler. It follows

$$\dot{x}_{i} = (A_{i} + B_{i}K_{1i})x_{i} - B_{i}K_{1i}\bar{x}_{i} + B_{i}K_{2i}w_{i} + E_{i}d(t)$$

$$\dot{\bar{x}}_{i} = (A_{i} - K_{3i}C_{i})\bar{x}_{i}$$

$$y_{i} = C_{i}x_{i}, \quad i \in \mathcal{N}$$

$$(17)$$

where $\bar{x}_i = x_i - \xi_i$. Since $\bar{x}_i(0) \ge \mathbf{0}$, $\bar{x}_i(t) \ge \mathbf{0}$ for any t. This further implies the nonnegativity of $-B_i K_{1i} \bar{x}_i + B_i K_{2i} w_i + E_i d(t)$. Consequently, we have $x_i(t) \ge \mathbf{0}$ for any $t \ge 0$.

To show the rest two properties, we focus on the following error system:

$$\dot{\tilde{x}}_{i} = (A_{i} + B_{i}K_{1i})\tilde{x}_{i} - B_{i}K_{1i}\bar{x}_{i} + B_{i}K_{2i}\tilde{w}_{i} + E_{i}d(t)$$

$$\dot{\bar{x}}_{i} = (A_{i} - K_{3i}C_{i})\bar{x}_{i}$$

$$\dot{\tilde{w}} = (\mathbb{I}_{N} \otimes A_{0} - \mu L_{\sigma(t)} \otimes \mathbb{I}_{n_{0}})\tilde{w}$$

$$e_{i} = C_{i}\tilde{x}_{i}$$
(18)

Following similar arguments in the proof of Theorem 1, one can further determine constant $c_1 > 0$ such that $\hat{A}_i^{\top} P_i + P_i \hat{A}_i \prec -c_1 \mathbb{I}_{n_i}$ holds for any $i \in \mathcal{N}$. Then we take $V_i(t) = \tilde{x}_i^{\top}(t)Q_i^{-1}\tilde{x}_i(t) + \iota_i V_{\tilde{w}}(t) + m_i \bar{x}_i^{\top}(t)P_i \bar{x}_i(t)$ with ι_i and m_i to be specified later. Using the theorem conditions, we can obtain that its derivative along system (18) satisfies

$$\begin{split} \dot{V}_{i}(t) &\leq -\tilde{c}_{0} \|\tilde{x}_{i}\|^{2} - \tilde{x}_{i}^{\top} Q_{i}^{-1} (\frac{1}{\gamma^{2}} E_{i} E_{i}^{\top} + Q_{i} C_{i}^{\top} C_{i} Q_{i}) Q_{i}^{-1} \tilde{x}_{i} \\ &+ 2\tilde{x}_{i}^{\top} Q_{i}^{-1} B_{i} K_{2i} \tilde{w}_{i} - 2\tilde{x}_{i}^{\top} Q_{i}^{-1} B_{i} K_{1i} \bar{x}_{i} \\ &+ 2\tilde{x}_{i}^{\top} Q_{i}^{-1} E_{i} d(t) - 2\iota_{i} \underline{\lambda} V_{\tilde{w}} - m_{i} c_{1} \|\bar{x}_{i}\|^{2} \end{split}$$

Completing the squares implies

$$\begin{split} \dot{V}_i(t) &\leq -\frac{\tilde{c}_0}{2} \|\tilde{x}_i\|^2 - (\iota_i \underline{\lambda} - \frac{4}{\tilde{c}_0} \|Q_i^{-1} B_i K_{2i}\|^2) \|\tilde{w}\|^2 \\ &- (m_i c_1 - \frac{4}{\tilde{c}_0} \|Q_i^{-1} B_i K_{1i}\|^2) \|\bar{x}_i\|^2 \\ &+ \gamma^2 \|d(t)\| - \|e_i\|^2 \end{split}$$

By letting $\iota_i \geq \frac{2}{\underline{\lambda}} \max\{\frac{4}{\overline{c}_0} \| Q_i^{-1} B_i K_{2i} \|^2, 1\}$ and $m_i \geq \frac{2}{c_1} \max\{\frac{4}{\overline{c}_0} \| Q_i^{-1} B_i K_{1i} \|^2, 1\}$, we have

$$\dot{V}_i(t) \le -\frac{c_0}{2} \|\tilde{x}_i\|^2 - \|\bar{x}_i\|^2 - \|\tilde{w}\|^2 + \gamma^2 \|d(t)\| - \|e_i\|^2$$

Integrating this inequality from 0 to ∞ yields that

$$V_i(\infty) - V_i(0) \le \int_0^\infty \gamma^2 ||d(s)||^2 \mathrm{d}s - \int_0^\infty ||e_i(s)||^2 \mathrm{d}s$$

Figure 2: The communication graphs in our example.

Using the fact that $V_i(t) \ge 0$ for any t, we have

$$\int_0^\infty \|e_i(s)\|^2 ds \le \int_0^\infty \gamma^2 \|d(s)\|^2 ds + V_i(0)$$

The proof is thus complete.

Remark 1 Compared with most existing positive consensus results [18, 20-23], we present a two-step design scheme to solve the problem. Although the controller (16), particularly the local reference part, reduces to the observer-based type of control laws as that in [22, 23], we are able to handle heterogeneous positive multi-agent systems whose dynamics can be different from each other in both system matrices and orders over switching communication topologies. Moreover, the expected consensus trajectory of the multi-agent system is allowed to be of a more general prespecified pattern including nonnegative static consensus in [23] as a special case.

Remark 2 It is interesting to remark that the presented algorithms are mainly built upon several matrix inequalities, which can be taken as positive counterparts of γ -suboptimal \mathcal{H}_{∞} design for similar problems [25, 26]. In practice, we can convert them to linear ones and then solve them using standard numerical softwares.

5 Simulation

In this section, we consider an eight-agent system to illustrate the effectiveness of our preceding designs.

Suppose the system matrices are as follows:

$$A_{i} = \begin{bmatrix} -2 & 1 & 1\\ 1 & -3 & 0\\ 1 & 1 & -1 \end{bmatrix}, B_{i} = \begin{bmatrix} 0\\ 0\\ 1 \end{bmatrix}, C_{i} = \begin{bmatrix} 0\\ 0\\ 1 \end{bmatrix}, D_{i} = \begin{bmatrix} 1\\ 0\\ 0 \end{bmatrix}, i = 1, 2, 7$$

and

$$A_i = \begin{bmatrix} -2 & 1\\ 0 & 0 \end{bmatrix}, B_i = \begin{bmatrix} 0\\ 1 \end{bmatrix}, C_i = \begin{bmatrix} 0\\ 1 \end{bmatrix}^\top, D_i = \begin{bmatrix} 1\\ 1 \end{bmatrix}, i = 3, 4$$

and

$$A_{i} = \begin{bmatrix} 0 & 0 \\ 1 & -3 \end{bmatrix}, B_{i} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, C_{i} = \begin{bmatrix} 2 \\ 0 \end{bmatrix}^{\top}, D_{i} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, i = 5, 6, 8$$

It can be verified by Lemma 1 that these agents are indeed positive. Suppose the communication graph is alternatively switching between \mathcal{G}_1 and \mathcal{G}_2 given in Fig. 2 every 10 seconds. Assumption 2 is then fulfilled.

Figure 3: Performance of (16) for positive consensus.

Consider a consensus pattern with

$$A_0 = \begin{bmatrix} 0.01 & 0.01 \\ 0 & 0 \end{bmatrix}, \quad C_0 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}^\top$$
(19)

Solving the regulator equations (5) gives

$$X_{i} = \begin{bmatrix} 0.5960 & 0.5960 \\ 0.1980 & 0.1980 \\ 1 & 1 \end{bmatrix}, U_{i} = \begin{bmatrix} 0.2160 \\ 0.2160 \end{bmatrix}^{\top}, i = 1, 2, 7$$
$$X_{i} = \begin{bmatrix} 0.4975 & 0.4975 \\ 1.0000 & 1.0000 \end{bmatrix}, U_{i} = \begin{bmatrix} 0.0100 \\ 0.0100 \end{bmatrix}^{\top}, i = 3, 4$$
$$X_{i} = \begin{bmatrix} 0.5000 & 0.5000 \\ 0.1661 & 0.1661 \end{bmatrix}, U_{i} = \begin{bmatrix} 0.0050 \\ 0.0050 \end{bmatrix}^{\top}, i = 5, 6, 8$$

Thus Assumption 3 is confirmed. We employ the output feedback controller (16) to solve our problem with $\gamma = 4$.

For this purpose, we solve the inequalities in Theorem 2 and obtain the following gain matrices: $K_{11} = K_{12} = K_{17} = [0 \ 0 \ -1], K_{13} = K_{14} = [0 \ -1], K_{15} = K_{16} = K_{18} = [-1 \ 0], K_{21} = K_{22} = K_{27} = [1.2160 \ 1.2160], K_{23} = K_{24} = [1.0100 \ 1.0100], K_{25} = K_{26} = K_{28} = [0.5050 \ 0.5050], K_{31} = K_{32} = K_{37} = [0 \ 0 \ 1]^{\top}, K_{33} = K_{34} = [0 \ 1]^{\top}$ and $K_{35} = K_{36} = K_{38} = [1 \ 0]^{\top}$. Let $w_i(0) = \operatorname{col}(i - 0.5, i), \xi_i(0) = \mathbf{0}$. Choose $\mu = 3$ for the generator and all other initials are randomly generated between 0 and 7,

(b) L_2 gain robust performance of (16)

Figure 4: State and L_2 gain robust performance of (16).

We first set $d(t) \equiv 0$ and obtain an exact positive consensus as depicted in Fig. 3. Then, let $d(t) = |\sin(0.01t)|$, the state and L_2 gain performance of controller (16) can be found in Fig. 4. It can be found that all agents reach a robust positive consensus even the expected consensus trajectory tends to be unbounded in this case. At the same time, the components of $x_1(t)$, $x_3(t)$ and $x_5(t)$ are observed to stay in the positive orthant. These observations verify the effectiveness of (16) to solve the robust positive consensus problem for heterogeneous multi-agent system (2).

6 Conclusion

We have formulated and solved the robust positive consensus problem for a group of high-order positive multi-agent systems with external inputs. To handle the positive constraint and heterogeneous and uncertain agent dynamics, we have proposed a two-step design method and finally developed two different kinds of effective rules for these agents to attain a robust consensus having the expected dynamic pattern while their states fulfill the positive constraints even under switching communication topologies. In the future, we may consider the same problem but for uncertain nonlinear positive multi-agent systems with more general communication graphs.
