## ABSTRACT

*Gaia* Data Release 2 revealed the presence of a population of ultramassive white dwarfs on the Q branch that are moving anomalously fast for a local disc population with the cooling ages determined using white dwarf cooling models, which has been presented as evidence of an extra cooling delay experienced by these white dwarfs. In this work, we investigate the kinematics of ultramassive white dwarfs in the solar neighbourhood using the improved *Gaia* Early Data Release 3 observations to explore this cooling delay explanation and alternate possibilities. We performed a kinematic analysis of the transverse motions of 0.95 – 1.25  $M_{\odot}$  white dwarfs within 200 pc of the Sun subdivided by mass and age and compared the result to the expectation based on the observed kinematics of main sequence stars. The distributions of the transverse velocity component in the direction of Galactic rotation for different mass and age ranges reveal a population of photometrically young ( $\sim 0.5$  – 1.5 Gyr) ultramassive ( $\sim 1.15$  – 1.25  $M_{\odot}$ ) white dwarfs that lags the local Galactic rotation and that is too dispersed in this velocity component to be explained by a cooling delay in white dwarfs originating from the local Galactic disc. The dispersion ratio of the velocity components in the Galactic plane for this population is also inconsistent with a local disc origin. We discuss some possible explanations of this kinematically anomalous population such as a halo origin or production through dynamical effects of stellar triple systems.

**Key words:** stars: evolution – stars: kinematics and dynamics – stars: white dwarfs – Galaxy: solar neighbourhood

## 1 INTRODUCTION

The kinematics of stars can encode important information about their history and origin. The dynamical history of the Galaxy is imprinted on the kinematics-age relations of stars in the solar neighbourhood, such as the trend for the velocity dispersion of stars from the local Galactic disc to increase with age due to disc heating, as seen in the age-velocity dispersion relation (AVR) (Strömberg 1946; Roman 1950a,b; Wielen 1977; Nordström et al. 2004; Holmberg et al. 2007; Seabroke & Gilmore 2007; Soubiran et al. 2008; Aumer & Binney 2009; Holmberg et al. 2009; Casagrande et al. 2011; Sharma et al. 2014; Yu & Liu 2018; Raddi et al. 2022). Since the epoch of the HIPPARCOS mission (Perryman et al. 1997), the kinematics of stars in the solar neighbourhood have been extensively studied (e.g. Dehnen & Binney 1998; Dehnen 1998; Skuljan et al. 1999; Chereul et al. 1999; Nordström et al. 2004; Famaey et al. 2005, 2008; Antoja et al. 2008), and the precise astrometry of the *Gaia* mission (*Gaia* Collaboration et al. 2016), the successor to HIPPARCOS, has further advanced these studies (e.g. Bovy 2017; Kushniruk et al. 2017; *Gaia* Collaboration et al. 2018b; Yu & Liu 2018; Rowell & Kilic 2019; Raddi et al. 2022; Mikkola et al. 2022).

The most recent *Gaia* data, *Gaia* Early Data Release 3 (EDR3; *Gaia* Collaboration et al. 2021), has been used to study the kinematics of white dwarfs in the solar neighbourhood, showing that the

kinematic structure of local white dwarfs (e.g. Mikkola et al. 2022) is similar to that of local main sequence stars (e.g. *Gaia* Collaboration et al. 2018b; Kushniruk et al. 2017; Antoja et al. 2012). For example, Raddi et al. (2022) performed a detailed 3-dimensional kinematics analysis of a sample of 3133 white dwarfs from *Gaia* EDR3 with radial velocity measurements from either *Gaia* or cross-matched spectroscopic observations, finding that their sample, which was mostly located within  $\sim 300$  pc of the Sun, consisted of  $\sim 90$  – 95% thin disc stars,  $\sim 5$  – 10% thick disc stars, and a few isolated white dwarfs and halo members. For the thin disc members, Raddi et al. (2022) determined their AVRs and found them to agree with previous AVR results that were determined from different samples of LAMOST-*Gaia* FGK-type stars without radial velocity information (Yu & Liu 2018).

*Gaia* has also revealed structure in the colour magnitude diagram of white dwarfs in the solar neighbourhood, which has implications for our understanding of white dwarf cooling. *Gaia* Data Release 2 (DR2) revealed the so called “Q branch” (*Gaia* Collaboration et al. 2018a), an observed sequence of massive white dwarfs in the colour-magnitude diagram that is transversal to the theoretical cooling sequences for white dwarfs with mass  $\gtrsim 1 M_{\odot}$  and coincides with the region of white dwarf crystallization (Tremblay et al. 2019). The phase transition from liquid to solid state during the process of crystallization results in the release of latent heat (van Horn 1968) and other energy associated with element sedimentation (Garcia-Berro et al. 1988; Segretain et al. 1994; Isern et al. 1997; Althaus et al. 2012) that slows the rate of white dwarf cooling, and this cooling

† email: ilariac@caltech.edu; Sherman Fairchild Fellow

‡ email: heyjl@phas.ubc.ca

delay results in a pile-up of white dwarfs that has been identified with the Q branch (Tremblay et al. 2019).

While a cooling delay due to white dwarf crystallization had been predicted for over 50 years prior to *Gaia* DR2, Cheng et al. (2019) presented evidence from *Gaia* DR2 for an extra cooling delay of  $\sim 8$  Gyr experienced by  $\sim 6\%$  of ultramassive ( $1.08 - 1.23 M_{\odot}$ ) white dwarfs on the Q branch that is not explained by standard crystallization models. Cheng et al. (2019) noted a discrepancy between the dynamic age inferred from the transverse velocity using the AVRs of Holmberg et al. (2009); Sharma et al. (2014) and the photometric isochrone age inferred from white dwarf cooling models among ultramassive *Gaia* DR2 white dwarfs on the Q branch, finding a population among  $\sim 1.08 - 1.23 M_{\odot}$  white dwarfs moving anomalously fast relative to the velocity expected from the AVR for their photometric ages. Cheng et al. (2019) argued that this discrepancy could only be explained by an extra cooling delay, in addition to the delay due to crystallization and double white dwarf mergers, and suggested modifications to the treatment of  $^{22}\text{Ne}$  sedimentation in white dwarf cooling models as a possible mechanism. This prompted many efforts to explain this cooling anomaly through modifications to white dwarf cooling models (Bauer et al. 2020; Horowitz 2020; Caplan et al. 2020, 2021; Blouin et al. 2020, 2021; Blouin & Daligault 2021; Camisassa et al. 2021).

In our recent work (Fleury et al. 2022), we used the improved *Gaia* EDR3 data to re-investigate this cooling anomaly by analysing the photometric cooling age distribution of massive ( $0.95 - 1.25 M_{\odot}$ ) white dwarfs identified in the white dwarf catalogue of Gentile Fusillo et al. (2021). We considered a variety of publicly available white dwarf cooling models of different compositions with standard core crystallization, and found cooling age distributions that were consistent with the expectation from the star formation rate observed for *Gaia* main sequence stars (Mor et al. 2019). From our analysis of the white dwarfs' photometry, we did not see evidence of an extra cooling delay beyond what could be explained by standard core crystallization and the presence of an appreciable fraction of double white dwarf merger products among the most massive ( $1.15 - 1.25 M_{\odot}$ ) white dwarfs.

In this work, we follow up the work of Fleury et al. (2022) with a kinematic analysis of the transverse motions of the same sample of  $0.95 - 1.25 M_{\odot}$  white dwarfs in the solar neighbourhood that was considered in Fleury et al. (2022), sub-divided into the same mass bins of  $0.95 - 1.05 M_{\odot}$ ,  $1.05 - 1.15 M_{\odot}$ , and  $1.15 - 1.25 M_{\odot}$  and with masses and cooling ages determined using white dwarf cooling models found in Fleury et al. (2022) to produce photometric cooling age distributions consistent with the expectation from the star formation history. For each of these mass bins, we estimate the transverse velocity dispersion as a function of age using different estimators and analyse the distributions of the separate transverse velocity components for several age ranges. We compare the empirical distributions to the expectation from the AVRs measured for main sequence stars in the local thin disc and find a population of anomalously fast-moving ultramassive white dwarfs on the Q branch with kinematic features that are not explained by an extra cooling delay in white dwarfs originating from the local thin disc.

The structure of this paper is as follows. The data and models used in this work, along with the formal procedure for determining transverse motions, are described in section 2. The results are presented in section 3, and the implications for the origin of anomalously fast-moving ultramassive white dwarfs on the Q branch are discussed in section 4. Finally, the results and discussion are summarized in section 5.

## 2 METHODS

### 2.1 Data and Cooling Models

We use the data and white dwarf cooling models described in Fleury et al. (2022). The data consist of *Gaia* EDR3 white dwarfs identified in the Gentile Fusillo et al. (2021) catalogue with at least 90% probability, as determined by the Pwd parameter of the catalogue, and located within 200 pc of the Sun. The magnitude and colour observations were de-reddened following the prescription of Gentile Fusillo et al. (2021).

Using the publicly available `WD_models` package provided by Cheng (2020)<sup>1</sup>, we use white dwarf cooling models to determine the photometric age and mass of each white dwarf from its G-band magnitude,  $M_G$ , and colour,  $G_{BP} - G_{RP}$ . In our previous work (Fleury et al. 2022), we assessed the consistency of the photometric cooling age distribution determined using various models available through `WD_models` with the star formation history observed for *Gaia* DR2 main sequence stars (Mor et al. 2019). In this work, we use only the thick Montreal white dwarf cooling models (Bédard et al. 2020). These models gave the best-fitting cooling age distribution for the  $1.05 - 1.15 M_{\odot}$  and  $1.15 - 1.25 M_{\odot}$  mass bins in Fleury et al. (2022). For the  $0.95 - 1.05 M_{\odot}$  mass bin, the Plata models (Camisassa et al. 2019, 2017; Renedo et al. 2010) and thick Montreal models were both determined to produce cooling age distributions consistent with the star formation history and yielded similar p-values, so for consistency we use the thick Montreal models for all three mass bins. Using the La Plata models instead of the thick Montreal models for the lightest mass bin produces similar results.

Since the publication of Fleury et al. (2022), the La Plata group has produced cooling models for ultramassive white dwarfs ( $\geq 1.15 M_{\odot}$ ) with carbon-oxygen cores (Camisassa et al. 2022). These models implement more realistic physics in the core of the white dwarfs than the Bédard et al. (2020) models such as element diffusion and abundance ratios determined by progenitor evolution simulations, though there is still a great deal of uncertainty regarding the abundances expected for carbon-oxygen white dwarfs (e.g. Althaus et al. 2021; Salaris et al. 2010; De Gerónimo et al. 2017; Wagstaff et al. 2020). While an analysis of the photometric cooling age distributions determined by the Camisassa et al. (2022) models, particularly in comparison to the star formation rate, as was done in Fleury et al. (2022) is worthwhile, our choice of cooling model will not change the salient results presented in this work. Using the Camisassa et al. (2022) models instead of the Bédard et al. (2020) models would shift the particular ages at which the key features of the velocity dispersion appear, but it would not remove these features. Likewise, using oxygen-neon core models (e.g. Camisassa et al. 2019) instead of carbon-oxygen core models would shift the inferred cooling ages and, to a lesser extent, masses of our white dwarf sample, but it would not affect the values of the velocities and therefore would not eliminate the key features presented in this work.

### 2.2 Kinematics

#### 2.2.1 Streaming Motion

The observed velocity of a star in the solar neighbourhood consists of the local (average) streaming velocity, which includes both the

<sup>1</sup> The `WD_models` package is publicly available at [https://github.com/SihaoCheng/WD\\_models](https://github.com/SihaoCheng/WD_models)

average motion due to Galactic rotation and reflex solar motion relative to the local standard of rest, plus the peculiar velocity of the star due to random motion. In this work, we are interested in the random motion of white dwarfs about the local mean, so we correct the observed velocities for both Galactic rotation and solar motion.

Olling & Dehnen (2003) give a concise derivation of the local streaming motion in the Galactic plane to first order in a two-dimensional Taylor series expansion of the mean velocity field about the location of the Sun. To first order in this expansion, the Galactic rotation can be parametrized by the four Oort constants  $A$ ,  $B$ ,  $C$ , and  $K$ , with  $C = K = 0$  in the case of axisymmetry. The proper motions corresponding to the streaming velocity in Galactic coordinates are

$$\bar{\mu}_{\ell*} = (U_0 \sin \ell - V_0 \cos \ell) \bar{\omega} + \cos b (A \cos 2\ell - C \sin 2\ell + B) \quad (1)$$

$$\bar{\mu}_b = [(U_0 \cos \ell + V_0 \sin \ell) \sin b - W_0 \cos b] \bar{\omega} - \sin b \cos b (A \sin 2\ell + C \cos 2\ell + K), \quad (2)$$

where the proper motions  $\bar{\mu}_{\ell*}$  and  $\bar{\mu}_b$  are given in units of  $\text{km s}^{-1} \text{kpc}^{-1}$ ,  $\bar{\mu}_{\ell*} \equiv \bar{\mu}_{\ell} \cos b$ ,  $\bar{\omega}$  is the inverse distance in units of  $\text{kpc}^{-1}$  (corresponding to a parallax angle measured in mas),  $\ell$  is the Galactic longitude,  $b$  is the Galactic latitude, and  $(U_0, V_0, W_0)$  is the velocity of the Sun relative to the local streaming in a heliocentric Cartesian coordinate system with  $\hat{\mathbf{x}}$  pointing in the direction  $(\ell, b) = (0^\circ, 90^\circ)$ ,  $\hat{\mathbf{y}}$  in the direction  $(\ell, b) = (90^\circ, 90^\circ)$ , and  $\hat{\mathbf{z}}$  in the direction of  $b = 0^\circ$ . The components of the transverse streaming velocity in the  $\hat{\ell}$  and  $\hat{b}$  directions, in units of  $\text{km s}^{-1}$ , are

$$(\bar{v}_{\ell}, \bar{v}_b) = (\bar{\mu}_{\ell*}, \bar{\mu}_b) / \bar{\omega}. \quad (3)$$

We calculate the streaming velocities using values reported in the literature for both the solar motion and the Oort constants. For the solar motion, we use the peculiar solar velocity measurements of Wang et al. (2021), with values of  $U_0 = 11.69 \text{ km s}^{-1}$ ,  $V_0 = 10.16 \text{ km s}^{-1}$ , and  $W_0 = 7.67 \text{ km s}^{-1}$ . For the Galactic rotation, we assign the Oort constants the values measured by Bovy (2017) using *Gaia* DR1 main sequence stars from the Tycho-*Gaia* Astrometric Solution (TGAS) catalogue, with values of  $A = 15.3 \text{ km s}^{-1} \text{kpc}^{-1}$ ,  $B = -11.9 \text{ km s}^{-1} \text{kpc}^{-1}$ ,  $C = -3.2 \text{ km s}^{-1} \text{kpc}^{-1}$ , and  $K = -3.3 \text{ km s}^{-1} \text{kpc}^{-1}$ .

A conversion factor of  $\kappa = 4.74047$  is needed to convert proper motions given in  $\text{mas yr}^{-1}$  to units of  $\text{km s}^{-1} \text{kpc}^{-1}$ . Including this conversion factor, the observed velocities (in  $\text{km s}^{-1}$ ) in the  $\hat{\ell}$  and  $\hat{b}$  directions are

$$(v_{\ell}^{(\text{obs})}, v_b^{(\text{obs})}) = \kappa (\mu_{\ell*}^{(\text{obs})}, \mu_b^{(\text{obs})}) / \bar{\omega}. \quad (4)$$

*Gaia* only provides proper motions in ICRS coordinates, so we convert the observed proper motions from ICRS coordinates to Galactic coordinates using the `astropy`<sup>2</sup> package for Python (Astropy Collaboration et al. 2013, 2018).

We calculate the peculiar velocities,  $v_{\ell}$  and  $v_b$ , of the white dwarfs by correcting the observed velocities for solar motion and Galactic rotation

$$v_{\ell} = v_{\ell}^{(\text{obs})} - \bar{v}_{\ell} \quad (5)$$

$$v_b = v_b^{(\text{obs})} - \bar{v}_b. \quad (6)$$

These two velocities, together with the sky coordinates and parallax, completely specify the random transverse motion of our sample relative to the local standard of rest.

## 2.2.2 Random Transverse Motion

Since most sources in *Gaia* EDR3 do not have radial velocity measurements, we perform our analysis of the kinematics using only the transverse motion. Following the procedure of Dehnen & Binney (1998), we relate the transverse motion to the full 3-dimensional motion through use of a projection operator  $\mathbf{P}$  that projects the 3-dimensional space velocity  $\mathbf{v}$  onto the celestial sphere.

We write this formulation explicitly using matrix notation with vectors as column matrices and work in Cartesian Galactic coordinates in which  $\hat{\mathbf{x}}$  points towards the Galactic centre ( $\ell = 0^\circ$ ,  $b = 90^\circ$ ),  $\hat{\mathbf{y}}$  points in the direction of Galactic rotation ( $\ell = 90^\circ$ ,  $b = 90^\circ$ ),  $\hat{\mathbf{z}}$  points towards the North Galactic Pole ( $b = 0^\circ$ ), and  $\mathbf{v} = (U, V, W)^T$ . Letting  $\hat{\mathbf{r}} = (\cos b \sin \ell, \cos b \cos \ell, \sin b)^T$  be the unit position vector pointing to the location of the star, the projection operator in matrix notation is

$$\mathbf{P} \equiv \mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}^T, \quad (7)$$

where  $\mathbf{I}$  is the  $3 \times 3$  identity matrix. The tangent velocity vector  $\mathbf{v}_{\perp}$  is then related to  $\mathbf{v}$  by

$$\mathbf{v}_{\perp} = \mathbf{P} \mathbf{v}, \quad (8)$$

where  $\mathbf{v}_{\perp}$  is the component of the  $\mathbf{v}$  in the tangent plane at the angular position of the star.

The rectangular components of the tangential velocity vector can be written explicitly as

$$\mathbf{v}_{\perp} = \begin{pmatrix} U_{\perp} \\ V_{\perp} \\ W_{\perp} \end{pmatrix} = \begin{pmatrix} -\sin \ell v_{\ell} - \cos \ell \sin b v_b \\ \cos \ell v_{\ell} - \sin \ell \sin b v_b \\ \cos b v_b \end{pmatrix}, \quad (9)$$

and the magnitude of the transverse velocity,  $v_t = |\mathbf{v}_{\perp}|$ , is simply given by

$$v_t = \sqrt{v_{\ell}^2 + v_b^2}. \quad (10)$$

We calculate  $v_t$  and the components of  $\mathbf{v}_{\perp}$  for the white dwarfs in our sample using  $v_{\ell}$  and  $v_b$  as given by eqs. (5) and (6). Since the mean local motion due to both Galactic rotation and solar motion has already been removed, the velocities here are the peculiar velocities, corresponding to the random motion about the mean.

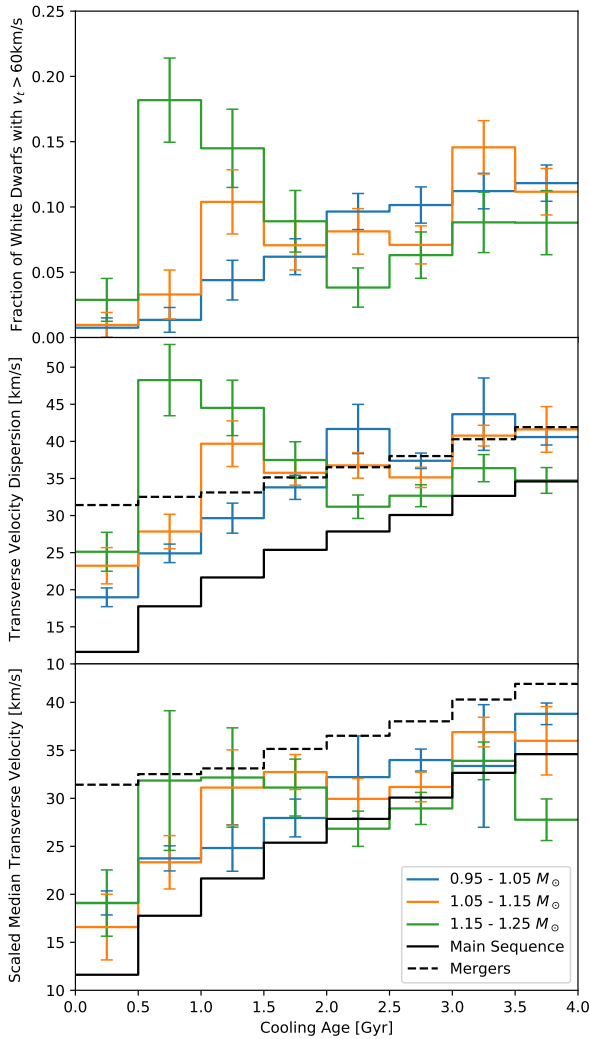

If the full 3D space velocities (including radial motion) have a diagonal dispersion tensor  $\sigma^2 = \text{diag}(\sigma_U^2, \sigma_V^2, \sigma_W^2)$  and the positions of the white dwarfs are uncorrelated with the velocities, then the dispersion of the transverse velocity can be quantified by

$$\sigma_t^2 = E \left[ \text{Tr} \left( \mathbf{P} \sigma^2 \mathbf{P}^T \right) \right], \quad (11)$$

where  $\text{Tr}$  denotes the matrix trace, which is equivalent to the sum of eigenvalues of the matrix, and  $E$  denotes the expectation value for a particular distribution of sky coordinates, which can be estimated by a statistic such as the sample mean.

Throughout this work, we compare the results we find for the white dwarf transverse kinematics relations with the expectation assuming the dispersions of their full 3-dimensional velocities follow the AVRs determined by Holmberg et al. (2009) for main sequence stars from the local thin disc. While more recent determinations of these AVRs exist (e.g. Yu & Liu 2018), they are similar to the AVRs of Holmberg et al. (2009) and do not change our results. As evidence for a cooling anomaly among ultramassive white dwarfs was presented by Cheng et al. (2019) with reference to the thin disc AVRs of Holmberg et al. (2009), using the Holmberg et al. (2009) AVRs facilitates comparison of our results with earlier work on this topic.

<sup>2</sup> <http://www.astropy.org>

**Figure 1.** Upper: Fraction of Fast-Moving Massive White dwarfs for Three Mass Bins. The fast-moving white dwarfs are defined as those with transverse velocity greater than 60 km/s. Middle: Transverse Velocity Dispersion Accounting for Uncertainties in Proper Motion. Lower: Scaled Median Transverse Velocity (Robust Estimator of Velocity Dispersion). In the middle and lower panels, the solid black line traces the results for main-sequence stars from [Holmberg et al. \(2009\)](#) with the same sky distribution as the white dwarfs, and the dashed black lines trace the results from main-sequence stars including a merger delay.

### 3 RESULTS

Fig. 1 shows various probes of the AVR for *Gaia* EDR3 white dwarfs in three different mass bins,  $0.95 - 1.05 M_{\odot}$  (blue),  $1.05 - 1.15 M_{\odot}$  (orange), and  $1.15 - 1.25 M_{\odot}$  (green). The masses and cooling ages were calculated from the observed photometry using (single stellar evolution) white dwarf cooling models determined by [Fleury et al. \(2022\)](#) to give a cooling age distribution consistent with the star formation rate observed for *Gaia* DR2 main sequence stars ([Mor et al. 2019](#)).

The upper panel of Fig. 1 shows the fraction of fast-moving white dwarfs with  $v_t > 60 \text{ km s}^{-1}$  as a function of photometric cooling age. The empirical distributions, shown as histograms, were constructed using cooling age bins of 0.5 Gyr width over the range 0–4 Gyr. The

fraction of fast-movers in each age bin was calculated using weighted counts for that bin, where each white dwarf was assigned a weight according to the procedure of [Fleury et al. \(2022\)](#) to correct for the reduced sampling volume that ensures completeness.

The fraction of fast-moving ultramassive white dwarfs in *Gaia* EDR3 as a function of photometric cooling age shows a trend with cooling age that is similar to what [Cheng et al. \(2019\)](#) found for *Gaia* DR2 white dwarfs, though we see a less pronounced peak for young  $1.05 - 1.15 M_{\odot}$  white dwarfs on the Q branch than what was found by [Cheng et al. \(2019\)](#) for this bin. For the  $0.95 - 1.05 M_{\odot}$  white dwarfs, the fraction of fast-movers tends to increase with cooling age, which is the expected behaviour if the white dwarf velocities follow an AVR similar to what has been observed for main sequence (G and F dwarf) stars in the thin disc ([Holmberg et al. 2009](#)). Of particular note is the distribution for  $1.15 - 1.25 M_{\odot}$  white dwarfs, for which the fraction of young fast-movers in the age range 0.5–1.5 Gyr is larger than the fraction in either the younger or older age bins. This corresponds to an excess of young fast-movers on the Q branch relative to the expectation based on the AVR observed for stars in the thin disc ([Holmberg et al. 2009](#)). While we see a hint of a similar excess in the 1.5–2.0 Gyr bin of the  $1.05 - 1.15 M_{\odot}$  white dwarfs, we do not see a clear signal of an excess of fast-movers within the uncertainties. Some of the difference between our distribution and that of [Cheng et al. \(2019\)](#) for the  $1.05 - 1.15 M_{\odot}$  could be due to the difference in models used to determine the masses: we used the carbon-oxygen core models of [Bédard et al. \(2020\)](#) while [Cheng et al. \(2019\)](#) used the oxygen-neon core models of [Camisassa et al. \(2019\)](#) for masses above  $1.10 M_{\odot}$  and the carbon-oxygen models of [Fontaine et al. \(2001\)](#) for masses below  $1.05 M_{\odot}$ .

The middle and lower panels of Fig. 1 show estimates of the transverse velocity dispersion as a function of age using different estimators of  $\sigma_t$ , one based on the sample mean in each bin (middle panel) and the other based on the sample median (lower panel), the latter of which is more robust to outliers. Random variation in the observed values of  $v_t$  will arise both from the intrinsic randomness in the motion of the white dwarfs about the local mean (i.e. the peculiar motion of the white dwarfs) that we are interested in and from random measurement error. We correct for the latter effect in both methods of estimating  $\sigma_t$  from the observations. The random error for each value of  $v_t$  was calculated by propagating the standard errors and correlations provided by *Gaia* for the proper motions and parallax from which the observed transverse velocity (without corrections for Galactic rotation or solar motion). The error was propagated using the expression  $e_{v_t,(\text{obs})}^2 = J \Sigma J^T$ , where  $\Sigma$  is the covariance matrix,  $J$  is the Jacobian matrix, and  $e_{v_t,(\text{obs})}$  is the random error for the observed transverse velocity.

The middle panel of Fig. 1 shows the transverse velocity dispersion calculated using the mean for each age (and mass) bin with a correction for random measurement error according to the expression

$$\sqrt{\langle v_t^2 \rangle - \langle e_{v_t,(\text{obs})}^2 \rangle}, \quad (12)$$

where  $v_t$  is the transverse velocity after correcting for Galactic rotation and reflex solar motion (i.e. calculated from the sky-projected velocity after subtracting the mean velocity),  $e_{v_t,(\text{obs})}$  is the standard error for the transverse velocity calculated from observed proper motions and parallax without subtracting the mean Galactic rotation and reflex solar motion, and the angle brackets  $\langle \rangle$  denote a weighted sample average (e.g.  $\langle v_t^2 \rangle = (\sum_i w_i v_t^2) / (\sum_i w_i)$  with  $i$  an index labeling the data points in the sample).

The lower panel of Fig. 1 shows the scaled median velocity cor-

rected for random measurement error is calculated for each joint mass and photometric cooling age bin using the formula

$$\sqrt{\frac{\tilde{v}_t^2}{\ln 2} - \langle e_{v_t, (\text{obs})}^2 \rangle}, \quad (13)$$

where  $\tilde{v}_t$  is the sample median of  $v_t$ , determined for each bin using the weighted cumulative fraction for white dwarfs in that bin. The motivation for scaling the median is that we empirically find the transverse velocities to be approximately Rayleigh-distributed. A Rayleigh distribution parametrized by mode  $\sigma$  has a mean of  $\sigma\sqrt{\pi/2}$ , median of  $\sigma\sqrt{2\ln 2}$ , and variance of  $\sigma^2(2 - \pi/2)$ , yielding a transverse velocity dispersion of  $\sigma\sqrt{2}$  and  $\tilde{v}_t^2 = (\ln 2)\langle v_t^2 \rangle$ .

In both the middle and lower panels of Fig. 1, the solid black line shows the expected relation according to the AVRs of main sequence (G and F dwarf) stars found by Holmberg et al. (2009) for the sky distribution of the sample of  $1.15 - 1.25 M_\odot$  white dwarfs in each age bin. The transverse velocity dispersion value for each bin was calculated by taking the sample average of the sum of the eigenvalues of  $P \sigma^2 P^T$  (equivalent to the trace of this matrix),

$$\langle \text{Tr} (P \sigma^2 P^T) \rangle, \quad (14)$$

where  $P$  is the projection operator that projects the velocity  $\mathbf{v}$  onto the tangent plane of the celestial sphere such that  $\mathbf{v}_\perp = P \mathbf{v}$ ,  $v_t = |\mathbf{v}_\perp|$ , and  $\sigma^2 = \text{diag}(\sigma_U^2, \sigma_V^2, \sigma_W^2)$  is the dispersion tensor of the full 3-dimensional space velocities before projection. The values of  $\sigma_U$ ,  $\sigma_V$ , and  $\sigma_W$  are calculated for each white dwarf using the AVRs determined by Holmberg et al. (2009) with the photometric cooling age of that white dwarf. The AVRs of Holmberg et al. (2009) for the three velocity components and the total velocity (giving  $\sigma_U$ ,  $\sigma_V$ ,  $\sigma_W$ , and  $\sigma_{\text{tot}}$  as a function of age) each follow a power law with exponents of 0.39, 0.40, 0.53, and 0.40 for  $U$ ,  $V$ ,  $W$ , and total dispersion, respectively.

We similarly determined the expected relation for the Holmberg et al. (2009) AVRs if all of the white dwarfs are the product of double-white dwarf mergers, which is shown as the dashed black curve in the middle and lower panels of Fig. 1. Instead of using the photometric cooling age inferred directly using the white cooling models applicable for single stellar evolution to calculate the predicted  $\sigma_U$ ,  $\sigma_V$ , and  $\sigma_W$  values from the AVRs, the relation for merger products was calculated using the expected true age after accounting for a merger delay time, with the expectation value calculated using the merger delay distribution of Cheng et al. (2020).

Double white dwarf mergers can produce photometrically young white dwarf with transverse velocities faster than what would be expected for single stellar evolution products of the same photometric age because the true age of the white dwarf merger products (accounting for the lifetime of the merger progenitors) is typically older than the age inferred from photometry (Temink et al. 2020). Estimates of the merger fraction from both simulations (Temink et al. 2020; Bogomazov & Tutukov 2009, e.g.) and *Gaia* data (e.g. Fleury et al. 2022; Cheng et al. 2020; Kilic et al. 2021) indicate that merger products constitute an appreciable fraction of ultramassive white dwarfs, with estimates ranging from  $\sim 20\%$  to over 50%. However, while the presence of a large fraction of double white dwarf merger products among ultramassive white dwarfs contributes to the peak in transverse velocity dispersion observed for photometrically young white dwarfs coinciding with the Q branch, it does not explain the large fraction of fast-movers with  $v_t$  in excess of 60 km/s.

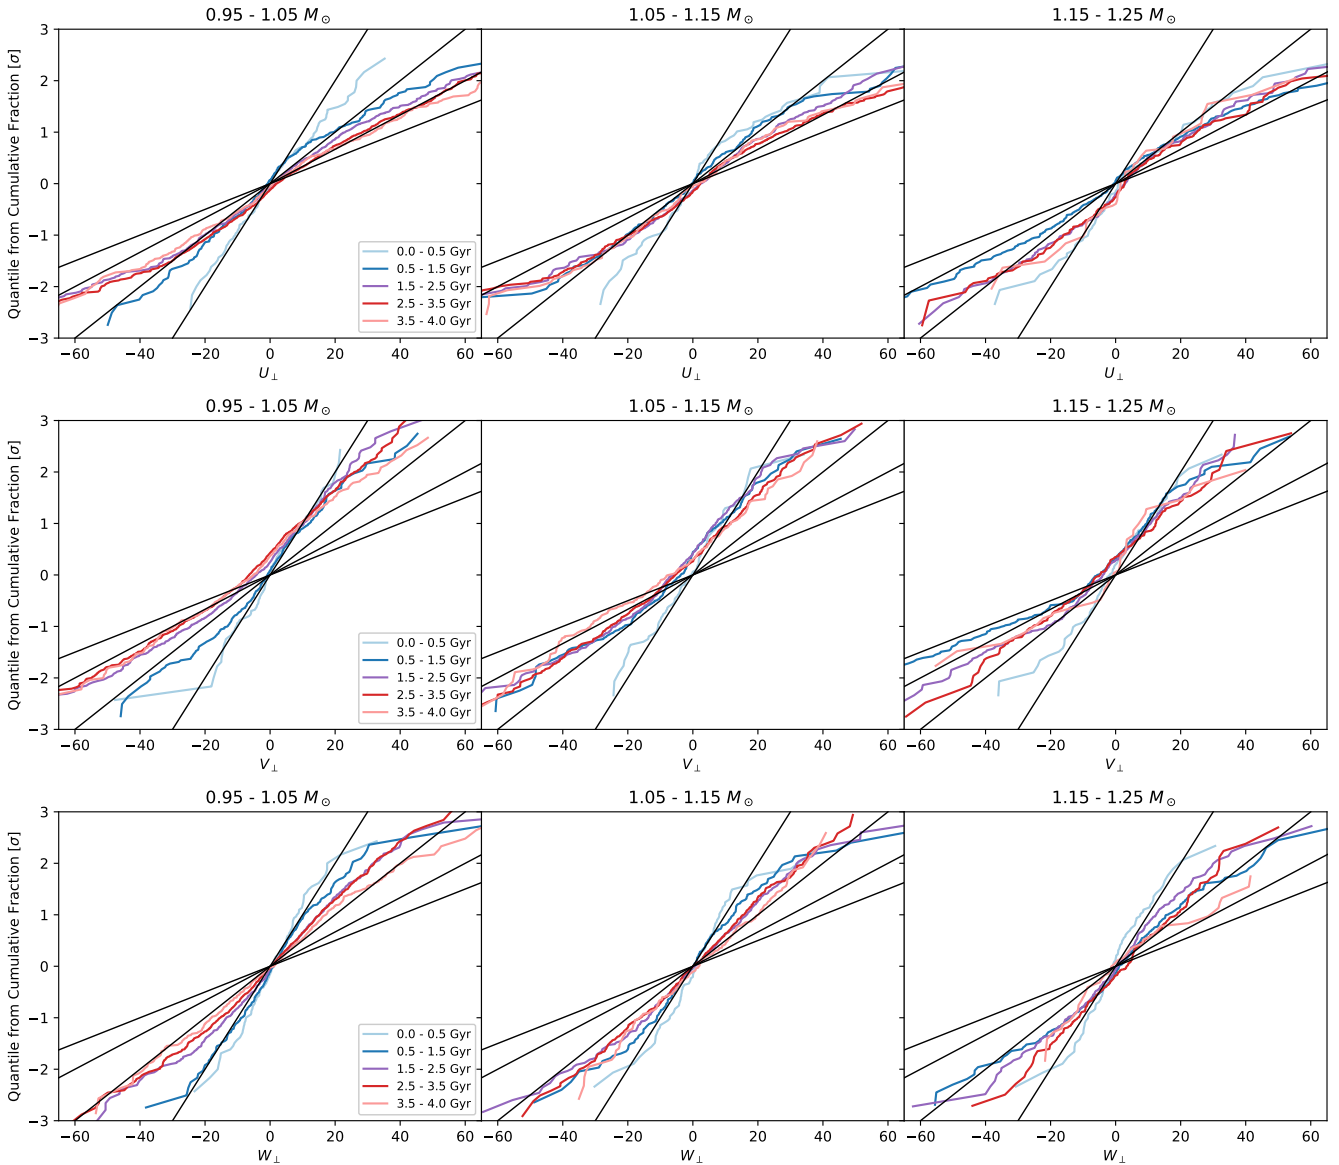

The behaviour of the AVRs that we measure for the transverse velocities aligns with the behaviour of the observed fraction of fast-movers as a function of cooling age. For both the non-robust and

robust estimators of transverse velocity dispersion, we see that the lightest ( $0.95 - 1.05 M_\odot$ ) white dwarfs tend to become more dispersed with age, as inferred from the fraction of fast-movers and expected from the AVRs of main sequence stars. The  $1.05 - 1.15 M_\odot$  white dwarfs mostly follow this trend as well, but with a small peak for cooling ages of  $\sim 1.0 - 2.0$  Gyr. The most massive ( $1.15 - 1.25 M_\odot$ ) white dwarfs show a prominent peak for cooling ages of  $\sim 0.5 - 2.0$  Gyr. The peak in transverse velocity dispersion of ultramassive white dwarfs inferred using the non-robust estimator (mean) is much larger than that inferred using the robust estimator (median), suggesting that the fast-movers in these age bins are outliers or comprise a separate population that is much more dispersed than the main population.

To better understand the kinematic features of the population of young fast-movers, we consider the distribution of each Cartesian component of the transverse velocities in each mass and age bin. Fig. 2 shows quantile-quantile (Q-Q) plots comparing the sample distribution of transverse Cartesian velocity components  $U_\perp$  (upper row),  $V_\perp$  (middle row), and  $W_\perp$  (bottom row) to the quantile function for a normal distribution with zero mean. The quantile function of a distribution is the inverse of the cumulative distribution; for an input percentile  $p$ , it gives the value of the random variable for which there is  $p$  probability of the random variable being less than or equal to the output value. For a 1D normal distribution with mean  $\mu$  and variance  $\sigma^2$ , the quantile function is  $\mu + \sigma \sqrt{2} \text{erfc}^{-1}(2[1-p])$ , where  $p \in [0, 1]$  is the percentile (i.e. cumulative probability) and  $\text{erfc}^{-1}$  is the inverse complementary error function. In Fig. 2, the measured value of the velocity component is used as the x-axis variable, while the y-axis variable is the value of the quantile function in units of standard deviation calculated from the weighted cumulative fraction. Written explicitly, the y-axis variable is  $y_i = \sqrt{2} \text{erfc}^{-1}(2[1-p_i])$  for the  $i$ th ordered data point (in order of increasing  $x$ ) with  $p_i = \sum_{j \leq i} w_j$  where  $j$  runs over all points for which  $x_j \leq x_i$ . For reference, we also show quantile functions for normal distributions with zero mean and  $\sigma = 10, 20, 30$ , and 40 km/s in order of decreasing slope as black lines. If the transverse velocity in a particular direction is normally-distributed for a particular sample, the corresponding Q-Q plot in Fig. 2 should appear as a straight line. A non-zero mean will simply cause a shift of the distribution along the horizontal axis, as can be seen in the plots for  $V_\perp$  due to asymmetric drift.

Observations of main sequence stars (e.g. Holmberg et al. 2009) indicate that the velocity dispersion of stars in the local thin disc increases with age. If the white dwarf velocities follow the AVRs of main sequence stars (Holmberg et al. 2009), the slope of the distribution in Fig. 2 should get progressively less steep with increasing cooling age for a given mass bin and velocity component. For the age bins considered in Fig. 2, this effect should be more pronounced for younger ages due to the power law form of the AVRs with exponents  $< 1$ . This is the approximate behaviour seen for the lightest two bins,  $0.95 - 1.05 M_\odot$  and  $1.05 - 1.15 M_\odot$  (left and middle columns of Fig. 2). For the ultramassive  $1.15 - 1.25 M_\odot$  white dwarfs, however, we see that the curves for the  $0.5 - 1.5$  Gyr white dwarfs have a shallower slope and thus larger dispersion than what would be predicted by the Holmberg et al. (2009) AVRs, particularly for negative  $U_\perp$  and  $V_\perp$ . The dispersions for these  $0.5 - 1.5$  Gyr white dwarfs are notably larger than the dispersions for the older  $1.5 - 2.5$  and  $2.5 - 3.5$  Gyr white dwarfs with mass in the range  $1.15 - 1.25 M_\odot$ . Furthermore, for the  $0.5 - 1.5$  Gyr age bin of  $1.15 - 1.25 M_\odot$  white dwarfs, the white dwarfs with negative  $V_\perp$  are much more dispersed in  $V_\perp$  than in  $U_\perp$ , indicating that these white dwarfs likely do not originate from the local thin disc.

The AVRs of Holmberg et al. (2009) indicate that local thin disc stars are more dispersed in  $U$  than  $V$ , and we show in Fig. 3 that

**Figure 2.** Quantile-Quantile Plots of Transverse Velocity Components. The vertical axis is the quantile function in units of standard deviation  $\sigma$  for a normal distribution with zero mean, calculated from the empirical cumulative fraction corresponding to the velocity component shown on the horizontal axis. The black lines correspond to normal distributions with  $\sigma = 10, 20, 30,$  and  $40$  km/s in order of decreasing slope.

this expectation holds for the tangential velocity components  $U_{\perp}$  and  $V_{\perp}$  as well. Since the [Holmberg et al. \(2009\)](#) AVRs describe the full 3-dimensional space velocities, we converted those relations to the expected AVRs of the projected velocities for the sky coordinate distribution of our  $1.15 - 1.25 M_{\odot}$  sample with  $0.5 - 2.5$  Gyr photometric ages. This enables us to properly compare the results of [Holmberg et al. \(2009\)](#) for main sequence stars from the local thin disc to the dispersion values of the tangential velocity components inferred from Fig. 2 for our ultramassive white dwarf sample. The expected AVRs of the projected velocities are given by the square root of the diagonal elements of the expectation of the matrix  $P\sigma^2P^T$ . Fig. 3 shows the AVRs from [Holmberg et al. \(2009\)](#) for the full 3-dimensional space velocities for each of the U, V, and W components (as solid blue, orange, and green curves, respectively), compared to the computed AVRs expected from the projected velocities for our sample’s empirical sky distribution (dashed lines). We also analyt-

ically evaluated the expected AVRs for the projected velocities for an isotropic distribution (shown as the dotted curves in Fig. 3) and found them to be nearly the same as the AVRs determined using the empirical sky distribution of our sample.

From Fig. 3 we see that the expected dispersions for the projected velocities are typically notably smaller than the corresponding dispersion of the un-projected velocities, but that the relative size of the dispersion for  $V_{\perp}$  compared to  $U_{\perp}$  is similar to the relative sizes of  $\sigma_U$  and  $\sigma_V$ . Of particular note is that, throughout the age of the thin disc, the dispersion of  $V_{\perp}$  is smaller than the dispersion of  $U_{\perp}$ . For the population of anomalously fast white dwarfs (mass bin  $1.15 - 1.25 M_{\odot}$  and photometric age bin  $0.5 - 1.5$  Gyr) with negative  $V_{\perp}$ , however, the dispersion of  $V_{\perp}$  is actually larger than the dispersion of  $U_{\perp}$ . A population in equilibrium in the disc should have a dispersion ratio for V relative to U of  $\sigma_V/\sigma_U = 2/3$  ([Binney & Tremaine 2008](#)), and the AVRs measured by [Holmberg et al. \(2009\)](#)

**Figure 3.** AVRs of Projected and Un-Projected Velocities. AVRs are shown for  $U$ ,  $V$ , and  $W$  in blue, orange, and green, respectively. The solid curves show the AVRs for the full 3-dimensional space velocities determined by Holmberg et al. (2009) for main-sequence stars. The dotted curves show the expected AVRs for the projected velocities assuming that the un-projected velocities follow the AVRs of Holmberg et al. (2009) and that the sky distribution is isotropic. The dashed curves also show the expected AVRs for the Holmberg et al. (2009) projected velocities but assuming that the sky distribution is that observed for  $1.15 - 1.25 M_{\odot}$  white dwarfs with  $0.5 - 2.5$  Gyr cooling ages.

for thin disc main-sequence stars have a dispersion ratio nearly equal to this equilibrium ratio (though actually slightly smaller). The dispersion of  $V_{\perp}$  being larger than the dispersion of  $U_{\perp}$  in the anomalous population thus indicates that this population is not in equilibrium in the disc and thus does not originate from the local thin (or thick) disc.

#### 4 DISCUSSION

The presence of a population of anomalously fast young, massive white dwarfs on the Q branch was first discovered in *Gaia* DR2 observations by Cheng et al. (2019), who argued this population must experience an extra cooling delay on the Q branch of  $\sim 6 - 8$  Gyr that is not accounted for in current white dwarf cooling models. Fig. 2 shows, however, that the dispersion of the anomalously fast ultramassive white dwarfs is actually too large to be explained entirely by a cooling delay in (thin) disc white dwarfs. If white dwarfs with a true age of 10 Gyr produced through single stellar evolution in the Galactic thin disc follow the AVRs determined by Holmberg et al. (2009), then the expected dispersions for the projected velocity components  $U_{\perp}$ ,  $V_{\perp}$ , and  $W_{\perp}$  in the tangent plane averaged over the sky distribution of the  $1.15 - 1.25 M_{\odot}$  white dwarfs with photometric ages  $0.5 - 2.5$  Gyr would be approximately 38 km/s, 26 km/s, and 25 km/s, respectively. From Fig. 2, we see that the anomalous  $1.15 - 1.25 M_{\odot}$  white dwarfs with  $0.5 - 1.5$  Gyr photometric ages have a dispersion for  $V_{\perp}$  of  $\sim 40$  km/s when  $V_{\perp}$  is negative (i.e. among white dwarfs that are moving in the opposite direction of Galactic rotation). The Galactic thin disc is not old enough to produce white dwarfs with such a high dispersion given the observed AVRs (Holmberg et al. 2009). While stars in the older thick disc have slightly higher dispersion (e.g. Sharma et al. 2014), the expected dispersion of  $\sim 33$  km/s for  $V_{\perp}$  is still too small to explain this dispersion through a cooling delay in a thick disc population.

Cheng et al. (2019) dismiss the possibility of alternate explanations for the anomalous fast-movers that do not invoke a cooling delay

by running a simple test in which the authors model the velocity distribution of the fast movers on the Q branch as a single Gaussian and determine kinematic relations expected for a disc in equilibrium, notably an asymmetric drift of approximately  $\bar{V} = -\sigma_U^2 / (80 \text{ km s}^{-1})$  and a dispersion ratio  $\sigma_U / \sigma_V$  of approximately  $2/3$ . However, as noted earlier and seen in Fig. 2, we find a population of highly dispersed ultramassive white dwarfs coincident with the Q branch that do not follow the equilibrium dispersion ratio, suggesting that these white dwarfs do not originate from the Milky Way disc.

The true origin of this population, however, is unclear. These white dwarfs may have originated from elsewhere in the galaxy such as from the halo. The halo is older than the Galactic disc (e.g. Gallart et al. 2019) and halo stars are typically more dispersed (Gaia Collaboration et al. 2018b). This scenario still requires a mechanism by which photometrically young white dwarfs acquire velocities faster than their photometric age would indicate, which could be a merger delay.

Another possible explanation of the anomalously fast movers is that they are the merger remnant of the inner binary of a hierarchical triple system whose outer companion was ejected. Observations indicate that triple systems are common, constituting about 10% of multiples with F and G dwarf primaries (Eggleton & Tokovinin 2008; Raghavan et al. 2010; Tokovinin 2014; Moe & Di Stefano 2017) and much larger fractions for higher mass B- and O-type primaries (Sana et al. 2014; Moe & Di Stefano 2017), and population synthesis simulations indicate that stellar interactions occur in the majority of triple systems (Toonen et al. 2020; Stegmann et al. 2021). The evolution of triple systems is significantly more complicated than that of isolated binaries due to the combination of stellar evolution, stellar interactions, and three-body dynamics (see e.g. Toonen et al. 2016, for a review). Triple systems tend to be hierarchical, with an inner binary and distant companion (Hut & Bahcall 1983). Such systems have a large variety of possible evolution channels (Toonen et al. 2020; Stegmann et al. 2021; Toonen et al. 2021) and can result in mergers and ejections (Mardling & Aarseth 2001; Perets & Kratter 2012; Hamers et al. 2022a,b; Glanz & Perets 2021; Grishin & Perets 2022; Toonen et al. 2021). The secular gravitational effects between the outer companion and inner binary can drive the inner binary to high eccentricity in Zeipel-Lidov-Kozai oscillations (von Zeipel 1910; Kozai 1962; Lidov 1962; Naoz 2016; Ito & Ohtsuka 2019), which can enhance mergers of compact objects (e.g. Blaes et al. 2002; Thompson 2011; Hamers et al. 2013; Antognini et al. 2014; Antonini et al. 2017; Silsbee & Tremaine 2017; Liu & Lai 2017, 2018; Hamers et al. 2018; Hoang et al. 2018; Randall & Xi-anyu 2018a,b; Toonen et al. 2018; Fragione & Loeb 2019; Stegmann et al. 2021). For example, dynamical effects of the outer companion can enhance the merger rate of inner compact double white dwarf binaries relative to isolated binary systems (Thompson 2011). Destabilised stellar triple systems in the field can eject a component with runaway speeds of tens of km/s (Toonen et al. 2021).

Unstable triple systems in star clusters can also result in the ejection of the tertiary perturber and escape from the cluster (Mardling & Aarseth 2001). From their N-body simulations of open clusters, Mardling & Aarseth (2001) describe a particular event in which an initially stable triple system became unstable and the tertiary companion was ejected; the resulting binary and single star both escaped the cluster with respective terminal velocities of 20.6 km/s and 65.7 km/s. Star clusters are known to harbour exotica such as blue stragglers, which can be formed through the dynamical evolution of stellar triple systems (Iben & Tutukov 1999) and have been found in both open clusters (Ahumada & Lapasset 2005; de Marchi et al. 2006) and globular clusters (Ferraro et al. 2012; Parada et al. 2016). Furthermore, cluster members can display different kinematic

relations than what is expected for a disc in equilibrium, and many nearby clusters are moving at speeds of tens of km/s relative to the local standard of rest (Gaia Collaboration et al. 2018a; Soubiran et al. 2018, 2019; Lodieu et al. 2019). The kinematically anomalous population we observe could thus conceivably originate from old open clusters or globular clusters that are close to the Galactic disc. While open clusters are typically younger than the members of the anomalous population, some open clusters are old enough to be a source of these white dwarfs, and those old open clusters are also typically rich (Gaia Collaboration et al. 2018a; Soubiran et al. 2018, 2019). As open clusters are only loosely gravitationally bound, stars can also readily escape from them; for example, observations indicate that the Pleiades has lost  $\sim 20\%$  of its mass over the past 100 Myr (Heyl et al. 2022). Though globular clusters are more tightly bound than open clusters and thus less prone to the escape of cluster members, they are also much typically much more populated (Gaia Collaboration et al. 2018a) and only a small fraction of escapees is needed to explain the anomalous population that we observe in this work.

## 5 CONCLUSIONS

As a follow-up to our previous work on the distribution of photometric cooling ages of massive white dwarfs in *Gaia* EDR3 (Fleury et al. 2022), we analysed the kinematics of the transverse motion of  $0.95 - 1.25 M_{\odot}$  *Gaia* EDR3 white dwarfs. We find that the population of anomalously fast ultramassive white dwarfs on the Q branch reported by Cheng et al. (2019) for *Gaia* DR2 is still present in *Gaia* EDR3. These white dwarfs appear photometrically young according to single stellar evolution models, but are moving faster than expected for stars of that age according to AVRs observed for the local thin disc. Using white dwarf cooling models for which the photometric age distributions are consistent with the expectation from the star formation history (Fleury et al. 2022) to infer the masses and ages of our sample of white dwarfs and sorting our full sample into mass and age bins, we find that this population of fast-movers is concentrated to masses of  $1.15 - 1.25 M_{\odot}$  and photometric cooling ages of  $0.5 - 1.5$  Gyr.

Our analysis of the distributions of the individual components of the transverse velocity reveals that among the white dwarfs in the mass range  $1.15 - 1.25 M_{\odot}$  and age range  $0.5 - 1.5$  Gyr, there is a population of white dwarfs lagging the local Galactic rotation that is too dispersed in  $V_{\perp}$  to be explained solely by a cooling delay in white dwarfs born in the local thin disc. According to the AVRs determined from observations of main sequence stars in the local thin disc (Holmberg et al. 2009; Sharma et al. 2014), it would take longer than the age of the thin disc (10 Gyr) for disc heating to produce a dispersion large enough to explain this anomalous population of white dwarfs. Furthermore, we find this population to be more dispersed in  $V_{\perp}$  than in  $U_{\perp}$ , which suggests that this population does not originate from the local disc. Some potential explanations of this population include a halo origin with a long merger delay or that they are produced through triple system dynamics such as the merger of the inner binary of a hierarchical triple system whose tertiary companion was ejected resulting in a large velocity for the binary that ultimately merges to form the white dwarf. However, the precise origin of this population of young ultramassive white dwarfs is an open question for future work.

## ACKNOWLEDGEMENTS

This work has been supported by the Natural Sciences and Engineering Research Council of Canada through the Discovery Grants program and Compute Canada. I.C. is a Sherman Fairchild Fellow at Caltech and thanks the Burke Institute at Caltech for supporting her research.

This work has made use of data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>) Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement. We used the “Synthetic Colors and Evolutionary Sequences of Hydrogen- and Helium-Atmosphere White Dwarfs” website at <http://www.astro.umontreal.ca/~bergeron/CoolingModels/>.

## DATA AVAILABILITY

The data used in this paper are available through TAP Vizier and the *Gaia* archive. We constructed the 200-pc white dwarf catalogue from [https://warwick.ac.uk/fac/sci/physics/research/astro/research/catalogues/gaiaedr3\\_wd\\_main.fits.gz](https://warwick.ac.uk/fac/sci/physics/research/astro/research/catalogues/gaiaedr3_wd_main.fits.gz). The corresponding author can also provide software to perform the analysis presented in this paper.
