November 22, 2022

Abstract

Learning neural networks using only few available information is an important ongoing research topic with tremendous potential for applications. In this paper, we introduce a powerful regularizer for the variational modeling of inverse problems in imaging. Our regularizer, called patch normalizing flow regularizer (patchNR), involves a normalizing flow learned on small patches of very few images. In particular, the training is independent of the considered inverse problem such that the same regularizer can be applied for different forward operators acting on the same class of images. By investigating the distribution of patches versus those of the whole image class, we prove that our model is indeed a MAP approach. Numerical examples for low-dose and limited-angle computed tomography (CT) as well as superresolution of material images demonstrate that our method provides very high quality results. The training set consists of just six images for CT and one image for superresolution. Finally, we combine our patchNR with ideas from internal learning for performing superresolution of natural images directly from the low-resolution observation without knowledge of any high-resolution image.

1 Introduction

Solving inverse problems with limited access to training data is an active field of research. In inverse problems, we aim to reconstruct an unknown ground truth image x from some observation

$$y = \text{noisy}(f(x)), \quad (1)$$

where f is an ill-posed forward operator and “noisy” describes some noise model. In the recent years learning-based reconstruction methods as supervisely trained neural networks on large datasets [36, 65] and conditional generative models [6, 27, 55, 72] attained a lot of attention. However, for many applications like medical or material imaging, the acquisition of a large database of ground truth images or pairs of ground truth images and observations is very costly or even impossible [47, 83]. Model-based approaches assume that the forward operator f is known and aim to minimize a variational functional of the form

$$\mathcal{J}(x; y) = \mathcal{D}(f(x), y) + \lambda \mathcal{R}(x), \quad \lambda > 0, \quad (2)$$

where \mathcal{D} is a data-fidelity term which depends on the noise model and measures how well the reconstruction fits to the observation and \mathcal{R} is a regularizer which copes with the ill-posedness and incorporates prior information. Over the last years, learned regularizers like the total deep variation [45, 46] or adversarial regularizers [53, 56, 60] as well as extensions of plug-and-play methods [23, 75, 80] with learned denoisers [31, 34, 64, 84] showed promising results, see [8, 57] for an overview.

Furthermore, many papers leveraged the tractability of the likelihood of normalizing flows to learn a prior [9, 29, 81, 82]. They utilize the invertibility to optimize over the range of the flow together with the Gaussian assumption on the latent space. Also, diffusion models [38, 39, 73, 74] have shown great generative modelling capabilities and have been used as a prior for inverse problems. Moreover, other generative models, such as GANs [4, 25, 58] or VAEs [43], have been used as a regularizer, see the recent review [19] and references therein. However, even if these methods allow an unsupervised reconstruction, their training is often computationally costly and a huge amount of training images is required.

One possibility to reduce the training effort consists in using only small image patches. Denoising methods based on the comparison of similar patches provided state-of-the-art methods [12, 15, 48, 49] for a long time. Recently, the approximation of *patch distributions* of images was successfully exploited in certain papers [3, 17, 26, 30, 32, 33, 68]. In particular, [86] proposed the negative log likelihood of all patches of an image as a regularizer, where the underlying patch distribution was assumed to follow a Gaussian mixture model (GMM) which parameters were learned from few clean images. This method is still competitive to many approaches based on deep learning and several extensions were suggested recently [21, 59, 69]. However, even though GMMs can approximate any probability density function if the number of components is large enough, they suffer from limited flexibility in case of a fixed number of components, see [22] and the references therein. Moreover the subsequent reconstruction procedure detailed in [86] is computationally expensive.

In this paper, we propose to use a regularizer which incorporates a normalizing flow (NF) learned on small image patches, usually of size 6×6 . NFs were introduced in [18, 63], see also [67] for its continuous counterpart. They build upon invertible neural networks and allow for explicit density evaluation. Our PatchNR consists of a NF which is trained to approximate the distribution of patches. As the structure of small patches is usually much simpler than those of whole images, it appears that their approximation is more accurate. Moreover, as a large data base of patches can be extracted from few images, we require only a very small amount of training images. Once the patchNR is learned, we use

the negative log likelihood of all patches as regularizer in (2) for its reconstruction. Indeed we will prove that our model can be obtained by a maximum a posteriori (MAP) approach. Since the regularizer is only specific to the considered image class, but not to the inverse problem, it can be applied for different forward operators as, e.g., for low-dose CT and limited-angle CT without additional training. This is in contrast to data-based methods as FBP+UNet, where the network has to be trained for each new forward operator separately.

We demonstrate by numerical examples that our patchNR admits high quality results for low-dose and limited-angle CT as well as superresolution. Moreover, we combine patchNRs with ideas from internal learning to perform superresolution on natural images without any training data. Internal learning [24, 70] is based on the observation that the patches within natural images are self-similar across the scales. In our case, this leads to the idea to train the patchNR on the low-resolution observation instead of a dataset of training images. We demonstrate on the BSD68 dataset that zero-shot superresolution with patchNRs outperforms comparable methods including the original ZSSR paper by [70]. Finally, let us mention that recent works have explored meta-learning for efficient one gradient step reconstruction [71], applications to light field superresolution [14] and CT superresolution [85].

The paper is organized as follows: We start by explaining the training of our patchNR and the variational reconstruction model in Section 2. Our approach is integrated into the MAP framework in Section 3, i.e., the patchNR defines a probability density on the full image space. In Section 4, we evaluate the performance of our model in CT and superresolution and use the patchNR also for zero-shot superresolution. Finally, conclusions are drawn in Section 5.

2 Patch Normalizing Flows in Variational Modeling

In the following, we assume that we are given a small number of high quality example images $x_1, \dots, x_M \in \mathbb{R}^{d_1 \times d_2}$ - indeed $M = 1$ or $M = 6$ in our numerical examples - from a certain image class as CT, material or texture images. Our method consists of two steps, namely i) learning a NF for approximating the patch distribution of the example images, and ii) establishing a variational model which incorporates the learned patchNR in the regularizer.

Learning patchNRs Let $p_1, \dots, p_N \in \mathbb{R}^{s_1 \times s_2}$, $s_i \ll d_i$, $i = 1, 2$ denote all possibly overlapping patches of the example images, where we assume that the patches p_1, \dots, p_N are realizations of an absolute continuous probability distribution Q with density q . We aim to approximate q by a NF. For simplicity, we rearrange the images and the patches columnwise into vectors of size $d = d_1 d_2$ and $s := s_1 s_2$, respectively. Then we learn a diffeomorphism $\mathcal{T} = \mathcal{T}_\theta: \mathbb{R}^s \rightarrow \mathbb{R}^s$ such that $Q \approx \mathcal{T}_\# P_Z := P_Z \circ \mathcal{T}^{-1}$, where P_Z is a s -dimensional standard normal distribution. To this end, we set our normalizing flow \mathcal{T} to be an invertible neural network with parameters collected in θ . There were several approaches in the literature to construct such invertible neural networks [5, 13, 18, 42, 52]. In this paper, we adapt the architecture from [5]. In order to train our NF, we aim to

minimize the (forward) Kullback-Leibler divergence

$$\text{KL}(Q, \mathcal{T}_{\#}P_Z) := \int_{\mathbb{R}^s} \log \left(\frac{dQ}{d\mathcal{T}_{\#}P_Z} \right) dQ = \mathbb{E}_{p \sim Q} [\log (q(p))] - \mathbb{E}_{p \sim Q} [\log (p_{\mathcal{T}_{\#}P_Z}(p))],$$

where we set the expression to $+\infty$ if Q is not absolutely continuous with respect to $\mathcal{T}_{\#}P_Z$. The first term on the right-hand side is a constant independent of the parameters θ . Thus, using the change-of-variables formula for probability density functions of push-forward measures $p_{\mathcal{T}_{\#}P_Z} = p_Z(\mathcal{T}^{-1})|\det(\nabla\mathcal{T}^{-1})|$, we obtain that the above formula is up to a constant equal to

$$-\mathbb{E}_{p \sim Q} [\log (p_Z(\mathcal{T}^{-1}(p)) + \log (|\det(\nabla\mathcal{T}^{-1}(p))|)],$$

where $\nabla\mathcal{T}^{-1}$ denotes the Jacobian matrix of \mathcal{T}^{-1} . By replacing the expectation by the empirical mean of our training set, inserting the standard normal density p_Z and neglecting some constants, we finally obtain the loss function

$$\mathcal{L}(\theta) := \frac{1}{N} \sum_{i=1}^N \frac{1}{2} \|\mathcal{T}^{-1}(p_i)\|^2 - \log (|\det(\nabla\mathcal{T}^{-1}(p_i))|). \quad (3)$$

We minimize this loss function using the Adam optimizer [41].

Reconstruction with PatchNRs Once the patchNR \mathcal{T} is learned, we aim to use it within a regularizer of the variational model (2) to solve the inverse problem (1). To this end, denote by $E_i: \mathbb{R}^d \rightarrow \mathbb{R}^s$, $i = 1, \dots, N_p$ the operator, which extracts the i -th (vectorized) patch from the unknown (vectorized) image $x \in \mathbb{R}^d$. Then, we define our regularizer by the negative log likelihood of all patches under the probability distribution learned by the patchNR. More precisely, we define the patchNR based prior

$$\frac{1}{s} \sum_{i=1}^{N_p} -\log (p_{\mathcal{T}_{\#}P_Z}(E_i(x))),$$

where N_p is the number of patches in the image x and $s = s_1 s_2$ the number of pixels in a patch. Similar to (3), this can be reformulated by the change-of-variables formula and by ignoring some constants as

$$\text{patchNR}(x) := \frac{1}{s} \sum_{i=1}^{N_p} \frac{1}{2} \|\mathcal{T}^{-1}(E_i(x))\|^2 - \log (|\det(\nabla\mathcal{T}^{-1}(E_i(x)))|).$$

Note that if we ignore the boundary of the image, the patchNR is translation invariant. That is, a translation of the image does not change the value of the regularizer. Now, we reconstruct our ground truth by finding a minimizer of the variational problem

$$\mathcal{J}(x; y) = \mathcal{D}(f(x), y) + \lambda \text{patchNR}(x), \quad \lambda > 0. \quad (4)$$

For the minimization, we use the Adam optimizer [41]. To speed up the numerical computations, we do not consider all overlapping patches in x , but choose randomly a subset

of N_p possibly overlapping patches in each iteration. Note that the resulting optimization problem is non-convex and therefore the choice of the initialization is important. In our experiments we initialize this optimization with a coarse reconstruction, i.e., a bicubic interpolation for superresolution or the filtered backprojection (FBP) for CT.

Remark 1 (Relation to EPLL). *Our patchNR is closely related to the expected patch log likelihood (EPLL) prior proposed by [86]. Here, the authors use the prior defined as*

$$\text{EPLL}(x) = \frac{1}{N_p} \sum_{i=1}^{N_p} -\log(p(E_i(x))),$$

where p is the probability density function of a GMM approximating the patch distribution of the image class of interest. However, GMMs have a limited expressiveness and can only hardly approximate complicated probability distributions induced by patches [22]. Further, the reconstruction process proposed in [86] is computationally very costly even though a reduction of the computational effort was considered in several papers [59, 69]. Indeed, we will show in our numerical examples that the patchNR clearly outperforms the reconstructions from EPLL.

3 Analysis of Patch Normalizing Flows

In this section, we investigate the patch distribution which is approximated by the patchNR. More precisely, we show that any probability density on the class of images induces a probability density on the space of patches and vice versa. We will use this to interpret the minimization of the variational problem (4) as maximizing the posterior distribution.

Remark 2. *Considering the inverse problem (1) as a Bayesian inverse problem*

$$Y = \text{noisy}(f(X)),$$

where X and Y are random variables, Bayes' theorem implies that maximizing the log-posterior distribution $\log(p_{X|Y=y}(x))$ can be written as

$$\arg \max_x \{\log(p_{X|Y=y}(x))\} = \arg \min_x \left\{ -\log p_{Y|X=x}(y) - \log p_X(x) \right\}.$$

Consequently, the data-fidelity term and the regularizer in (2) correspond to the negative log likelihood $\mathcal{D}(f(x), y) = -\log p_{Y|X=x}(y)$ and to the negative log prior $\mathcal{R}(x) = -\log p_X(x)$, respectively.

Let $X: \Omega \rightarrow \mathbb{R}^d$ with $X \sim P_X$ be a d -dimensional random variable on the space of images. By $\tilde{E}_i: \mathbb{R}^d \rightarrow \mathbb{R}^{d-s}$ we denote the operator which extracts all pixels from a d -dimensional image, which do not belong to the i -th patch. Let $I: \Omega \rightarrow \{1, \dots, N_p\}$ be a random variable which follows the uniform distribution on $\{1, \dots, N_p\}$. Then, the random variable $\omega \mapsto E_{I(\omega)}(X(\omega))$ describes the selection of a random patch from a random image. We call the distribution Q of $E_I(X)$ the patch distribution corresponding to P_X . The following lemma provides an explicit formula for the density of Q .

Lemma 3. Let P_X be a probability distribution on \mathbb{R}^d with density p_X . Then, also the corresponding patch distribution Q is absolute continuous with density

$$q(p) = \frac{1}{N_p} \sum_{i=1}^{N_p} \int_{\mathbb{R}^{d-s}} p_X(E_i^T(p) + \tilde{E}_i^T(\tilde{x})) d\tilde{x}.$$

Proof. Let $A \in \mathcal{B}(\mathbb{R}^s)$ be an arbitrary Borel set. Then, we have by Bayes' theorem that

$$Q(A) = \sum_{i=1}^{N_p} \mathbb{P}(I = i) E_{i\#} P_X(A) = \frac{1}{N_p} \sum_{i=1}^{N_p} P_X(E_i^{-1}(A)) = \frac{1}{N_p} \sum_{i=1}^{N_p} \int_{\mathbb{R}^d} 1_A(E_i(x)) p_X(x) dx.$$

Now, we use the decomposition

$$\mathbb{R}^d = \text{Ker}(E_i) \oplus \text{Im}(E_i^T) = \text{Im}(\tilde{E}_i^T) \oplus \text{Im}(E_i^T).$$

With Fubini's theorem, $E_i E_i^T = I$ and $E_i \tilde{E}_i^T = 0$, this is equal to

$$\begin{aligned} Q(A) &= \frac{1}{N_p} \sum_{i=1}^{N_p} \int_{\mathbb{R}^s} \int_{\mathbb{R}^{d-s}} 1_A(E_i(E_i^T(p) + \tilde{E}_i^T(\tilde{x}))) p_X(E_i^T(p) + \tilde{E}_i^T(\tilde{x})) d\tilde{x} dp \\ &= \frac{1}{N_p} \sum_{i=1}^{N_p} \int_{\mathbb{R}^s} \int_{\mathbb{R}^{d-s}} 1_A(p) p_X(E_i^T(p) + \tilde{E}_i^T(\tilde{x})) d\tilde{x} dp \\ &= \int_A \frac{1}{N_p} \sum_{i=1}^{N_p} \int_{\mathbb{R}^{d-s}} p_X(E_i^T(p) + \tilde{E}_i^T(\tilde{x})) d\tilde{x} dp. \end{aligned}$$

This proves the claim. \square

For the proof of the reverse direction, namely that given a probability measure Q on the space of patches, the patchNR defines a probability density function on the space of all images, we need the following lemma. It states that the density induced by a NF with a Gaussian latent distribution is up to a constant bounded from below and above by the density of certain normal distributions. In particular, it has exponential asymptotic decay. Note that similar questions about bi-Lipschitz continuous diffeomorphisms were investigated more detailed in [28, 35].

Lemma 4. Let $\mathcal{T}: \mathbb{R}^s \rightarrow \mathbb{R}^s$ be a diffeomorphism with Lipschitz constants $\text{Lip}(\mathcal{T}) \leq K$ and $\text{Lip}(\mathcal{T}^{-1}) \leq L$ and let $P_Z = \mathcal{N}(0, I)$. Then, it holds

$$\frac{1}{L^s K^s} \mathcal{N}(p|\mathcal{T}(0), \frac{1}{L^2} I) \leq p_{\mathcal{T}\#P_Z}(p) \leq L^s K^s \mathcal{N}(p|\mathcal{T}(0), K^2 I)$$

for any $p \in \mathbb{R}^s$.

Proof. Using the Lipschitz continuity of \mathcal{T} , we obtain

$$\frac{1}{K^2} \|p - \mathcal{T}(0)\|^2 = \frac{1}{K^2} \|\mathcal{T}(\mathcal{T}^{-1}(p)) - \mathcal{T}(0)\|^2 \leq \|\mathcal{T}^{-1}(p) - 0\|^2 = \|\mathcal{T}^{-1}(p)\|^2.$$

Now, applying the change-of-variables formula and that $|\det(\nabla \mathcal{T}^{-1}(\mathbf{p}))| \leq L^s$, we conclude

$$\begin{aligned} p_{\mathcal{T}_{\#}P_Z}(\mathbf{p}) &= p_Z(\mathcal{T}^{-1}(\mathbf{p}))|\det(\nabla \mathcal{T}^{-1}(\mathbf{p}))| \leq \frac{L^s}{(2\pi)^{s/2}} \exp(-\tfrac{1}{2}\|\mathcal{T}^{-1}(\mathbf{p})\|^2) \\ &\leq \frac{L^s}{(2\pi)^{s/2}} \exp(-\tfrac{1}{2K^2}\|\mathbf{p} - \mathcal{T}(0)\|^2) = L^s K^s \mathcal{N}(\mathbf{p}|\mathcal{T}(0), K^2 I). \end{aligned}$$

This shows the second inequality. For the first inequality, note that by the inverse function theorem

$$\nabla \mathcal{T}^{-1}(\mathbf{p}) = \nabla \mathcal{T}^{-1}(\mathcal{T}(\mathcal{T}^{-1}(\mathbf{p}))) = (\nabla \mathcal{T}(\mathcal{T}^{-1}(\mathbf{p})))^{-1}.$$

Using the Lipschitz continuity of \mathcal{T} , this implies

$$|\det(\nabla \mathcal{T}^{-1}(\mathbf{p}))| = \left| \det(\nabla \mathcal{T}(\mathcal{T}^{-1}(\mathbf{p}))) \right|^{-1} \geq 1/K^s.$$

Further, by the Lipschitz continuity of \mathcal{T}^{-1} it holds that

$$\|\mathcal{T}^{-1}(\mathbf{p})\|^2 = \|\mathcal{T}^{-1}(\mathbf{p}) - \mathcal{T}^{-1}(\mathcal{T}(0))\|^2 \leq L^2 \|\mathbf{p} - \mathcal{T}(0)\|^2.$$

Putting the things together yields

$$\begin{aligned} p_{\mathcal{T}_{\#}P_Z}(\mathbf{p}) &= p_Z(\mathcal{T}^{-1}(\mathbf{p}))|\det(\nabla \mathcal{T}^{-1}(\mathbf{p}))| \geq \frac{1}{K^s(2\pi)^{s/2}} \exp(-\tfrac{1}{2}\|\mathcal{T}^{-1}(\mathbf{p})\|^2) \\ &\geq \frac{1}{K^s(2\pi)^{s/2}} \exp(-\tfrac{L^2}{2}\|\mathbf{p} - \mathcal{T}(0)\|^2) = \frac{1}{L^s K^s} \mathcal{N}(\mathbf{p}|\mathcal{T}(0), \tfrac{1}{L^2} I). \end{aligned}$$

This completes the proof. \square

Now, we can show that the patchNR defines a probability distribution on the space of all images. This allows a MAP interpretation of the variational problem (4).

Proposition 5. *Let $P_Z = \mathcal{N}(0, I)$ and let $\mathcal{T}: \mathbb{R}^s \rightarrow \mathbb{R}^s$ be a bi-Lipschitz diffeomorphism, i.e., $\text{Lip}(\mathcal{T}) < \infty$ and $\text{Lip}(\mathcal{T}^{-1}) < \infty$. Then, for any $\rho > 0$, the function $\varphi(x) = \exp(-\rho \text{patchNR}(x))$ belongs to $L^1(\mathbb{R}^d)$, where*

$$\text{patchNR}(x) = \frac{1}{s} \sum_{i=1}^{N_p} -\log(p_{\mathcal{T}_{\#}P_Z}(E_i(x))).$$

Proof. Using Lemma 4, there exists some $C > 0$ such that it holds

$$\begin{aligned} \int_{\mathbb{R}^d} \varphi(x) dx &= \int_{\mathbb{R}^d} \left(\prod_{i=1}^{N_p} p_{\mathcal{T}_{\#}P_Z}(E_i(x)) \right)^{\rho/s} dx \\ &\leq C \int_{\mathbb{R}^d} \left(\prod_{i=1}^{N_p} \mathcal{N}(E_i(x)|\mathcal{T}(0), K^2 I) \right)^{\rho/s} dx \\ &= C \int_{\mathbb{R}^d} \prod_{i=1}^{N_p} \prod_{j=1}^s \mathcal{N}((E_i(x))_j | (\mathcal{T}(0))_j, K^2)^{\rho/s} dx, \end{aligned}$$

where $(E_i(x))_j$ is the j -th element from $E_i(x)$. Since $(E_i(x))_j = x_{\sigma(i,j)}$ for some mapping $\sigma: \{1, \dots, N_p\} \times \{1, \dots, s\} \rightarrow \{1, \dots, d\}$ and using Fubini's theorem, this simplifies to

$$\begin{aligned} & C \int_{\mathbb{R}^d} \prod_{i=1}^{N_p} \prod_{j=1}^s \mathcal{N}(x_{\sigma(i,j)} | (\mathcal{T}(0))_j, K^2)^{\rho/s} dx \\ &= C \int_{\mathbb{R}^d} \prod_{k=1}^d \prod_{(i,j) \in \sigma^{-1}(\{k\})} \mathcal{N}(x_k | (\mathcal{T}(0))_j, K^2)^{\rho/s} dx \\ &= C \prod_{k=1}^d \int_{\mathbb{R}} \prod_{(i,j) \in \sigma^{-1}(\{k\})} \mathcal{N}(x | (\mathcal{T}(0))_j, K^2)^{\rho/s} dx. \end{aligned}$$

Here $\sigma^{-1}(\{k\})$ denotes the preimage of σ which denotes the set of all index pairs (i, j) such that $(E_i(x))_j = x_k$ for $x \in \mathbb{R}^d$. As each pixel in the images is covered by at least one patch, this set is non-empty. Using the fact that products and powers of normal densities are integrable, we obtain that this expression is finite and the proof is complete. \square

4 Numerical Examples

In this section, we demonstrate the performance of our method. We focus on linear inverse problems, but the approach can also be extended to non-linear forward operators. First, in Subsection 4.1, we apply the patchNR to low-dose CT in a full angle and a limited angle setting and present an empirical convergence study for the optimization of the objective functional. Afterwards, in Subsection 4.2, we consider superresolution on material data. This is a typical setting, where only little data is available and superresolution is needed to obtain sufficient detail for material research [16, 37, 62]. Lastly, we extend our findings to zero-shot superresolution in Subsection 4.3. To get a better impression on the very good performance of our method, we added more numerical examples in B¹.

Comparison Methods We compare our method with established methods from the literature, in particular with

- Wasserstein Patch Prior (WPP) [3, 30],
- Expected Patch Log Likelihood (EPLL) [86],
- Local Adversarial Regularizer (localAR) [60],

since these methods also work on patches and are model-based. Note that we optimized the EPLL GMM prior using a gradient descent optimizer ourselves, as the half quadratic splitting proposed originally by the authors of [86] is much more expensive for the superresolution and CT forward operator. Moreover, we include comparisons with

- Plug-and-Play Forward Backward Splitting with DRUNet (DPIR) [84],

¹the code for all experiments is available at <https://github.com/FabianAltekrueger/patchNR>

- Deep Image Prior in combination with a TV prior (DIP+TV) [78, 10],
- data-based methods as the post-processing UNet (FBP+UNet) [36, 65] for CT and an asymmetric CNN (ACNN) [77] for superresolution.

Details on the comparison methods are given in A. Note that post-processing approaches are no longer the state-of-the-art for CT reconstruction, but are still widely used and serve as comparison methods. Currently some learned iterative methods provide better results [2].

Architecture of PatchNR For the architecture we use there exists a universal approximation theorem [76]. Therefore, a sufficiently large normalizing flow can approximate arbitrary probability distributions. We use 5 GlowCoupling blocks and permutations in an alternating manner, where the coupling blocks are from the freely available FrEIA package². The 3-layer subnetworks are fully connected with ReLU activation functions and 512 nodes resulting in 2908520 learnable parameters. The patchNR is trained on 6×6 patches, i.e., $s = 36$. For each image class, we trained the patchNR using Adam optimizer [41] with a learning rate of 0.0001, a batch size of 32 and for 750000 optimizer steps. Training took about 2.5 hours on a single NVIDIA GeForce RTX 2080 super GPU with 8 GB GPU memory.

4.1 Computed Tomography

For computed tomography (CT) we use the LoDoPaB dataset [50]³ for low-dose CT imaging. It is based on scans of the Lung Image Database Consortium and Image Database Resource Initiative [7] which serve as ground truth images, while the measurements are simulated. The dataset contains 35820 training images, 3522 validation images and 3553 test images. Here the ground truth images have a resolution of 362×362 px. The LoDoPab dataset uses a two-dimensional parallel beam geometry with equidistant detector bins. The forward operator is the discretized linear Radon transformation and the noise can be modelled using a Poisson distribution. Concretely, we consider the inverse problem

$$y = f(x) + \eta, \text{ where } \eta = -f(x) - \frac{1}{\mu} \log \left(\frac{\tilde{N}_1}{N_0} \right), \tilde{N}_1 \sim \text{Pois}(N_0 \exp(-f(x)\mu)).$$

Here $N_0 = 4096$ is the mean photon count per detector bin without attenuation and $\mu = 81.35858$ is a normalization constant. In order to compute the corresponding data-fidelity term, we see that the observation y can be rewritten by

$$y = -\frac{1}{\mu} \log \left(\frac{\tilde{N}_1}{N_0} \right)$$

and thus $\exp(-y\mu)N_0 = \tilde{N}_1 \sim \text{Pois}((N_0 \exp(-f(x)\mu)))$. Since we assume that the pixels are corrupted independently and the negative log-likelihood of a Poisson distributed

²available at <https://github.com/VLL-HD/FrEIA>

³available at <https://zenodo.org/record/3384092#.Y1glz3VBwgM>

Figure 1: Ground truth images used for training the patchNR (CT).

random variable is given by the Kullback-Leibler divergence, we have

$$\begin{aligned} -\log p(\exp(-y\mu)N_0 | \exp(-f(x)\mu)N_0) &= \sum_{i=1}^d -\log p(\exp(-y_i\mu)N_0 | \exp(-f(x)_i\mu)N_0) \\ &= \sum_{i=1}^d e^{-f(x)_i\mu} N_0 + e^{-y_i\mu} N_0 (f(x)_i\mu - \log(N_0)) \end{aligned}$$

Thus, the concrete form of (4) we aim to minimize, is given by

$$\mathcal{J}(x; y) = \sum_{i=1}^d e^{-f(x)_i} N_0 + e^{-y_i} N_0 (f(x)_i - \log(N_0)) + \lambda \mathcal{R}(x).$$

We trained the patchNR using patches of a small set of $M = 6$ handpicked CT ground truth images of size 362×362 illustrated in Figure 1. Once trained, the patchNR can be used both for the full angle CT and the limited angle CT setting, where we use a regularization parameter $\lambda = 700 \frac{s}{N_p}$, a random subset of $N_p = 40000$ overlapping patches in each iteration and the Adam optimizer with a learning rate of 0.005. While for full angle CT we optimized over 300 iterations, for limited angle CT 3000 iterations are used.

Full angle CT For full angle CT we consider 1000 equidistant angles between 0 and π . In Figure 2 we compare different methods for full angle low-dose CT imaging. Here the patchNR yields better results than DIP+TV and localAR, in particular the edges are sharper and more realistic in the reconstruction of patchNR. Visually, there are only small differences between patchNR and FBP+UNet observable, although FBP+UNet is a data-based method trained on 35820 image pairs, while we only used 6 ground truth images for training the patchNR. The quality measures averaged over the first 100 test

	FBP	DIP + TV	EPLL	localAR	patchNR	FBP+UNet (data-based)
PSNR	30.37 ± 2.95	34.45 ± 4.20	34.89 ± 4.41	33.64 ± 3.74	35.19 ± 4.52	35.48 ± 4.52
SSIM	0.739 ± 0.141	0.821 ± 0.147	0.821 ± 0.154	0.807 ± 0.145	0.829 ± 0.152	0.837 ± 0.143
Runtime	0.03s	1514.33s	36.65s	30.03s	48.39s	0.46s

Table 1: Full angle CT. Averaged quality measures and standard deviations of the reconstructions.

images of the LoDoPaB dataset in Table 1 confirm these observations. PSNR and SSIM were evaluated on an adaptive data range. Note that the diversity of the test set causes relatively high standard deviations.

Limited angle CT Now we consider the limited angle CT reconstruction problem, i.e., instead of considering equidistant angles between 0 and π we only have a subset of angles. In our experiment we cut off the first and last 100 angles, i.e., we cut off 36° out of 180° . This leads to a much worse FBP reconstruction. In Figure 3, we compare the different reconstruction methods for the limited angle problem. Although the FBP shows a very bad reconstruction in the 36° part, where the angles are cut off, the patchNR can reconstruct these details well and in a realistic manner. In particular, the edges of patchNR reconstruction are preserved, while for the other methods these have a pronounced blur, see Table 2 for an average of the quality measures over the first 100 test images.

Empirical convergence analysis for full angle CT To reconstruct the ground truth image from given measurements y , we minimize the functional $\mathcal{J}(x; y)$ in (4) w.r.t. x using the Adam optimizer. The resulting optimization problem is non-convex and the final minimizer could depend on the initialization. In our experiments, it has proven useful to start the optimization with a rough reconstruction. For both full angle CT

	FBP	DIP + TV	EPLL	localAR	patchNR	FBP+UNet (data-based)
PSNR	21.96 ± 2.25	32.57 ± 3.25	32.78 ± 3.46	31.06 ± 2.95	33.20 ± 3.55	33.75 ± 3.58
SSIM	0.531 ± 0.097	0.803 ± 0.146	0.801 ± 0.151	0.779 ± 0.142	0.811 ± 0.151	0.820 ± 0.140
Runtime	0.02s	1770.89s	127.21s	53.47s	485.93s	0.53s

Table 2: Limited angle CT. Averaged quality measures and standard deviations of the reconstructions.

Figure 3: Limited angle reconstruction of the ground truth CT image using different methods. The zoomed-in part is marked with a white box in the ground truth image. and limited angle CT we choose a FBP reconstruction. In order to empirically test the convergence of $\mathcal{J}(x; y)$ we evaluated the PSNR during the optimization process. In Figure 4 we visualize the PSNR per iteration for the first two images of the test dataset and show reconstructions at iteration 0, 150 and 300. It can be seen that the PSNR is steadily rising during the optimization. Arguably for the left image in Figure 4 we could have chosen even more iterations.

Ablation studies for full angle CT First, we trained the patchNR for patch sizes 4×4 , 6×6 , 8×8 and 10×10 . In Table 3 we tested the sensitivity w.r.t. the patch size. For all patch sizes we extracted 40000 patches per iteration and used the optimal regularization parameter λ (which is set to 1600, 700, 400 and 250 for the patch sizes 4×4 , 6×6 , 8×8 and 10×10 , respectively). We can observe that a larger patch size lead to slightly more blurry images. However the PSNR seems to change very little within different patch sizes, therefore we observe that our method is quite robust against the choice of the patch size.

Next, in Table 4 we show reconstruction results for different numbers of patches used

Patch size	$s = 4 \times 4$	$s = 6 \times 6$	$s = 8 \times 8$	$s = 10 \times 10$
PSNR	35.00 ± 4.45	35.19 ± 4.52	35.20 ± 4.58	35.17 ± 4.56
SSIM	0.825 ± 0.153	0.829 ± 0.152	0.827 ± 0.154	0.828 ± 0.154

Table 3: Comparison of full angle CT results for different patch sizes. Averaged quality measures and standard deviations of the reconstructions.

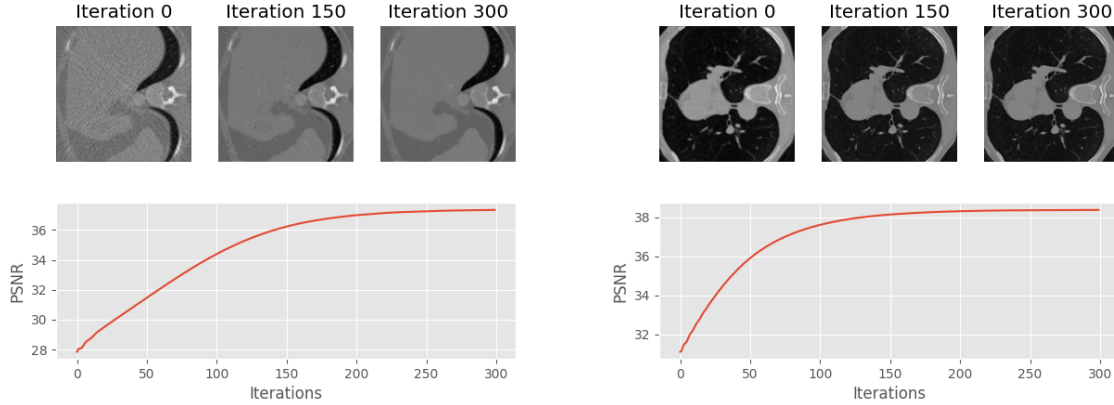

Figure 4: The PSNR for the first two test images per iteration of the optimization process.

Extracted patches per iteration	20000	30000	40000	50000	60000
PSNR	35.04 ± 4.39	35.16 ± 4.49	35.19 ± 4.52	35.21 ± 4.55	35.21 ± 4.56
SSIM	0.829 ± 0.148	0.829 ± 0.151	0.829 ± 0.152	0.828 ± 0.153	0.828 ± 0.154

Table 4: Comparison of full angle CT results for varying number of patches per iteration. Averaged quality measures and standard deviations of the reconstructions.

per iteration. Here we consider the patch size 6×6 and use the regularization parameter $\lambda = 700$. We see that the PSNR slightly increases with number of patches, while the SSIM seems to get worse at some point.

Finally, we examine the choice of the training set. In Table 5 we evaluate the patchNR with patch size 6×6 and $\lambda = 700$, when trained on 1, 6 or 50 images. Obviously, for the CT dataset one training image is not enough to learn the patch distribution. This can be explained by the diversity of the CT dataset, see e.g. Figure 1.

In Table 6 we varied the training set of 6 images and evaluated the model on 3 different choices. In total we trained the patchNR 15 times on 6 randomly chosen training images of the LoDoPaB dataset and then evaluated on the test set. Again we consider the patch size 6×6 and a regularization parameter $\lambda = 700$ and used 40000 extracted patches per iteration. Note that the bad case in Table 6 comes from a very noisy ground truth training set of the patchNR.

Overall, we see that the method is quite robust towards certain hyperparameter changes, and it can even be a matter of taste which ones to prefer as the image metrics do not

Number of training images	1	6	50
PSNR	33.68 ± 3.57	35.19 ± 4.52	35.24 ± 4.60
SSIM	0.802 ± 0.127	0.829 ± 0.152	0.827 ± 0.156

always agree.

4.2 Superresolution

We choose the forward operator f as a convolution with a 16×16 Gaussian blur kernel with standard deviation 2 and subsampling with stride 4. To keep the dimensions consistent, we use zero-padding. For the experiments, we extract a dataset of 2D slices of size 600×600 from a 3D material image of size $2560 \times 2560 \times 2120$, which has been acquired by synchrotron micro-computed tomography. We consider a composite ("SiC Diamonds") obtained by microwave sintering of silicon and diamonds, see [79]. We generate low resolution images by using the predefined forward operator and adding additive Gaussian noise with standard deviation $\sigma = 0.01$, i.e. we have

$$y = f(x) + \eta, \text{ where } \eta \sim \mathcal{N}(0, \sigma^2 I).$$

Consequently, from a Bayesian viewpoint the negative log likelihood $-\log(p_{Y|X=x}(y))$ can be, up to a constant, rewritten as

$$-\log(p_{Y|X=x}(y)) \propto -\log(\exp(-\|f(x) - y\|^2 / (2\sigma^2))) = \frac{1}{2\sigma^2} \|f(x) - y\|^2.$$

Thus the concrete form of (4) is given by

$$\mathcal{J}(x) = \frac{1}{2\sigma^2} \|f(x) - y\|^2 + \rho \mathcal{R}(x) = \|f(x) - y\|^2 + \lambda \mathcal{R}(x),$$

with $\lambda = 2\rho\sigma^2$.

The patchNR is trained on patches of only $M = 1$ example image of size 600×600 . For reconstruction, we use the regularization parameter $\lambda = 0.15 \frac{s}{N_p}$, the random subset

	bicubic (not shown)	DPIR (not shown)	DIP+TV	EPLL	WPP	patchNR	ACNN (data-based)

of overlapping patches is of size $N_p = 130000$ in each iteration and we optimize over 300 iterations using the Adam optimizer with a learning rate of 0.03. Since we do not want to consider boundary effects, we cut off a boundary of 40 pixels before evaluating the quality measures.

In Figure 5 we compare different methods for reconstructing the high resolution image x from the given low-resolution observation y . As initialization we choose the bicubic interpolation. The patchNR yields very clear and better images than the other model-based methods, visually and in terms of the quality metrics; see Table 7 for an average over 100 test images. In particular, the reconstruction of patchNR is less blurry than the DIP+TV and WPP reconstruction, specifically in regions between edges.

4.3 Zero-shot Superresolution with PatchNRs

In the case of superresolution, we can train the patchNR even without any training image. To this end, we combine some concepts of zero-shot superresolution by internal learning [24, 70] with patchNRs. In these approaches, the main assumption is that the patch distribution of natural images is self-similar across the scales. Consequently, the patch distributions of the same image at different resolutions should be similar. Motivated by this observation, we train the patchNR on the low-resolution observations such that we do not longer require any sample from the high-resolution ground truth.

In the following, we consider the case, where we have given one single low-resolution observation at training time and additionally the forward operator at test time. In particular, we do not require access to any high-resolution ground truth image and therefore the method is fully unsupervised. We train the patchNR on the patches from the low-resolution observation, where the training data is enriched by rotating and mirror reflecting of the patches such that we get 8 times more training patches. Note that in this setting the patchNR needs to be retrained for every new observation.

	L^2 -TV	DIP+TV	ZSSR	DualSR	patchNR
PSNR	28.35 ± 3.55	28.44 ± 3.69	28.83 ± 3.57	28.64 ± 3.47	29.08 ± 3.58
SSIM	0.820 ± 0.072	0.821 ± 0.087	0.834 ± 0.066	0.829 ± 0.061	0.846 ± 0.061
Runtime	13.12s	171.51s	56.64s	53.47s	132.36s

Table 8: Zero-shot superresolution. Averaged quality measures and standard deviations of the reconstructions of BSD68 dataset.

First we use a convolution with a 16×16 Gaussian blur kernel with standard deviation 1 and stride 2 as forward operator and add Gaussian noise with standard deviation 0.01 on the low-resolution observation. The patchNR is trained for 10000 optimizer steps with a learning rate of 0.0001, a batch size of 128 and a patch size of 6×6 . Then, for reconstruction, we use a random subset of $N_p = 80000$ patches per iteration, a regularization parameter $\lambda = 0.25 \frac{s}{N_p}$ and optimize over 60 iterations using the Adam optimizer with a learning rate of 0.01. As comparison baselines we use L^2 -TV [66], DIP+TV, ZSSR [70] and DualSR [20]. We test the methods on the BSD68 dataset [54] and the resulting quality measures are given in Table 8. In Figure 6 we present three reconstruction examples of the test set. Reconstructions of the patchNR lead to less blurry images and in particular structures and edges are preserved. In contrast, in L^2 -TV and DIP+TV some parts of the images are smoothed out.

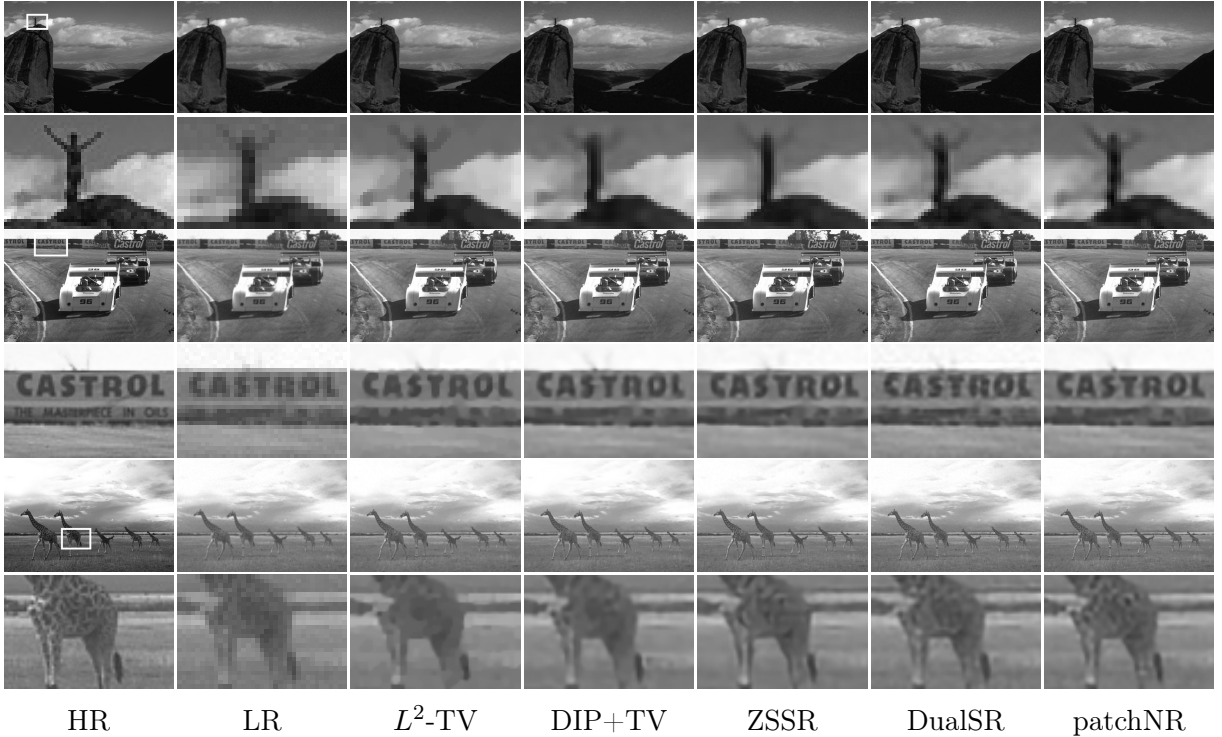

Figure 6: Zero-shot superresolution for three images from the BSD68 dataset. The zoomed-in part is marked with a white box in the ground truth image. *Top*: full image. *Bottom*: zoomed-in part.

	L^2 -TV	DIP+TV	ZSSR	DualSR	patchNR
PSNR	27.85 ± 0.55	27.99 ± 0.54	27.44 ± 0.55	27.64 ± 0.57	27.94 ± 0.55
SSIM	0.768 ± 0.008	0.764 ± 0.007	0.758 ± 0.008	0.764 ± 0.008	0.776 ± 0.009
Runtime	38.11s	234.00s	42.43s	46.55s	120.47s

Table 9: Zero-shot superresolution. Averaged quality measures and standard deviations of the high-resolution reconstructions.

In a second experiment we consider the same forward operator as in Section 4.2, that is a convolution with a 16×16 Gaussian blur kernel with standard deviation 2 and stride 4, and add Gaussian noise with standard deviation 0.01 on the low-resolution observation. The patchNR is trained for 10000 optimizer steps with a learning rate of 0.0001, a batch size of 128 and a patch size of 6×6 . Then, for reconstruction, we use a random subset of $N_p = 50000$ patches per iteration, a regularization parameter $\lambda = 0.25 \frac{s}{N_p}$ and optimize over 60 iterations using the Adam optimizer with a learning rate of 0.01

We test the methods on the same test images as in Section 4.2. In Figure 7 we compare the reconstructions of the different methods. We can observe a visually similar quality of the reconstructions for the DIP+TV and patchNR, while the other methods lead to a significant blur in the reconstructions. This can be also seen in the resulting quality measures given in Table 9. Note that here we do not consider natural images but material data and the assumption of self-similarity between different scales is not fulfilled. Consequently, we cannot expect a good reconstruction of the both methods ZSSR and DualSR. The methods L^2 -TV and DIP+TV do not need these assumptions and thus perform well on the data, while there is a slight worsening in the quality of the patchNR in contrast to Section 4.2. This nicely demonstrates the gain of using a small amount of ground truth data for training the patchNR.

5 Discussion and Conclusions

In this paper, we introduced patchNRs, which are patch-based NFs used for regularizing the variational modeling of inverse problems. Learning patchNRs requires only few ground truth images. In particular no paired data is necessary. We demonstrated the performance of our method by numerical examples and showed that it leads to better results than comparable, established methods, visually and in terms of the quality measures. Note that it is not clear how patch based learning influences biases in datasets. Using a small number of images can be very dangerous as these datasets are easily imbalanced. Further research needs to be invested into understanding how many images are sufficient for an adequate patch representation of a dataset and when the patch representation can be used as a prior for inverse problems. Moreover, quality measures for images are not sufficient for judging the quality of an image, in particular in medical applications. Further evaluation with medical expertise needs to be done before drawing any conclusions. Moreover, all patch-based methods are essentially limited in the sense that they can not capture global image correlations. Furthermore, normalizing flows are often not able to capture out of distribution data [44], so if a patch is far away from the patch "manifold", the likelihoods might be meaningless. However, it is an open question whether patch-based learning mitigates this effect.

The patchNR can be extended into several directions. First, we want to use the regularizer for training NNs in an model-based way for a fast reconstruction of several observations. Then the patchNR can be applied for uncertainty quantification by using, e.g., invertible architectures [5, 18, 27] or Langevin sampling methods [74].

A Comparison Methods

- **Bicubic interpolation.** For superresolution, the simplest comparison is the bicubic interpolation [40], which is based on the local approximation of the image by polynomials of degree 3.
- **Filtered Backprojection and UNet.** For CT a classical method is the Filtered Backprojection (FBP), described by the adjoint Radon transform [61]. We used the ODL implementation [1] for our experiments. There we choose the filter type Hann and a frequency scaling of 0.641. In order to improve the image quality of the FBP, a post-processing network can be learned. Here we consider the popular choice of a UNet (FBP+UNet) [65], which was used in [36] for CT imaging. We use the implementation from [51]⁴, which is trained on the 35820 training images of LoDoPaB dataset.
- **Wasserstein Patch Prior.** The idea of the Wasserstein Patch Prior (WPP) [3, 30]⁵ is to use the Wasserstein-2 distance between the patch distribution of the reconstruction and the patch distribution of a given reference image. Here a high resolution reference image \tilde{x} (or a high-resolution cutout) with a similar patch distribution as the unknown high resolution image x is needed. For a representation of structures of different sizes, x and \tilde{x} are considered at different scales $x_1 = x, \tilde{x}_1 = \tilde{x}, x_l = Ax_{l-1}, \tilde{x}_l = A\tilde{x}_{l-1}$ for a downsampling operator A .

Then the aim is to minimize the functional

$$\mathcal{J}(x) = \mathcal{D}(f(x), y) + \lambda \sum_{l=1}^L W_2^2(\mu_{x_l}, \mu_{\tilde{x}_l}),$$

where the patch distributions of x and \tilde{x} are defined by

$$\mu_{x_l} = \frac{1}{N_l} \sum_{i=1}^{N_l} \delta_{P_i x_l}, \mu_{\tilde{x}_l} = \frac{1}{\tilde{N}_l} \sum_{i=1}^{\tilde{N}_l} \delta_{P_i \tilde{x}_l}.$$

- **Deep Image Prior with TV regularization.** The idea of the Deep Image Prior (DIP) [78] is to solve the optimization problem

$$\hat{\theta} \in \arg \min_{\theta} \mathcal{D}(f(G_{\theta}(z)), y),$$

where G_{θ} is a convolutional neural network with parameters θ and z is a randomly chosen input. Then, the reconstruction \hat{x} is given by $\hat{x} = G_{\theta}(z)$. It was shown in [78] that DIP admits competitive results for many inverse problems. A combination

⁴available at https://jleuschn.github.io/docs/dival/dival.reconstructors.fbpunet_reconstructor.html

⁵We use the original implementation from [30] available at https://github.com/johhertrich/Wasserstein_Patch_Prior

of DIP with the TV (DIP+TV) regularizer was successfully used in [10]⁶ for CT reconstruction. Here the optimization problem is extended to

$$\hat{\theta} \in \arg \min_{\theta} \mathcal{D}(f(G_{\theta}(z)), y) + \text{TV}((G_{\theta}(z))),$$

Note that each reconstruction with the DIP+TV requires the training of a neural network. In contrast to WPP and patchNR, the DIP+TV is a data-free method, i.e., it does not require any clean image for training. We tested a pre-trained variant of the DIP+TV on the same training images. However, this did not improve the results significantly. Note that warm-start initialization techniques were proposed in [11]. Here, the authors observed faster reconstruction times for a pre-trained DIP but not significantly better results. Therefore we stick to the random initialization.

- **Plug-and-Play Forward Backward Splitting with DRUNet.** In Plug-and-Play methods, first introduced by [80], the main idea is to consider an optimization algorithm from convex analysis for solving (2) and to replace the proximal operator with respect to the regularizer by a more general denoiser. Here, modify the forward backward splitting algorithm

$$x_{n+1} = \text{prox}_{\eta R}(x_n - \eta \nabla_x \mathcal{D}(f(x_n), y))$$

for minimizing the functional (2) by the iteration

$$x_{n+1} = \mathcal{G}(x_n - \eta \nabla_x \mathcal{D}(f(x_n), y)), \quad (5)$$

where \mathcal{G} is a neural network trained for denoising natural images. We use the DRUNet (DPIR) from [84] as denoiser and run (5) for 100 iterations. Note that the denoiser is trained on natural images and not on images from the specific image domain. However, as we have given only very few clean images from the considered image domain it is impossible to train a denoiser with comparable quality on them.

- **Local Adversarial Regularizer.** The adversarial regularizer was introduced in [53] and this framework was recently applied for learning patch-based regularizers (localAR) [60]. The idea is to train a network r_{θ} as a critic between patch distributions in order to distinguish between clean and degraded patches. The network is trained by minimizing

$$D(\theta) = \mathbb{E}_{z \sim \mathbb{P}_c} [r_{\theta}(z)] - \mathbb{E}_{z \sim \mathbb{P}_n} [r_{\theta}(z)] + \mu \mathbb{E}_{z \sim \mathbb{P}_i} [(\|\nabla_z r_{\theta}(z)\|_2 - 1)^2],$$

where \mathbb{P}_c and \mathbb{P}_n are the distributions of clean and noisy patches, respectively, and \mathbb{P}_i is the distribution of all lines connecting samples in \mathbb{P}_c and \mathbb{P}_n . Then the aim is to minimize the functional

$$\mathcal{J}(x) = \mathcal{D}(f(x), y) + \lambda \frac{1}{|I|} \sum_{i \in I} r_{\theta}(P_i(x))$$

⁶For superresolution, we use the original implementation from [78] available at <https://github.com/DmitryUlyanov/deep-image-prior> in combination with a TV regulariser; for CT, we use the original implementation from [10] available at <https://github.com/jleuschn/dival/blob/master/dival/reconstructors>

For our experiments we used the code of [60], but instead of patch size 15 we used the patch size 6 and replaced the fully convolutional discriminator by a discriminator with 2 convolutional layers, followed by 4 fully connected layers.

- **Expected Patch Log Likelihood.** The Expected Patch Log Likelihood (EPLL) prior [86] assumes that the patch distribution of the ground truth can be approximated by a GMM p fitted to the patch distribution of the reference images. Reconstruction is done by minimizing the functional

$$\mathcal{J}(x) = \mathcal{D}(f(x), y) - \lambda \sum_{i=1}^N p(P_i(x)).$$

In [86] the authors used half quadratic splitting to optimize this objective function. For our experiments we implemented the GMM in PyTorch and used the Adam [41] optimizer. This is because we are not aware how to efficiently implement the half quadratic splitting for the CT forward operator.

- **Asymmetric CNN.** The asymmetric CNN (ACNN) [77] is a 23-layer CNN trained in a data-based way on 28 paired images pairs of the composite "SiC Diamonds" using the L^2 loss function.
- **Zero Shot Super-Resolution.** For Zero Shot Super-Resolution (ZSSR) [70] the main assumption is that the patch distribution of natural images is self-similar across the scales. Exploiting this fact, a lightweight CNN is trained in a supervised fashion on a paired dataset generated by the low-resolution image itself. This dataset is created by downsampling the low-resolution image to obtain a lower-resolution image and is enlarged by data augmentation like random rotations, random crops or mirror reflections. A high-resolution prediction is then created by applying the trained model to the low-resolution observation. For our experiments we reimplemented the ZSSR.
- **DualSR.** The idea of DualSR [20]⁷ is a dual-path pipeline, where an upsampling GAN learns the upsampling process and a downsampling GAN learns the degradation model, trained on cropped parts of the low-resolution image. This method can be used for blind superresolution, but since we know the forward operator in our case, we replace the downsampling GAN by the given degradation process.

B Further examples

Here we give some more examples of our experiments from Section 4; see Figure 10, Figure 8 and Figure 9.

⁷We use the original implementation available at <https://github.com/memad73/DualSR>
