Abstract

The mass storage and removal in solid conductors always played vital role on the technological applications such as modern batteries, permeation membranes and neuronal computations, which were seriously lying on the ion diffusion and kinetics in bulk lattice. However, the ions transport was kinetically limited by the low diffusional process, which made it a challenge to fabricate applicable conductors with high electronic and ionic conductivities at room temperature. It was known that at essentially all interfaces, the existed space charge layers could modify the charge transport, storage and transfer properties. Thus, in the current study, we proposed an acid solution/ WO_3 /ITO structure and achieved an ultrafast hydrogen transport in WO_3 layer by interfacial job-sharing diffusion. In this sandwich structure, the transport pathways of the protons and electrons were spatially separated in acid solution and ITO layer respectively, resulting the pronounced increasing of effective hydrogen diffusion coefficient (D_{eff}) up to 10^6 times. The experiment and theory simulations also revealed that this accelerated hydrogen transport based on the interfacial job-sharing diffusion was universal and could be extended to other ions and oxide materials as well, which would potentially stimulate systematic studies on ultrafast mixed conductors or faster solid-state electrochemical switching devices in the future.

Introduction

The element doping and ion migration in solid oxide compounds could regulate the properties of functional materials(1-3), which always played vital role on various applications, such as electrochromic windows(4-7), electrical tri-state phase transition(8, 9), selective electrocatalysis(10), surface self-assembling(11), ion storage(12) and synaptic transistors(13, 14). Naturally, as a key process in material and physical science(15-17), the migration or diffusion of atoms in solid, was also significant to be investigated for more tunable and high-performance devices(18-23). Quick transport of atoms doping in films could shorten the dynamic process to improve the performance of devices effectively(22, 24). This kinetic process was characterized by a key parameter, chemical diffusion coefficient (D_{eff}), which was very important in the field of diffusion in solids(25, 26).

Normally the ions transport was kinetically limited by the extremely low diffusional process driven by the concentration gradient or even by external electric field, which made it a challenge to fabricate applicable conductors with high electronic and ionic conductivities at room temperature. It had been suggested that at essentially all interfaces, the existed space charge layers could modify the charge transport, storage and transfer properties (25, 26). The recent reports showed that quick diffusion of lithium(27) and other alkali elements(16) had been realized in multilayer graphene, owing to its fast-track between layers and the collective effects(16). Another inspiring progress was the realization of ultrafast Ag storage and removal in the interface of RbAg₄I₅-graphite due to the chemical diffusion along the interface(26), which resulted the diffusion coefficient of Ag atoms along this interface up to $D_{eff} \sim 10^{-4} \text{ cm}^2/\text{s}$.

However, it was still a challenge to realize an ultrafast atomic migration in bulk solid, such as oxide solid materials. Though it had been reported that in oxides films, external energy input, such as applying electrostatic(21) or static magnetic(23) field, was a useful way to realize tunable mass transport. This route could change the initial and final energy state through inducing external field, as shown in [Supplementary Fig. S1A](#). To accelerate the atomic diffusion process without external energy input, reducing

the diffusion activation energy (E_a) was the possible way according to the Fick's laws of diffusion and the Arrhenius equation of diffusion coefficient:

$$D \propto \exp(-E_a/k_B T),$$

where k_B was the Boltzmann constant and T was the surrounding temperature(16, 28). The schematic evolution of energy barrier was show in [Supplementary Fig. S1B](#). According to this strategy, many attempts had been made in oxide material to improve the D_{eff} value with low E_a by lattice defect engineering(18-20, 22, 24, 29), while the final increase was not such pronounced. For example, by increasing the density of domain boundaries in VO₂ crystal as the “highway”, the diffusion coefficient of H atoms only improved by about twenty times(22).

It was known that the atomic diffusion consisted of cationic and electronic migration, which could be described by the concept of ambipolar diffusion(30) and was successfully applied in plasma physics and astrophysics(31). From this viewpoint, it was possible to achieve ultrafast diffusion of doped atoms along an artificial hetero-junctions or interfaces in multi-phase systems. This fabricated interface composited of ion and electron conducting phases, which made the transport pathways of ions and electrons spatially separated and driven the transport of a neutral component via space charge effect.

Based on the above strategy, in the current study, we proposed an acid solution/WO₃/ITO structure and achieved an ultrafast hydrogen transport in WO₃ layer with the D_{eff} value of about 10⁻¹ cm²/s, which was almost ~10⁶ times higher than that in WO₃ bulk lattice. Interestingly, due to the distinct electrochromic property of WO₃, this ultrafast hydrogen transport could be directly observed by eyesight. The experiment and theory simulations also revealed that the accelerated hydrogen transport was mainly lying on the interfacial job-sharing diffusion of the protons and electrons in acid solution and ITO layer respectively. Furthermore, this proposed proton-electron synergistic diffusion mechanism was universal and could be extended to other ions and oxide materials as well, which would potentially stimulate systematic studies on ultrafast mixed conductors or other emerging ionic devices in the future.

Accelerated diffusion of H atoms with proton and electron bridges

As a member of transition metal oxides, WO_3 was an ideal prototype to investigate the diffusion of doping atom in oxide films, owing to its electrochromic property by M (M = H, Li, Al etc.) intercalating. For example, H atoms could be easily driven into WO_3 film by external voltage gating, which was applicable for WO_3 based smart window device ([Supplementary Fig. S2A](#)). It was suggested that the reduction of W^{6+} was responsible to H (or other M atoms) doping induced color change of WO_3 , which was originated from the optical absorptions of small-polaron (32, 33). The detailed XRD and SEM/TEM investigations for the $\sim 580\text{nm}$ amorphous WO_3 film before and after the H atoms insertion showed no obvious thickness and crystal structure changes ([Supplementary Fig. S3](#)). While due to color contrast between the initial transparent state and the H-doped blue state(7), the transport of H atom in WO_3 films could be directly visualized even by eyesight if the atomic diffusion was fast enough to be traced by the film color change. However, the concentration gradient induced dopants diffusion behavior in solid WO_3 lattice was always negligible, since the effective diffusion coefficients were extremely slow. For example, according to the references (13-17), the effective diffusion coefficient of H atoms in WO_3 bulk was only $\sim 10^{-10} \text{ cm}^2/\text{s}$ in crystal and $\sim 10^{-8} \text{ cm}^2/\text{s}$ in amorphous at room temperature (RT).

This extremely slow diffusion of H atoms in $\text{WO}_3/\text{sapphire}$ film was directly reflected in the optical image of [Fig. 1A](#). The blue region of the film was related to the heavily H doped WO_3 film (H_xWO_3), while the transparent region was the pure WO_3 film. It was observed that there existed a clear borderline between the deep-blue H_xWO_3 and transparent WO_3 area. Though a large H concentration gradient existed at the interface, almost no migration of the borderline was observed from the optical image after one day or even one week at ambient condition. Since the H atoms diffusion was directly associated with the color change of WO_3 film, the detailed transmittance-position curve plotted in [Supplementary Fig. S4A](#) showed that the borderline was almost kept at the same position even after one week, confirming this ignored H atoms diffusion in WO_3 film (34). It was reasonable if considering this ultra-low H atoms

diffusion was just driven by the H concentration gradient at the H_xWO_3 - WO_3 interface lattice as shown [Fig.1D](#). In fact, previous studies also demonstrated that the H atoms doping induced micro/nano patterns in WO_3 film showed no obvious diffusions at ambient condition, which was suitable for functional devices applications (35).

It was known that the neutral H atom diffusion could be separated by the proton and electron migrations, thus based on the H_xWO_3/WO_3 interface, we established a protonic bridge by covering a sulfuric acid layer ([Fig. 1E](#)), which showed a high proton conductivity. From the optical image in [Fig. 1B](#), it was observed the considerable borderline migration within several minutes, which indicated that this protonic bridge could greatly accelerate the in-plane transport process of H atoms. The ultrafast immigration of H atoms in WO_3 layer was also examined by XPS in [Supplementary Fig. S2C~S2F](#), confirmed the H atoms insertion in WO_3 layer and resulted the blue color change.

In addition, if we deposited similar WO_3 film on a conductive ITO-glass substrate, an electronic bridge was established due to the excellent conductivity of ITO layer. If covering a sulfuric acid layer on the top surface of WO_3 /ITO-glass, a protonic bridge was also established as shown in the schematic diagram of [Fig. 1F](#). Based on this configuration, the migration of H atoms induced blue-color spread occurred in several seconds ([Fig. 1C](#)). This quick color change of WO_3 layer was also reflected by the detailed optical variation tests shown in [Supplementary Fig. S4C](#). The observation was clearly demonstrated that the added electronic bridge could further accelerate the atomic migration if combined with the existed protonic bridge. The dynamic diffusion processes were visualized in the [Supplementary Movie 1](#). From the different diffusional behaviors of H atom transport in WO_3 with and without cationic/electronic bridge (blue arrows in [Supplementary Fig. S4](#)), it was suggested that an intriguing mechanism existed behind this accelerated diffusion phenomenon.

The polarized proton-electron synergistic diffusion

To understand the H atoms diffusion in WO_3 crystal film driven by the concentration gradient within the micro/nano scale size, we have fabricated an H_xWO_3 - WO_3 - H_xWO_3 hetero-junction on the deposited WO_3 /sapphire film as shown in the optical image of Fig. 2A. The prepared WO_3 nanogap (as shown by the red circle) was about 5 μm , which was fabricated by the selected area hydrogenation based on the combination of UV lithography and metal-acid treated H doping process (see Methods). The topography image (Fig. 2B) mapped by scanning of Atom Force Microscopy (AFM) showed that the WO_3 nanogap had clear interfaces between the H_xWO_3 parts. The step analysis curve implied that the hydrogenation treatment would lead some corrosion of WO_3 layer, which made the H_xWO_3 section ~ 4.3 nm thinner than the intrinsic WO_3 area. The potential distribution of this H_xWO_3 - WO_3 - H_xWO_3 hetero-junction was also probed by Kelvin Probe Force Microscopy (KPFM) in Fig. 2C. It was observed that there existed clear potential difference between H_xWO_3 and WO_3 sections and obviously the potential value of WO_3 was much lower. Since this potential value was closely associated with the work function of the tested materials, it was inferred that the H_xWO_3 should have lower work function than that of WO_3 crystal.

This potential distribution was reasonable if considering the hydrogenation induced electron doping in WO_3 crystal, which would raise the Fermi level (E_F) of WO_3 . The theoretical calculation results (Fig. 2D and Supplementary Fig. S5) were also consistent with the above observations. In fact, from the projected densities of state (PDOS) of H-doped WO_3 , it was clear that a transition from semi-conducting to metallic characteristic would be existed. This H doping induced continuous phase transitions were also verified by the resistance measurement in dynamic hydrogenation process via external voltage gating treatment, which showed that the WO_3 resistance decreased and transformed to metallic state gradually as the function of gating time (Supplementary Fig. S6).

In addition, due to the different work function at the H_xWO_3 - WO_3 junction,

pronounced electron transfer from H_xWO_3 to WO_3 side would occurred. This electron transfer and the interfacial polarization were also confirmed by the first-principles calculations as shown in Fig. 2E. Though the electrons was easily transferred from H_xWO_3 to WO_3 side as shown in the scheme of Fig. 2F, the H^+ ions (protons) was quite difficult to move simultaneously even driven by the interfacial polarization, mainly due to the high diffusion barrier height in WO_3 lattice. Resultantly, the H atoms showed extremely low diffusion behavior in WO_3 crystal, as observed in Fig.1A or previous reports (13-17).

However, if adding a liquid acid solution layer covering the H_xWO_3 - WO_3 junction, an effective H^+ bridge was quickly established via the solid-liquid interfaces. Accordingly, a polarized H^+ - e^- synergistic diffusion was formed for this system(9). It was suggested that at the first stage, the electrons transport from the H_xWO_3 side to pure WO_3 area under the driving force of work function difference (Fig. 2F). Then due to the charge redistribution, a localized interfacial polarization would drive the H^+ intercalating to the lower concentration area and extrapolating from the higher area via the H^+ bridge (acid solution), as shown in the scheme of Fig. 2G. Simultaneously, H^+ and e^- recombination occurs in WO_3 part, resulting a quick in-plane hydrogen migration. Furthermore, if adding an electronic bridge (ITO layer was used) to improve the interfacial electron transfer process, the polarized H^+ - e^- synergistic diffusion would be further enhanced. It was pointed out that here the H diffusion in WO_3 films was obviously separated by protonic/electronic bridges at the solid-liquid interfaces, resulting an effective “job-share” diffusion. This proposed “job-share” diffusion greatly accelerated the H diffusion speed, which was quite consistent with the experimental observations for the quick color change in WO_3 layer within several minutes or even several seconds as shown in Fig.1A or 1B.

Controllable ultrafast atomic diffusion in oxide

From the experimental observations, it was revealed that the “job-share” diffusion

behavior greatly enhanced the H atoms diffusion in WO_3 layer due to the protonic/electronic bridges at the solid-liquid interfaces. In addition, the diffusion process should be closely associated with the conductivity of the protonic/electronic bridges respectively. Thus to gain more insight into the relationship between the diffusion rate and the protons/electrons conductivity, a detailed simulations by finite element analysis (FEA) was conducted to evaluate the diffusion behavior as the function of time and position (or the diffusion distance) in Fig. 3. According to the scheme of the H_xWO_3 - WO_3 junction in Fig.3A, the H atoms diffusion was separated by the directional movements of protons and electrons via the polarized H^+ or e^- bridges. This diffusion behavior could be described by the schematic circuit in Fig.3B, if considering the interfacial potential, the movement of electrons and protons through the H^+ or e^- bridges based on *the Kirchhoff's laws*.

During the simulation, the hypothesis of linear relationship of potential vs. charge doping concentration was adopted (see Methods). To examine the effect of conductivity of e-bridge (σ_e) on the diffusion behavior during the “job-sharing” diffusion route, the conductivity of H^+ bridge was kept as a constant value. Then the simulated time-dependent distributions of the H atoms in H_xWO_3 - WO_3 junction (Fig.3A) were plotted with the conductivity of e^- bridge varied from $\sigma_e = 10^3$ to 10^5 in Fig.3C~3E, respectively. The simulation results showed that H atoms would gradually diffuse from the H_xWO_3 side to undoped WO_3 side via the interface (position =0) and the H concentration showed a gradually decreased trend (from the position= -1 to 1). In addition, it was observed that the higher e^- bridge conductivity would lead to the faster diffusion of H atoms. When the conductivity was increased to $\sigma_e = 10^5$, the H atoms in H_xWO_3 - WO_3 junction could quickly go to a uniform distribution state as shown in Fig.3E, highlighting the important role of the conductivity of e^- bridge. Fig.3F showed the H atom diffusion behavior as the function of diffusion time and the length (from position=0 to position=1) via the H_xWO_3 - WO_3 junction if setting the H concentration to a constant value ($0.1C_{\text{max}}$). It was revealed that the diffusion time showed a quadratic-like relationship with the position when the conductivity of e^- bridge was low (less than 10^3). While when the conductivity was further increased to $\sigma_e = 10^4$ or 10^5 , the H atoms

distribution could reach a balance state within much faster time. These simulations were quite consistent with the experimental observations in Fig.1C, which showed the quick color change in WO₃ layer on ITO substrate.

In fact the conductivity of H⁺ bridge (or the H⁺ concentration in sulfuric acid) also played important role in the “job-share” diffusion strategy. Since the color of WO₃ layer could be changed upon the H atom doping and the related transmission were directly lying on the H atom concentration, thus the visible transmission value of the WO₃ layer was able to be used as the indicator to evaluate the H diffusion behavior. In the experiment, we used sulfuric acid layer with different H⁺ concentration (from 10⁻⁴ to 10⁻¹ M) as the proton bridge and then examined the related transmission at different position as the function of diffusion time. Then the positional transmission evolution mapping of H_xWO₃-WO₃ junction was figured in Supplementary Fig. S7. If setting the transmission value of T=75%, the diffusion time as the function of diffusion distance (position from 0.0 to 0.4) was obtained in Fig. 4A. The experimental results revealed that the conductivity of proton bridge had the similar effect as the electron bridge during the H atoms diffusion in WO₃ layer. Based on these experimental results, the effective diffusion coefficients were obtained and revealed the positive relationship with proton concentration (Fig. 4B and Supplementary Table S3).

Furthermore, the ambipolar diffusion model(30) showed that $D_{eff} \propto \sigma_{H^+} \sigma_{e^-} / (\sigma_{H^+} + \sigma_{e^-})$, where σ is the conductivity. Obviously, the σ value would greatly increase due to the collective effects in protonic bridge(16). The additional high conductivity of e-bridge would further improve the effective diffusion coefficient if considering the “job-share” diffusion. Thus, accelerated diffusion process was simulated by the combination of proton and electron bridges. Five different e⁻ conductivity values were considered in the diffusion coefficient calculation, which showed a positive relationship (Fig. 4C).

The effective diffusion coefficient D_{eff} values for the current study and previous reports were listed in Table 1 for comparison. It showed that about four orders of magnitude of promotion for the D_{eff} value could be achieved if applying the acid solution as protonic bridges. While if further combined the ITO as the e- bridge to form

the “job-share” diffusion, another two orders of magnitude of promotion for the D_{eff} value would be obtained as shown in Fig. 4D. This result showed that the D_{eff} value could be controlled by adjusting the conductivities of the fabricated bridges for protons or electrons transport. More importantly, our current diffusion coefficient D_{eff} values obtained through the “job-share” strategy were greatly increased up to $\sim 10^{-1} \text{ cm}^2/\text{s}$, obviously exceed all of the previous reports completely, showing the overwhelming advantage.

The universal of “job-share” diffusion behavior

According to the above ultrafast H atoms diffusion via the “job-share” mechanism, it was believed that this strategy was element independent and could be extended to other ions and materials (Fig. 5A). It was known that Li atoms intercalation and diffusion in electrode material were very important for the performance of Li-ion battery system. In the experiment, the accelerated diffusion of Li was also certified by the experimental results of $\text{Li}_x\text{WO}_3\text{-WO}_3$ junction, utilizing LiClO_4 dissolved in propylene carbonate (PC) as Li^+ bridges (Supplementary Fig. S8 and Supplementary movie 2).

Furthermore, it was also certified that this “job-share” diffusion strategy was suitable for another oxides. As a typical correlated oxide material, vanadium dioxide (VO_2) showed an insulator state at room temperature and had a typical metal-insulator phase transition property with the critical temperature of about 340K. While if doping some H atom into it, the VO_2 film would be stabilized in metallic state at room temperature. Accordingly, in the experiment, we just measured the film resistance distribution to monitor the H diffusion in VO_2 crystal lattice, which demonstrated that the H atoms diffusion in VO_2 crystal film was also greatly accelerated via the “job-share” diffusion route. From the surface resistance variation, it revealed that the quick hydrogenation induced metallization in the whole VO_2 film will be accomplished

within several minutes ([Supplementary Fig. S9](#)).

For many practical device applications, an all-solid-structure was highly desirable to improve the mechanical stability and security. Thus, we proposed a structure designed for element fast storage and removal in bulk, as shown in [Fig. 5B](#). In this structure, the catalyst, such as palladium (Pd), was utilized to split H_2 and inject H to the oxide. By this way, it was able to not only reduce the usage of expensive catalysts, but also make the structure more compact, comparing with classic device basing on films(12). To verify its advantages, prototype WO_3 film devices were fabricated in [Fig.5C](#). Here the WO_3 films were deposited on conductive ITO substrates, some nano-size Pd islands were deposited and covered partial area to act as the catalysts. Typically of exposing this system in H_2 gas, the Pd-covered area would become blue color due to the H atoms doping into WO_3 layer. The uncovered area would still be transparent.

To fabricate an effective proton conductor, we just soaked a solid polymer, polyacrylamide (PAAM) in sulfuric acid (1M) for 2 h, then a conductive proton conductor was obtained. Thus if we put this acid treated PAAM layer on H_xWO_3 - WO_3 junction as a solid protonic bridge, the uncovered WO_3 area would transfer to blue color quickly and confirmed the important role of the solid protonic bridge to accelerate H diffusion ([Supplementary movie 4](#)). This solid protonic bridge would greatly benefit the practical device fabrication and integration. For comparison, the normal polyimide layer also used to act as the protonic bridge. However, due to the poor conductivity, no H diffusion induced color change was observed for this system as shown in [Fig.5C](#), further confirming the importance of the conductive solid protonic bridge.

Conclusion and outlook

Achieving ultrafast atom diffusion in functional solids had been a challenge for many years. In the current study, we achieved an accelerated diffusion of doping atoms in oxide films via a synergistic job-share strategy, which separated the electronic and cationic transport pathways by configuring the artificial electrons/cations bridges.

Based on this polarized cation-electron synergistic diffusion route, an ultra-fast diffusion of H atom in WO_3 was directly visualized with the D_{eff} value up to $\sim 10^{-1} \text{ cm}^2/\text{s}$, which was about six orders of magnitude higher than that in the traditional WO_3 bulk and overwhelming the previous reports. This cation-electron synergistic diffusion was general and universal, which would be applicable for other doping elements and oxide systems. It was believed that the ultrafast atom diffusion would potentially stimulate various frontier research areas, such as ultra-fast charge batteries, high efficiency catalyst, neural network or other emerging ionic devices.
