## Abstract

The ongoing COVID-19 pandemic has had serious impacts on the airline industry. Ensuring that aviation policies in emergent situations both guarantee network connectivity and maintain competition among airlines is crucial in these circumstances. To this end, we aimed to understand the network dynamics of individual airlines. In this study, we quantitatively reveal the day-to-day dynamics of these US domestic airline networks, comprising 17 airlines, from January 2019 to December 2021. Specifically, we applied a framework for analyzing temporal networks, in which the network structure changes over time. We found that, first, even though the number of nodes and edges returned to pre-pandemic levels around July 2021, the structure of the entire US domestic airline network remained altered. We also found that the network dynamics varied significantly from airline to airline. Full-service carriers were less flexible in changing their network structure and suffered higher revenue losses. On the contrary, most regional carriers completely shifted to a new structure, which may have contributed to reducing their revenue losses. Low-cost carriers were characterized by more pronounced differences between airlines and drastically changed their network structure immediately after the declaration of a national emergency.

## 1. Introduction

The novel coronavirus, COVID-19, was first identified in China in December 2019 and subsequently caused a global pandemic. As of May 14, 2022, the cumulative number of worldwide cases had reached 520 million, with over six million deaths (World Health Organization, 2022). This pandemic has had a huge impact on many aspects of life, such as the environment, health, and the economy (Sarkodie and Owusu, 2021). Regarding the latter, according to the International Monetary Fund (IMF), the cumulative economic losses associated with the pandemic are expected to reach \$13.8 trillion in 2024 (International Monetary Fund, 2022).

Among others, the airline industry has been particularly severely affected (Suau-Sanchez et al., 2020; Sobieralski, 2020). The sudden decrease in air travel demand has been much worse than that seen after the 9/11 terrorist attacks and the 2008 financial crisis combined (Curley et al., 2020). Due to this unprecedented decrease in demand, many companies ceased almost all their operations (Sun et al., 2020), leading to many bankruptcies of airlines worldwide (Salman et al., 2020). Thus far, numerous papers have been published on air transport during the COVID-19 pandemic (Sun et al., 2021). As we will see in Sec. 2, some studies have analyzed airline networks, particularly at national and global levels. In these studies, airline networks are typically constructed by aggregating networks of individual airlines. However, each airline has its own corporate strategy, and the dynamics of their networks may vary widely depending on the airline. These kinds of dynamics at the airline level are largely unknown. However, understanding airline-level network dynamics is essential for ensuring aviation policies in emergent situations in order to both guarantee network connectivity and maintain competition among airlines.

In this study, we aim to quantitatively reveal the daily dynamics of airline networks during the COVID-19 pandemic for individual airlines. Specifically, we analyze the US domestic airline network for the following three reasons.

First, reliable and up-to-date daily flight data are available for the US domestic airline network. These data are publicly available from the US Bureau of Transportation Statistics and are based on monthly reports from airlines and are highly reliable (Bureau of Transportation Statistics, 2022). We analyzed data from January 2019 to December 2021 to track changes in the network structure before and after the pandemic. Second, there are multiple airlines based in the US. In fact, the dataset contains flight data from 17 airlines, including full-service carriers (FSCs), low-cost carriers (LCCs), and regional carriers (RCs). This is important for our study purpose, which is to determine the structural network changes for individual airlines. Third, the US is one of the countries most heavily affected by the COVID-19 pandemic. As of May 14, 2022, the cumulative number of COVID-19 cases in the US reached 82 million, which is the highest number of cases worldwide (World Health Organization, 2022). As such, we decided to analyze the US domestic airline network. It is important to note that the same analyses can be performed for any other country with the necessary available data, which will be a future task.

In terms of methodology, in addition to some fundamental measures used in network science, such as average degree, average clustering coefficient, and assortativity, we apply a method for analyzing so-called temporal networks, in which the network structure changes over time (e.g., Holme and Saramäki, 2012, 2019; Masuda and Lambiotte, 2020). Since airline networks change their structure over time, it is reasonable to consider them temporal networks (e.g., Pan and Saramäki, 2011; Rocha, 2017; Sugishita and Masuda, 2021). In emergent situations such as the COVID-19 pandemic, the network structure could be particularly variable on a daily basis. As an example, we show the networks for United Airlines on March 1 and May 1, 2020, in Fig. 1; as seen in the figure, the network shrunk substantially following the pandemic onset. Thus, to quantitatively show the changes in network structure over time, temporal network analyses are required. Specifically, in the present study, we analyze the dynamics of airline networks from the perspective of recurrence. Recurrence refers to the return of the network structure to something close to the past structure (Masuda and Holme, 2019). Recurrence in the evolution of network structure has been investigated for some real-world network systems (Masuda and Holme, 2019; Cruickshank and Carley, 2020; Gelardi et al., 2021; Sugishita and Masuda, 2021). However, to the best of our knowledge, it has not been applied to analyze airline networks during the COVID-19 pandemic. This analysis enables us to quantitatively determine how and when the network structure returned to the pre-pandemic structure or if it completely shifted to a new structure.

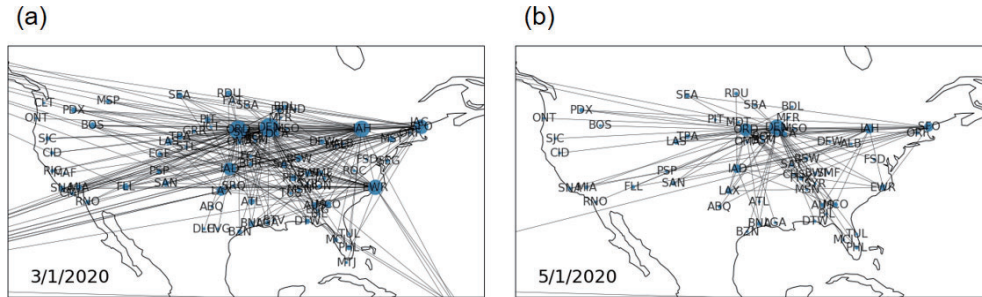

Figure 1: Networks of United Airlines on (a) March 1 and (b) May 1, 2020.

Our paper proceeds as follows. In Sec. 2, we review the relevant literature and further clarify our contributions in this study. In Sec. 3, we describe the methodology used to analyze airline networks. In Sec. 4, we show and discuss the results for both the overall US domestic airline network and the networks of individual airlines. In Sec. 5, we conclude our work and describe future tasks. In Appendix A, we show some additional results of network structure for individual airlines.

## 2. Literature review

To further highlight the contributions in this study, we review the relevant literature on air transport networks during the COVID-19 pandemic.

Even before the COVID-19 pandemic, it was well known that airline networks can be major contributors to the spread of infectious diseases (e.g., Tatem et al., 2006; Khan et al., 2009; Pigott et al., 2014). Now, in the face of

a global pandemic, many studies have investigated the relationships between airline networks and COVID-19 cases. Predicting cases and detecting early warning signals of outbreaks from airline networks has been a focus. For example, Christidis and Christodoulou (2020) predicted which countries had a high risk of infection using flight data in China. Similarly, Daon et al. (2020) presented a method to estimate the risk of COVID-19 outbreaks emerging from airline networks on a global scale. Tuite et al. (2020) quantified the size of the outbreak in Iran based on flight data between Iran and other countries, and predicted where outbreaks originating in Iran would spread next. Some studies have also investigated the relationships between COVID-19 cases and measures of network structure such as network density (Chu et al., 2020), shortest path length (Kuo and Chiu, 2021), centrality of nodes (Coelho et al., 2020; Ribeiro et al., 2020), and weight of edges (i.e., number of flights or passengers on each edge) (Zhang et al., 2020a; Lau et al., 2020). Additionally, several studies have proposed various models to investigate the virus' spread in airline networks, such as the SIR metapopulation model (Hossain et al., 2020), SEIR metapopulation model (Peirlinck et al., 2020), and epidemiological models (Nikolaou and Dimitriou, 2020; Riquelme et al., 2021).

Another research area involved airlines' financial conditions during the COVID-19 pandemic. In general, airlines can cover only a few months of revenue loss due to high capital costs (Zhang et al., 2020b). In fact, some airlines filed for bankruptcy during the pandemic, including Flybe, VA Australia, and Level Europe, among many others (Salman et al., 2020; Gössling et al., 2020; Florido-Benítez, 2021). In emergent situations, governments generally are motivated to financially support airlines. This is so they can maintain network connectivity to protect economic activities and jobs in the aviation industry itself, as well as in related industries such as tourism (Merkert and Williams, 2013; Gössling et al., 2017; Njoya et al., 2018). During normal economic times, airlines receive financial support from the private sector, like banks and investors; however, these supporters may have grown more cautious when aviation industry's future became uncertain (Truxal, 2020). This indicates that government support might be the only option for airlines. However, several studies have pointed out that this governmental support may prioritize specific airlines, which leads to concerns about competition among airlines (Akbar and Kisilowski, 2020; Abate et al., 2020).

In summary, many studies have analyzed the relationship between airline networks and COVID-19 outbreaks. These studies have typically analyzed airline networks by country or region and focused on the relationship between the network structure and the number of COVID-19 cases. However, little is known about the dynamics of the network structure for individual airlines. Our aim is to contribute to the filling of this gap. Furthermore, one important contribution of our study is its examination of daily network dynamics, which is a more specific analysis compared to that done by most previous studies. In fact, most research on airline networks has applied static network analysis, and of the few temporal network studies, most have analyzed networks on a monthly or yearly basis (Rocha, 2017). While network evolution over a long period of time can be adequately analyzed with such a time scale, a narrower time scale is more effective for analysis during emergency situations such as the COVID-19 pandemic.

### 3. Methods

#### 3.1. Data and construction of networks

We use a dataset available from the US Bureau of Transportation Statistics (Bureau of Transportation Statistics, 2022). The dataset contains the origin and destination airports of each flight, departure and arrival times, and operating airlines, among other information. We downloaded data from January 2019 to December 2021. In Table 1, we detail the 17 airlines included in the dataset.

From the data, we construct a daily snapshot of networks from January 2019 to December 2021, in which a node is an airport. We connect two nodes using an edge if there is at least one direct commercial flight between the two airports during the day. We construct both the entire network, including all the airlines, and the networks for each individual airline.

#### 3.2. Measurements for network structure

We model an airline network as graph  $G$  consisting of  $N$  nodes (i.e., airports) and  $M$  edges (i.e., direct flight connections). In addition to the number of nodes and edges, we measure four indices: average degree, average shortest path length, average clustering coefficient, and assortativity (Newman, 2018). These four indices enable us to understand the characteristics of networks from different perspectives: each node's connectivity with other

Table 1: The 17 airlines contained in the US Bureau of Transportation Statistics dataset.

Category	Airline name	International Air Transport Association code
Full-Service Carrier (FSC)	American Airlines	AA
	Alaska Airlines	AS
	Delta Air Lines	DL
	Hawaiian Airlines	HA
	United Airlines	UA
Low-Cost Carrier (LCC)	JetBlue	B6
	Frontier Airlines	F9
	Allegiant Air	G4
	Spirit Airlines	NK
	Southwest Airlines	WN
Regional Carrier (RC)	Endeavor Air	9E
	Envoy Air	MQ
	PSA Airlines	OH
	SkyWest Airlines	OO
	Mesa Airlines	YV
	Republic Airlines	YX
	ExpressJet*	EV

\* Note that ExpressJet ceased its operations between September 2020 and September 2021.

nodes (average degree) and tendency (assortativity), the connectivity of each node's neighbors (average clustering coefficient), and overall network connectivity (average shortest path length).

The degree of node  $i$ , denoted by  $k_i$ , is the number of edges that node  $i$  has. The average degree, denoted by  $\langle k \rangle$ , is the average value of the degree of all the nodes in the network:

$$\langle k \rangle = \frac{1}{N} \sum_{i=1}^N k_i. \quad (1)$$

The average shortest path length, denoted by  $L$ , is the average number of steps along the shortest path for all possible pairs of nodes in the network:

$$L = \frac{2}{N(N-1)} \sum_{1 \leq i < j \leq N} d_{ij}, \quad (2)$$

where  $d_{ij}$  represents the shortest path length between nodes  $i$  and  $j$ .

The clustering coefficient for node  $i$ , denoted by  $C_i$ , quantifies the connectivity of the neighbors of node  $i$ , which is defined as follows:

$$C_i = \frac{2M_i}{k_i(k_i - 1)}, \quad (3)$$

where  $M_i$  is the number of edges that connect the neighbors of node  $i$ . Note that the neighbors of node  $i$  include all nodes directly connected to it but exclude node  $i$  itself. A higher value of  $C_i$  means that the node has more connections among its neighbors. In a complete graph in which all pairs of nodes are directly connected,  $C_i$  of all nodes equals 1. Note that  $C_i$  of nodes with  $k_i = 1$  is defined to be 0. The average clustering coefficient, denoted by  $C$ , is the average value of the clustering coefficient of all the nodes in the network:

$$C = \frac{1}{N} \sum_{i=1}^N C_i. \quad (4)$$

A higher value of  $C$  implies that there are more triangles in the network and more detours between pairs of nodes.

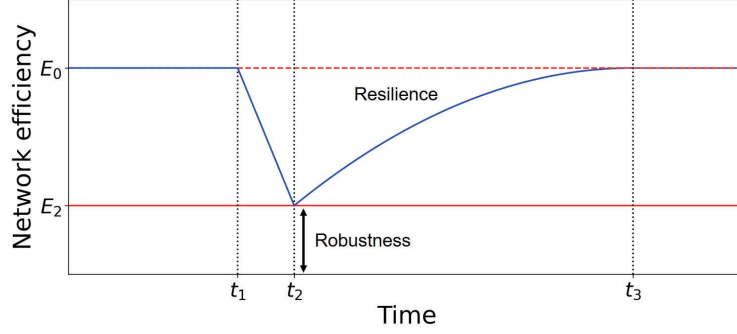

Figure 2: Schematic illustration of the definition of robustness and resilience.

Assortativity, denoted by  $r$ , is the Pearson correlation coefficient of degree between pairs of connected nodes:

$$r = \frac{\sum_{ij}(A_{ij} - k_i k_j / 2M) k_i k_j}{\sum_{ij}(k_i \delta_{ij} - k_i k_j / 2M) k_i k_j}, \quad (5)$$

where  $A_{ij}$  is the adjacency matrix, and  $\delta_{ij}$  is the Kronecker delta. If nodes with similar values of degree tend to be connected to each other, the value of  $r$  becomes positive (assortativity). Conversely, if nodes with a higher degree tend to be connected to nodes with a lower degree, then the value of  $r$  becomes negative (disassortativity).

### 3.3. Robustness and resilience

In addition to the measurements in the previous section, we also analyze the robustness and resilience of individual airline networks. Robustness and resilience of transportation networks have been studied intensively since the 1990s to assess damage caused by natural and manmade disasters (e.g., Mattsson and Jenelius, 2015; Taylor, 2017; Sugishita and Asakura, 2021). To evaluate robustness and resilience, it is necessary to quantitatively assess the degradation and recovery of network performance (Lordan et al., 2015; Zhou et al., 2019, 2021; Li et al., 2021). In this study, we measure network efficiency as a performance measurement, as proposed by Latora and Marchiori (2001). Network efficiency, denoted by  $E$ , is defined by

$$E = \frac{2}{N(N-1)} \sum_{1 \leq i < j \leq N} \frac{1}{d_{ij}}. \quad (6)$$

In this definition, the reciprocal of the shortest path length is regarded as the “efficiency” of individual paths.

Fig. 2 shows a schematic illustration of the definition of robustness and resilience. Robustness, denoted by  $R_o$ , quantifies the initial impact of the COVID-19 pandemic on the loss of network efficiency, which is defined by

$$R_o = \frac{E_2}{E_0}, \quad (7)$$

where  $E_0$  is the average value of the network efficiency in 2019, and  $E_2$  is the minimum value of the seven-day moving average of network efficiency after the declaration of a national emergency. The robustness  $R_o$  takes a value between 0 and 1, with closer to 1 meaning more robust.

Resilience, denoted by  $R_e$ , quantifies not only the decrease in network efficiency but also the recovery process (Bruneau et al., 2003), which is defined by

$$R_e = \frac{\int_{t_1}^{t_3} E(t) dt}{(t_3 - t_1) E_0}, \quad (8)$$

where  $t_3$  is the date when the seven-day moving average of network efficiency reaches  $E_0$  for the first time since the declaration of a national emergency. Resilience  $R_e$  takes a value between 0 and 1, with closer to 1 meaning more resilient.

### 3.4. Analysis of evolution patterns

Here, we apply the framework for analyzing evolution patterns in temporal networks, in which network structure changes over time (Masuda and Holme, 2019; Sugishita and Masuda, 2021), to airline networks. We measure the dissimilarity between two snapshot networks  $G$  and  $G'$  using the network distance defined by

$$d(G, G') = 1 - \frac{M(G \cap G')}{\sqrt{M(G)M(G')}}, \quad (9)$$

where  $M(G)$  and  $M(G')$  are the numbers of edges in  $G$  and  $G'$ , respectively, and  $M(G \cap G')$  is the number of edges that  $G$  and  $G'$  have in common. Network distance  $d$  ranges between 0 and 1. The distance matrix is a  $t_{\max} \times t_{\max}$  symmetric matrix of which the  $(t, t')$ th entry is given by  $d(G_t, G_{t'})$ , where  $G_t$  is the network on day  $t$ , and  $t_{\max}$  is the number of days observed. By analyzing the distance matrix, we can understand how each airline changes the network structure (e.g., whether the network structure returns to its pre-pandemic structure).

## 4. Results and discussion

### 4.1. The entire US domestic airline network

We show the changes in the six indices (i.e., nodes, edges, average degree, average shortest path length, average clustering coefficient, and assortativity) for the entire US domestic airline network in Fig. 3. We also show the number of new cases of COVID-19 per day in the US in gray (Centers for Disease Control and Prevention, 2022). All the measurements fluctuate slightly on a daily basis. We can observe periodic patterns, which can be considered weekly periodicity. To smooth out this weekly periodicity, we show the seven-day moving average of each measurement as orange curves. The dotted line indicates the declaration of the national emergency on March 13, 2020.

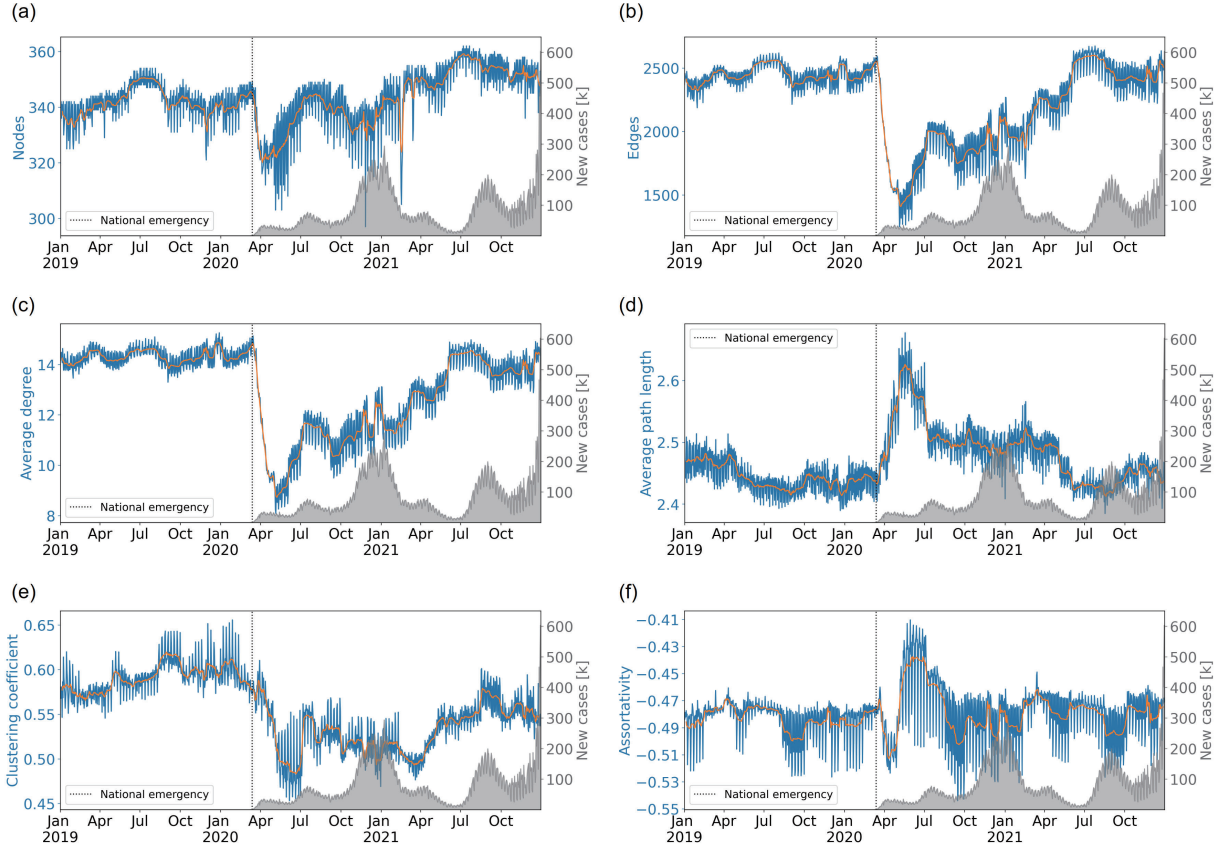

Figure 3: Evolution of the measurements for network structure: (a) nodes, (b) edges, (c) average degree, (d) average shortest path length, (e) average clustering coefficient, and (f) assortativity. We also show the number of new cases of COVID-19 per day in the US in gray.

All the indices significantly change after the declaration of the national emergency. The number of nodes fall by approximately 5% and return to its pre-pandemic level around July 2020. The number of edges then drops sharply by approximately 50% and then gradually increases, finally returning to its pre-pandemic level around July 2021. The variation in the average degree is similar to that of the number of edges. This means that it has taken more than one year for the average number of direct flight connections at each airport to return to that of the pre-pandemic level. This result also indicates that the value is continuously increasing and moving toward recovery, although it seems somewhat affected by the number of new cases (especially around a large peak of new cases in January 2021). The average shortest path length spikes by approximately 8% immediately after the declaration of the national emergency, drops somewhat around July 2020, stabilizes for approximately a year, and then returns to its pre-pandemic level around July 2021. Despite the aforementioned slow recovery of the number of edges and the average degree, the average shortest path length returns relatively quickly, suggesting that edges that had a significant impact on the overall connectivity of the network were recovered at an early stage. The average clustering coefficient meanwhile, is slightly lower than the pre-pandemic level even in 2021. This means that there are fewer triangles in the network and fewer detours. This change may reflect passengers' preference for fewer connecting flights during the pandemic. Assortativity takes negative values of approximately  $-0.4$  for all periods. This means that high-degree airports tended to connect with low-degree airports. There is a decrease immediately after the national emergency, followed by a large increase. This could be due to the loss of flights between the high-degree and the low-degree nodes, resulting in an increase of assortativity. It then decreases from around July 2020 and returns to its pre-pandemic level around October 2020.

Next, we show the distance matrix for the entire US domestic airline network in Fig. 4. The colors indicate the values of network distance  $d$  defined in Eq. (9). Higher values indicate more dissimilar networks. In Fig. 4, we can observe a blue block in the upper left corner of the distance matrix. This indicates that before the national emergency was declared, the network is relatively similar, although there are monthly or seasonal variations. However, around the declaration of the national emergency, we can see red rectangles. This suggests a dramatic change in the network, which is consistent with the significant changes in the network measurements in Fig. 3. Furthermore, most interestingly, we can observe that the structure of the network during the pandemic was largely different from the pre-pandemic network structure. In other words, even though the number of nodes and edges had already returned to their pre-pandemic levels in July 2021 (see Fig. 3a-b), the network structure was still largely different from that from before the pandemic. In the next sections, we examine the dynamics of the individual airline networks.

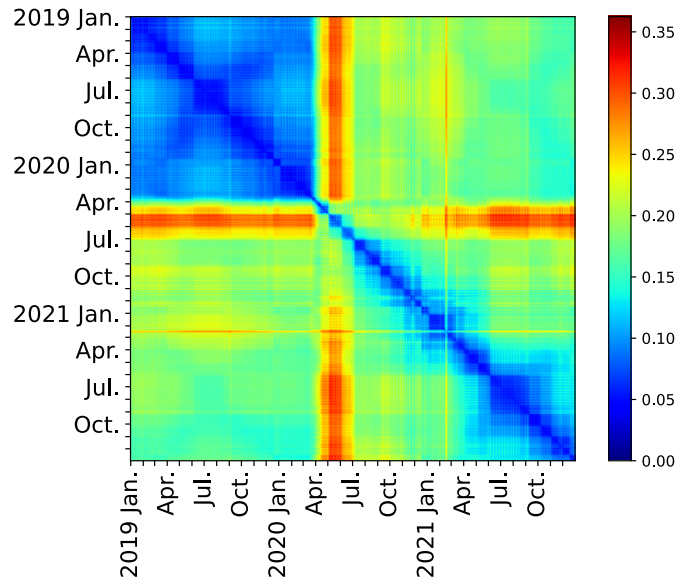

Figure 4: Distance matrix for the entire US domestic airline network. The color indicates the network distance  $d$  between pairs of networks.

#### 4.2. Networks for 16 airlines

In the previous section, we analyzed changes in the network structure of the entire US domestic airline network without separating by airline. In this section, we analyze changes in the network structure of each of the 16 airlines in the dataset (see also Table 1). Note that we excluded ExpressJet from the analyses in this section because it ceased its operations from September 2020 to September 2021.

##### 4.2.1. Evolution patterns

We show the distance matrices for the 16 airlines in Fig. 5. Recall that five airlines are FSCs (i.e., American, Alaska, Delta, Hawaiian, and United), five airlines are LCCs (i.e., JetBlue, Frontier, Allegiant, Spirit, and Southwest), and six airlines are RCs (i.e., Endeavor, Envoy, PSA, SkyWest, Mesa, and Republic) (see also Table 1). The results indicate that there are similarities and differences in changes in the network structure of each airline.

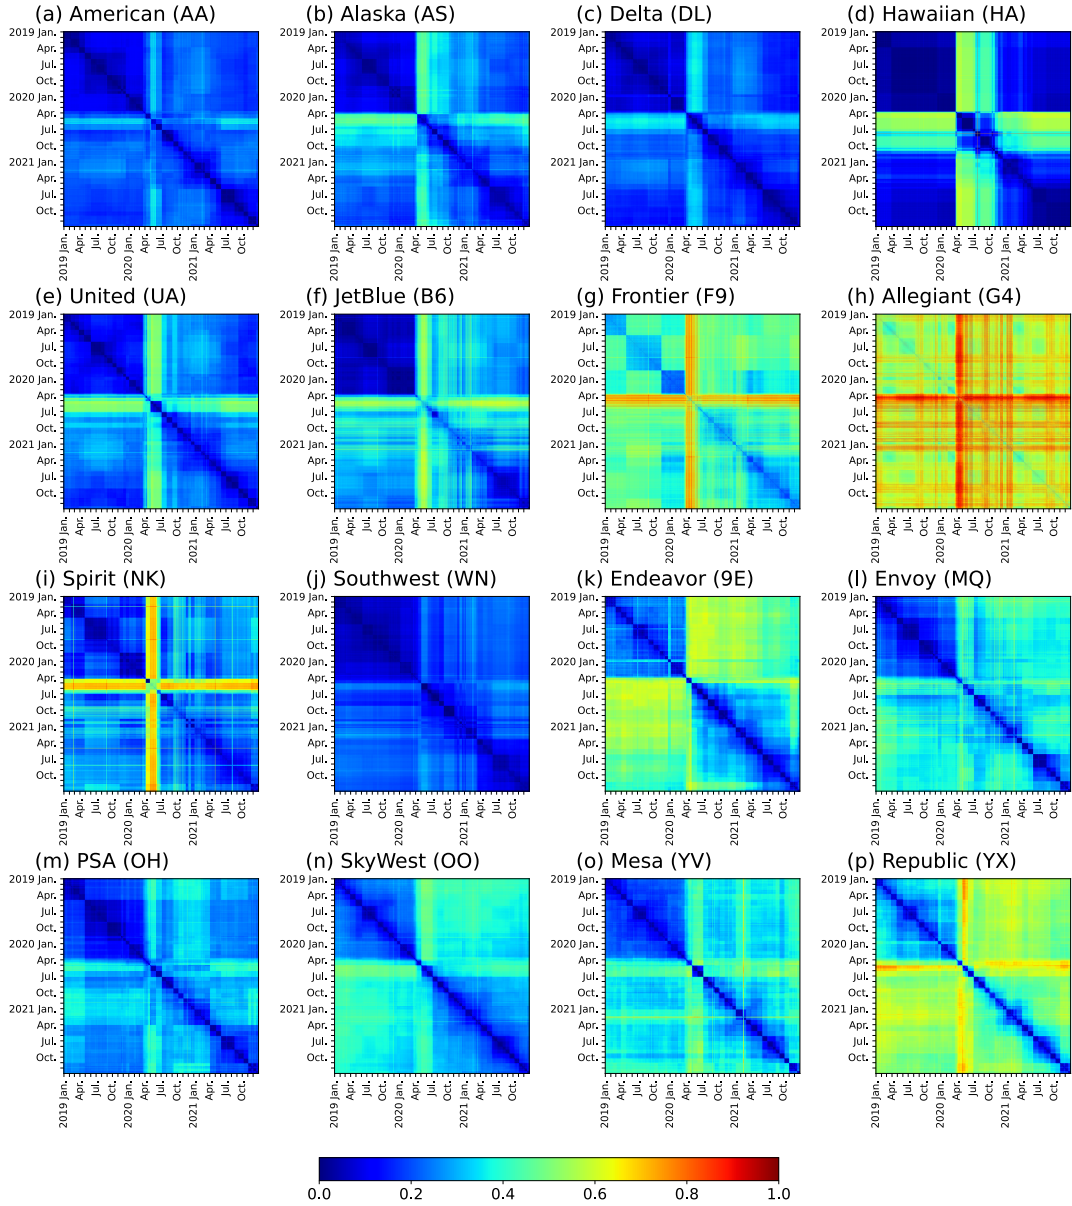

Figure 5: Distance matrices for 16 airlines. The color indicates network distance  $d$  between pairs of networks.

First, for the five FSCs (Figs. 5a-e), we observe that the network structure tends to return to the pre-pandemic structure a few months after the national emergency was declared. This is common to all five FSCs, although the timing of their return differs (e.g., Hawaiian took approximately seven months to return, as shown in Fig. 5d). There are several possible reasons for this relatively early return to the pre-pandemic structure. One is empty planes being flown to avoid losing slots at slot-constrained airports, ('ghost flights'). In fact, Haanappel (2020) pointed out that some airlines did this. There could also have been sole transportation of cargo. Furthermore, it is likely that they received financial aid from the government to maintain network connectivity. In fact, each of the three major FSCs (i.e., American, Delta, and United) received more than \$5 billion from the US Treasury Department between January and August 2020 (Statista, 2022). Neal and Kassens-Noor (2011) showed that FSCs have less flexible business models and are more affected by uncertain events than LCCs. Our results further suggest that FSCs may also be inflexible in terms of network structure during emergent situations.

Second, for the five LCCs (Figs. 5f-j), we observe significant changes, represented by the vivid red lines immediately after the declaration of a national emergency, except for Southwest. This is especially clear for Frontier, Allegiant, and Spirit (Figs. 5g-i). This result suggests that LCCs changed their network structure more dramatically than FSCs or RCs immediately after the national emergency was declared. We then compare such changes by airline type. As shown in Fig. 6a, we define  $d_{ave}^1$  as the average value of network distance  $d$  between March 13 and June 30, 2020. In Fig. 6b, we show the results of the comparison of  $d_{ave}^1$  among FSCs, LCCs, and RCs. The results show that LCCs tend to have larger values of  $d_{ave}^1$  than FSCs and RCs. In addition, we also notice that each airline has other unique characteristics. Allegiant has no clear blue blocks, which suggests that it had already been frequently changing its network structure before the pandemic. This result is consistent with the large fluctuations in the measurements for network structure shown in Appendix A (e.g., Fig. A.8h). Furthermore, Southwest had been evolving in a very unique way. That is, there is relatively little fluctuation immediately after the national emergency. In fact, even during the COVID-19 pandemic, among the 16 airlines, only Southwest expanded its network by increasing the number of nodes (see Fig. A.8j). Previous studies have also noted Southwest's distinctive characteristics (e.g., Czaplewski et al., 2001; Smith, 2004; Sugishita and Masuda, 2021), and our study quantitatively observes one more unique feature that arose during the COVID-19 pandemic.

Finally, for the six RCs (Figs. 5k-p), we observe that these airlines significantly changed their network structure and tended to shift to the new structure during the pandemic. Even though PSA returned to some extent to its pre-pandemic structure around April 2021, all the other RCs shifted to a new structure (especially Endeavor, SkyWest, and Republic). In the same way as  $d_{ave}^1$ , we define  $d_{ave}^2$  as the average value of network distance  $d$  between July 2020 and December 2021. In Fig. 6c, we show the results of the comparison of  $d_{ave}^2$  among FSCs, LCCs, and RCs. The quantitative results are consistent with our observations, which suggest that RCs tend to have larger values of  $d_{ave}^2$  than FSCs and LCCs. In general, RCs are subsidiaries of the FSCs (e.g., Endeavor operates as Delta Connection for Delta). Our results suggest that FSCs, which cannot flexibly change their network structure, have a strategy to significantly change the network structure of corresponding RCs. In the next section, we present the results on the relationship between robustness, resilience, and revenue loss of each airline and further discuss the characteristics of network dynamics of individual airlines.

#### 4.2.2. Robustness, resilience, and financial loss

In the previous section, we quantitatively identified the evolution patterns of each of the 16 airlines and found that these patterns varied significantly from airline to airline. In this section, we evaluate the robustness and resilience of each airline and analyze its relationship with revenue loss. The revenue loss for each airline is defined as the difference between operating revenue between April 2019 and March 2020 and that between April 2020 and March 2021. We used data from the Bureau of Transportation Statistics (Bureau of Transportation Statistics, 2022).

Fig. 7 shows the results of the correlation analysis between robustness, resilience, and revenue loss. First, we see that the revenue loss itself varies widely across airline types. The revenue loss for FSCs is approximately 70%, which is larger than that for LCCs and RCs. Hawaiian (HA), which took longer to return to its pre-pandemic structure among the FSCs, had the largest revenue loss of approximately 80%. Following the FSCs are the LCCs, with losses of approximately 60%. We also note that JetBlue (B6) and Southwest (WN) have revenue losses as high as those of the FSCs. On the other hand, RCs' revenue loss is approximately 30-40%, which is clearly smaller than that of FSCs and LCCs. These differences regarding revenue loss among FSCs, LCCs, and RCs were also observed after the 9/11 terrorist attacks (Franke, 2004). While further studies are desirable, this loss may be a universal occurrence during

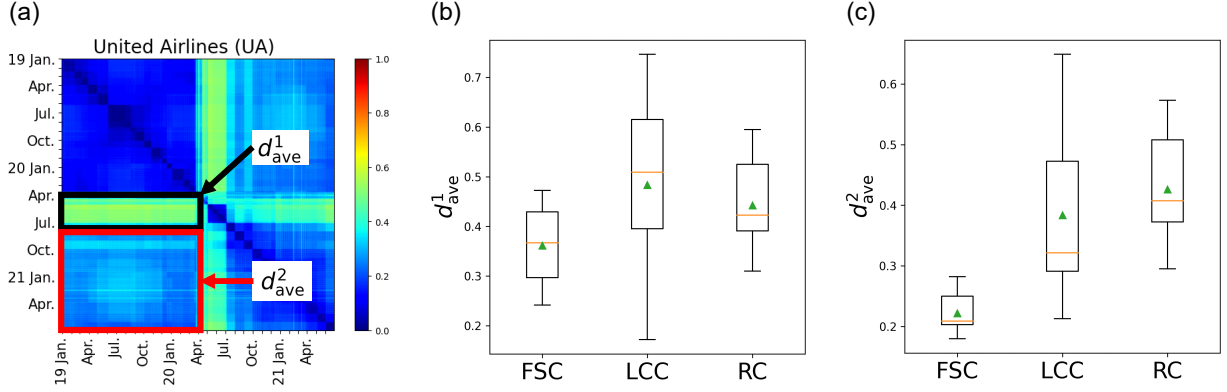

Figure 6: Quantitative comparison of changes in network structure among full-service carriers (FSCs), low-cost carriers (LCCs), and regional carriers (RCs). (a) The schematic illustration of the definition of  $d_{ave}^1$  and  $d_{ave}^2$ . (b) Comparison of  $d_{ave}^1$  among FSCs, LCCs, and RCs. We use box plots to show summaries of five distribution values: the first quartile ( $Q_1$ ), the median, the third quartile ( $Q_3$ ), the minimum ( $Q_1 - 1.5 \times IQR$ ), and the maximum ( $Q_3 + 1.5 \times IQR$ ), where  $IQR = Q_3 - Q_1$ . (c) Comparison of  $d_{ave}^2$  among FSCs, LCCs, and RCs.

emergent situations. Second, we find no correlation between robustness and revenue loss (Fig. 7a). Additionally, while there is no clear difference in robustness by airline type, Southwest shows high robustness: even though Southwest has a relatively high revenue loss of about 70%, the initial impact of the pandemic on network efficiency was limited. On the other hand, we find a negative correlation between resilience and revenue loss (Fig. 7b). In other words, the faster network efficiency recovers, the smaller the revenue loss, which is reasonable. However, here again, Southwest is unique. Specifically, Southwest quickly recovers its network structure despite the large revenue loss as noted earlier. As we already pointed out, Southwest is the only one of the 16 airlines that expanded its network by increasing the number of nodes, but this may be a network expansion in anticipation of future revenue. In summary, considering the previous section, our results suggest that FSCs are less flexible in changing their network structure and suffer higher revenue losses, while RCs may be able to reduce their revenue losses by significantly changing their network structure. LCCs fall between FSCs and RCs and are characterized by more pronounced differences between individual airlines.

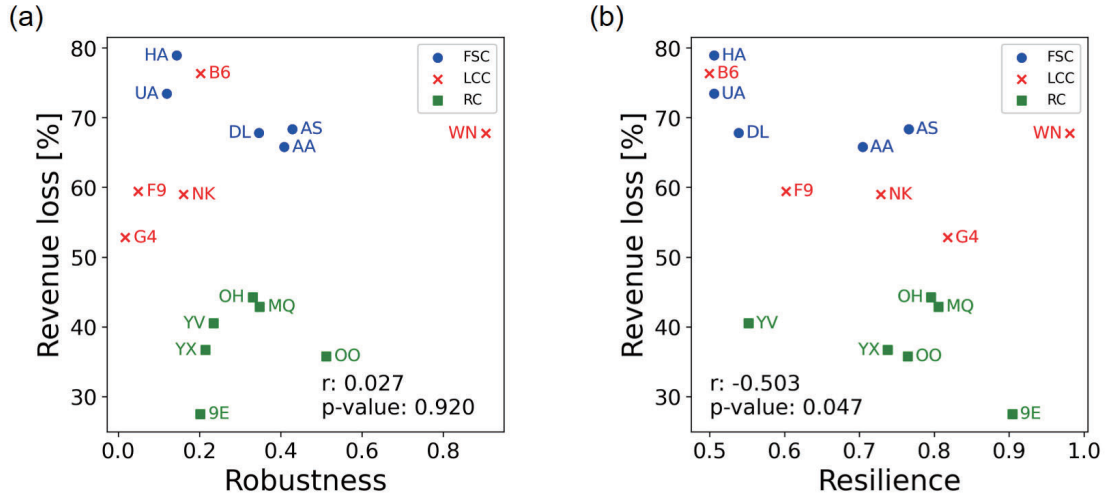

Figure 7: Correlation between robustness, resilience, and revenue loss. (a) The robustness and revenue loss. (b) The resilience and revenue loss.  $r$  represents the correlation coefficient. Recall that five airlines are full-service carriers (FSCs) (i.e., American (AA), Alaska (AS), Delta (DL), Hawaiian (HA), and United (UA)), five airlines are low-cost carriers (LCCs) (i.e., JetBlue (B6), Frontier (F9), Allegiant (G4), Spirit (NK), and Southwest (WN)), and six airlines are regional carriers (RCs) (i.e., Endeavor (9E), Envoy (MQ), PSA (OH), SkyWest (OO), Mesa (YV), and Republic (YX)).

## 5. Conclusion

In this study, we revealed the day-to-day dynamics of the US domestic airline network from January 2019 to December 2021. To summarize, first, for the entire US domestic airline network, we could observe the network recovery process after a sudden change following the declaration of a national emergency on March 13, 2020. The number of nodes returned to its pre-pandemic level within a few months, while the number of edges finally returned around July 2021. However, we found that, even though the number of nodes and edges returned to pre-pandemic levels by July 2021, the network structure was still largely different from what it was pre-pandemic. By analyzing the network changes for each of the 16 airlines, we further determined that the network dynamics varied greatly from airline to airline. Specifically, we found that all the FSCs, which suffered severe revenue loss, returned to their pre-pandemic structure within a few months after the national emergency was declared. In contrast, most of the RCs shifted to completely new networks during the pandemic, which may have contributed to reduced revenue losses. Furthermore, we also found that many of the LCCs made drastic changes in their network structure immediately after the national emergency was declared. At the same time, LCCs were characterized by more pronounced differences between airlines: Southwest in particular was the only one of the 16 airlines to expand its network despite its large revenue losses.

There are many interesting future directions that build on our results. First, in our study we have not been able to analyze how networks for individual airlines influence each other. Analyzing competition between airlines from network changes in emergency situations could be an interesting line for future research. For example, our study found that RCs have significantly changed their network structure, but whether this change has led to a more similar network to other airlines' networks—increasing competition on certain routes, or whether it has led to a more dissimilar network to others, opening up completely new routes—is currently unclear. We can reveal this by analyzing distance matrices constructed by comparing networks across airlines over time (see, Sugishita and Masuda, 2021). This is also relevant to the strategy of Southwest, which was the only airline to expand its network. Cho and Min (2018) pointed out that lower fares would be more attractive during periods of uncertainty. Our results imply that Southwest may be particularly well positioned to take advantage of this period of uncertainty. Further research is required to understand the long-term benefits of Southwest's network expansion identified in this study. Another limitation of this study is that we have not been able to determine how the network changed geographically. Integrating geographical factors into the temporal network analysis warrants future work. Finally, an analysis of airlines in countries other than the US during the COVID-19 pandemic should be conducted, as well as network analyses for other emergent situations such as other disease outbreaks, financial crises, terror-related events, and natural disasters. We found that the network dynamics of FSCs, LCCs, and RCs differed significantly during the COVID-19 pandemic, but this might be a universal occurrence regardless of country or type of emergency, which further research could help resolve.

## Appendix A. Measurements of network structure for individual airlines

In this section, we show the evolution of the measurements for the network structure of individual airlines (Figs A.8-A.13). In the same way as in Fig. 3, the gray curves represent the number of new COVID-19 cases per day in the US, and the orange curves represent the seven-day moving average of each measurement. The dotted line indicates the declaration of a national emergency on March 13, 2020.

We summarize some notable characteristics for individual airlines. First, as we already pointed out, Southwest has a unique evolution pattern. That is, the number of nodes does not change after the declaration of a national emergency and then increases (Fig. A.8j). The number of edges decreases slightly but then increases (Fig. A.9j). In other words, among the 16 airlines, only Southwest expanded its network during the pandemic. Next, we can see that Allegiant had already been frequently changing its network structure before the pandemic. All indicators are highly variable over the entire period. In addition, Endeavor recovers its number of nodes early and number of edges around July 2021 (Fig. A.8k and Fig. A.9k), but the clustering coefficient drops significantly compared to the pre-pandemic period (Fig. A.12k), suggesting that the network changes to one with many direct connections with few detours. Furthermore, we see that some airlines increase their weekly fluctuations after the pandemic. For example, when we examine the number of edges, they are particularly pronounced for LCCs and RCs (Fig. A.9). This suggests that these airlines became more sensitive to daily demand fluctuations and changed their network accordingly. Finally, we notice that

the average shortest path length recovers relatively quickly for all the airlines, which suggests that they may have preferentially recovered edges that have significant impact on network connectivity (Fig. A.11).
