

Point-defect avalanches mediate grain boundary diffusion

Ian Chesser¹ and Yuri Mishin¹

Abstract

Grain boundary (GB) diffusion in polycrystalline materials is a physical phenomenon of great fundamental interest and practical significance. Although the accelerated (“short circuit”) atomic transport along GBs has been known for decades, the current atomic-level understanding of GB diffusion remains poor. Experiments can measure numerical values of GB diffusion coefficients but provide little information about the underlying mechanisms. Previous atomistic simulations focused on relatively low temperatures when the GB structure is ordered or relatively high temperatures when it is highly disordered. Here, we report on molecular dynamics simulations of GB diffusion at intermediate temperatures, which are most relevant to applications. One of the surprising results of this work is the observation of strongly intermittent GB diffusion behavior and its system-size dependence unseen in previous work. We demonstrate that both effects originate from an intermittent, avalanche-type generation of point defects causing spontaneous bursts of GB diffusivity mediated by highly cooperative atomic rearrangements. We identify the length and time scales of the avalanches and link their formation to the dynamic heterogeneity phenomenon in partially disordered systems. Our findings have significant implications for future computer modeling of GB diffusion and mass transport in nano-scale materials.

Introduction

Most technological materials are composed of differently oriented crystallites (grains) separated by a network of grain boundaries (GBs) [1]. Atomic transport along GBs is known to be much faster than in the perfect lattice [2]. This “short-circuit” GB diffusion controls many processes in structural and functional materials, including microstructure development, phase transformations, and high-temperature modes of plastic deformation and fracture [1, 2]. In addition to the practical significance, GB diffusion is a phenomenon of great fundamental interest. Being in a frustrated state squeezed between misoriented crystals, the quasi-two-dimensional GB structure represents a unique state of matter “transitional” between ordered and disordered. Due to the structural complexity, the current understanding of GB diffusion mechanisms remains very limited. Experiments can only measure numerical values of GB diffusion coefficients but provide little information about the microscopic mechanisms. Hence, practically all existing knowledge about GB diffusion mechanisms comes from atomistic computer simulations [3].

Previous simulations have only addressed two limiting cases of relatively low and relatively high temperatures. It is now established that at low temperatures ($T \ll T_m$, where T_m is the melting point), GBs support both vacancies and interstitials, which can exist in a variety of structural forms, have strongly site-dependent but on average lower formation energies than in the lattice, and can contribute equally to GB diffusion [4–7]. GB atoms can diffuse by many different but predominantly collective mechanisms, typically in the form of a chain of highly coordinated displacements that can be open-ended (string) or looped (ring). In the other limit, when temperature approaches the bulk melting point, the GB structure becomes highly disordered. Some GBs premelt by transforming into a liquid-like layer near T_m [6–8]. The notion of individual point defects breaks down, but the diffusion mechanisms remain collective and closely resemble those in disordered bulk systems such as supercooled liquids, glasses, and crystalline super-ionic materials [9–12]. Accordingly, the statistical methods developed for the characterization of atomic dynamics in disordered bulk systems were successfully applied to study diffusion mechanisms in disordered GBs [7, 8]. Such studies revealed a remarkable similarity between the two types of systems, including the existence of string-like diffusion mechanisms and the dynamic heterogeneity occurring on multiple length and time scales.

Little is known about GB diffusion at intermediate temperatures, at which the GB structure is not liquid-like but rather retains a significant degree of structural order. It is presently unknown if the concepts of dynamic heterogeneity and dynamic facilitation developed for disordered systems can be applied to such boundaries. If they can, the length and time scales of the heterogeneous dynamics remain unexplored. It should also

be noted that the intermediate temperatures are more relevant to the service conditions of many technological materials than the two limiting cases mentioned above.

This work aims to fill this knowledge gap by studying the diffusion mechanisms in metallic GBs at intermediate temperatures. A surprising outcome of the study is the observation of a strongly intermittent diffusion behavior and its system-size dependence unseen in previous work. We show that both effects originate from an intermittent, avalanche-type generation of point defects causing spontaneous bursts of GB diffusivity. We carefully characterize the length and time scales of the avalanches and show that they fully explain the observed intermittent diffusion behavior and its size dependence. We discuss possible implications of our findings for the computer modeling of GB diffusion and for atomic transport in nano-scale systems.

The primary material chosen for this study is face-centered cubic (FCC) Al. Four different Al GBs were selected as shown in Table 1. Two of them are the high-angle tilt $\Sigma 3$ $\langle 110 \rangle$ and $\Sigma 17$ $\langle 100 \rangle$ GBs, where Σ is the reciprocal density of coincident sites and the angular brackets indicate the tilt axis [1]. The third boundary is a low-angle twist GB with the $\{100\}$ GB plane, and the last one is a high-angle asymmetric incommensurate (HAAI) boundary obtained by joining two crystal planes with incommensurate periodicities. Both the $\Sigma 3$ and HAAI boundaries have relatively low energies and are common in polycrystalline Al [13]. These four boundaries represent diverse GB crystallographies, symmetries, and atomic structures. Most of the results reported below are for the $\Sigma 3$ and $\Sigma 17$ GBs, with two remaining boundaries left for cross-checking. We use classical molecular dynamics (MD) with atomic interactions described with the interatomic potential [14] referred to here as Al-M. To demonstrate that our results are not a specific feature of a particular interatomic potential, some of the simulations are repeated with two other Al potentials. The results were found to be well-consistent with those obtained with the Al-M potential. Furthermore, additional simulations were performed for the $\Sigma 3$ GB in FCC Ni and $\Sigma 17$ GB in body-centered cubic (BCC) Fe, which revealed similar diffusion behaviors. These cross-checks confirm the robustness of our conclusions across different metals with different crystalline structures.

Results

The $\Sigma 3$ and $\Sigma 17$ GB structures optimized with the Al-M potential are shown in Fig. 1a,b. The GB construction and optimization protocol is explained in the Methods section. The $\Sigma 3$ GB, also known as incoherent twin boundary, is composed of asymmetric kite-shaped structural units. This structure closely matches the high-resolution transmission electron

microscopy observations [15, 16] and prior simulations [17]. The asymmetry arises from a small shift of the upper grain relative to the lower along the $\langle 111 \rangle$ axis (x -direction in the sample frame), whose magnitude (0.7 angstroms) is close to the experimental value (0.66 ± 0.07 angstroms) [16]). This boundary has also a symmetric structure (zero shift) [16, 18], but the latter has a higher energy. We thus use the asymmetric structure for the diffusion simulations. The $\Sigma 17$ GB has a zig-zag structure with the kite-unit spacing (0.59 nm) and energy consistent with prior simulations [19]. This boundary was previously used to study premelting diffusion mechanisms in copper [7].

Self-diffusion coefficients in the $\Sigma 3$ and $\Sigma 17$ GBs were extracted from MD trajectories using the Einstein relation as detailed in Methods. The results are summarized in the Arrhenius diagram in Fig. 1c. For comparison, the diagram also includes the diffusion coefficients in liquid Al computed in this work and the diffusion coefficients in FCC Al taken from the literature. In agreement with prior work [6], the GB diffusion coefficients are intermediate between those in supercooled liquid and in the perfect crystal. Both GBs exhibit diffusion anisotropy with faster diffusion along the tilt axis (y -axis) than normal to the tilt axis (x -axis). Diffusion in the $\Sigma 3$ GB displays a larger degree of anisotropy and is over an order of magnitude slower than diffusion in the $\Sigma 17$ GB (except close to the melting temperature when the two diffusivities tend to converge). This diffusion behavior correlates with the lower energy of the $\Sigma 3$ GB (418 mJ/m²) relative to the $\Sigma 17$ GB (488 mJ/m²).

Below the homologous temperature of $0.9 T_m$ ($T_m = 929$ K is the Al melting point predicted by the Al-M potential), the GB diffusion coefficients follow the Arrhenius relation

$$D_i = D_{0,i} \exp\left(-\frac{E_i}{k_B T}\right), \quad (1)$$

where the index i refers to the directions parallel (\parallel) or normal (\perp) to the tilt axis, $D_{0,i}$ is the entropic prefactor, E_i is the activation energy of diffusion, and k_B is Boltzmann's constant. Table 2 summarizes the Arrhenius parameters for each GB obtained by fitting Eq.(1) to the data below $0.9 T_m$. For the $\Sigma 3$ GB, the average activation energy (1.38 eV) is significantly higher than for the $\Sigma 17$ GB (0.77 eV) and comparable to the literature data for lattice diffusion (1.25-1.45 eV) [20]. At high temperatures, a premelting regime is observed in both GBs as evident from the rapid increase in the GB diffusivity with temperature. The $\Sigma 17$ GB fully premelts and its diffusivity comes close to that in liquid Al near T_m , which is consistent with previous work on this GB in copper [6, 19, 21]. The $\Sigma 3$ GB also premelts, but its diffusivity remains below the bulk liquid diffusivity. This work is focused on diffusion at intermediate temperatures, $T < 0.8 T_m$ ($T < 750$ K), at which both GBs are relatively flat and immobile on the MD timescale. This allows us to cleanly analyze the

diffusion mechanisms without the added complications from GB roughening, migration, or premelting.

Our first key observation is the significant intermittency of GB diffusion at the intermediate temperatures. The effect is illustrated in Fig. 2a, where we plot the mean-square displacement (MSD) of atoms in the $\Sigma 3$ GB core as a function of time. The remarkable feature of the plot is the existence of the slope fluctuations with stochastic switches between nearly horizontal and large-slope portions. The zig-zag shape of this plot points to the existence of two dynamic regimes with a very small and a relatively large GB diffusivity. We refer to the plateaus of the diffusivity as the *locked* states and to the surges of diffusion as *avalanches*. The times at which the avalanches nucleate correspond to abrupt increases in the number of mobile atoms in the GB core, as illustrated in Fig. 2b. In contrast, during the locked periods, most GB atoms remain immobile; only a few atoms execute jumps, often in the form of small rings of highly correlated displacements (Fig. 2c).

The diffusivity bursts are dynamic signatures of the avalanches, but they also have a structural signature. Each avalanche period is accompanied by a drastically increased point defect activity in the GB core and thus a temporary decrease in the structural order. An avalanche triggers a massive formation of vacancies and interstitials, which occur in nearly equal amounts. Comparison of Figs. 2a and 2e shows that the numbers of vacancies and interstitials in the GB core strongly correlate not only with each other but also with the occurrence of locked and avalanche time periods. The fluctuating point defect populations also correlate with the total number of mobile atoms (Fig. 2f,g), confirming that GB diffusion occurs by a defect-mediated mechanism. At 700 K, a typical avalanche creates hundreds of point defects and activates thousands of mobile atoms.

The questions then arise: how does an avalanche begin, and how does it end? Careful structural analysis (see Methods) reveals that a typical avalanche starts with the formation of an interstitial atom in the GB core that hops multiple times (on the ps timescale) before pushing a regular atom out of its preferred site (Fig. 2h). This event triggers a cascade of collective structural excitations with a string-like character in which multiple atoms move simultaneously in the same direction. A string-like excitation can be viewed as an extended Frenkel pair in which the leading atom has an interstitial character (associated with local compression) and the trailing atom has a vacancy character (local tension). This interpretation is confirmed by analyzing the free volume distribution in the population of mobile atoms (see Supplementary Fig. 1). Importantly, the avalanches involve the *facilitated dynamics* [22, 23] of the multiple Frenkel pairs and neighboring string-like excitations. Namely, a collective atomic displacement at one location triggers nearby diffusive events by creating a positive feedback for further propagation of the atomic displacement field that

rapidly grows in size into a full-fledged avalanche. As the point-defect population grows, so does the probability of their mutual recombination. Eventually, a bifurcation point is reached at which the dynamics switch to a recombination regime. We hypothesize that the locked states arise from such spontaneous switches of the diffusion process from the multiplication to the recombination regime. Self-annihilation of point defects across the periodic boundary conditions can also play a role.

Our second key finding is that the intermittent behavior of GB diffusion is system-size dependent on the ~ 10 nm length scale. This was demonstrated by increasing the GB cross-section and remeasuring the diffusion coefficients and the MSD curves. In the example shown in Fig. 3a, the initial zig-zag shape of the MSD curves is replaced by a linear function when the cross-section is increased from $(10 \text{ nm} \times 10 \text{ nm})$ to $(30 \text{ nm} \times 30 \text{ nm})$. In a more systematic test, the GB cross-section in the direction parallel to the tilt axis was increased incrementally while keeping the size normal to the tilt axis fixed. For each cross-section, the diffusivity was measured several times with different velocity seeds as shown in Fig. 3b. The scatter of the points at each cross-section is a measure of the intermittent diffusion behavior. The plot clearly shows that the scatter decreases with increasing GB size. (The average diffusivity values seem to increase with the size, but this trend does not pass statistical significance tests.) The probability of locked states can be used as another measure of intermittency. The plot Fig. 3c shows that, for a fixed $(10 \text{ nm} \times 10 \text{ nm})$ cross-section, the intermittency decreases with increasing temperature and vanishes at about 750 K. These tests demonstrate that the intermittent behavior of GB diffusion exists in a certain temperature-size domain and disappears at high temperatures and/or large GB sizes.

We posit that both phenomena, the GB diffusion intermittency and its size dependence, have the same physical origin: the finite size of the mobile atom clusters generated by the point-defect avalanches. In a large GB area, multiple avalanches can form at different moments of time at random locations. The measured diffusion coefficient then represents the atomic mobility averaged over multiple avalanches and exhibits a smooth and size-independent behavior. If the GB size is less than or comparable to the avalanche size, then the boundary conditions truncate the mobile cluster size to the GB size. Each mobility surge then quickly spreads over the entire GB area and later stops across the entire GB area, causing the on-and-off behavior seen in Figs. 2a and 3a. Due to the anisotropy of GB structure, the intermittency condition can be met when the mobile cluster size becomes comparable to the GB dimension in at least one direction. The disappearance of the diffusion intermittency at high temperatures is explained by a decrease in the mobile cluster size with temperature.

To provide mechanistic support to this explanation, we have analyzed the dynamic length scales of the GB diffusion in more detail. We find that the measures of dynamic length scales used in previous work [8, 11] predict lengths that are too small in magnitude to explain the observed diffusion intermittency. For example, the average (1.4 nm) and maximum (7 nm) string lengths computed for the $\Sigma 3$ GB at 700 K by the standard string-like segmentation method (see Methods) are smaller than the observed ~ 10 nm system-size effect. A method capturing the length scale of the entire avalanche region was required.

As stated above, the avalanches exist due to the dynamic facilitation of collective atomic displacements, in which a local excitation spreads in a self-catalytic manner by increasing the probability of atomic displacements in neighboring regions. Facilitated dynamics can be conveniently visualized using space-time diagrams [22]. To construct such a diagram, atomic displacement fields corresponding to a fixed time interval are stacked together along the time axis and viewed in a space-time cross-section (Fig. 4a,b). The diagram reveals the formation and disappearance of mobile and immobile clusters in space and time. The GB structural units blink between on and off states corresponding to the diffusive and quiescent time periods. The branching and coalescence of diffusion trajectories on the diagram are signatures of facilitated dynamics. We have developed a space-time clustering algorithm (see Methods) that identifies the mobile and immobile clusters and measures their dimensions in space and time. The time dimensions of these clusters are associated with the lifetimes of the avalanches and locked states. As demonstrated in Fig. 4c, we find that immobile clusters have a longer average lifetime than mobile clusters. This time scale separation is a known hallmark of facilitated dynamics [22, 23]. The spatial dimensions of the mobile and immobile clusters are measures of avalanche size. Fig. 4d shows the avalanche size probability distribution computed for the $\Sigma 3$ GB at 700 K. The plot reveals that the avalanches are elongated parallel to the tilt axis (which is consistent with the diffusion anisotropy) and have a significant probability of being 5 to 15 nm in size. Over 15 percent of the mobile atoms participate in avalanches larger than 10 nm along the tilt axis. The largest avalanches contain a thousand or more atoms and have linear dimensions up to 20 nm along the tilt axis. These dimensions are well-consistent with the length scale of the system-size effect of GB diffusion (cf. Figs. 2a and 3a). That the avalanche size decreases with temperature was confirmed by the analysis shown in Supplementary Fig. 2, in which the average avalanche size was estimated by the virtual system-size analysis explained in Methods.

All simulations discussed so far utilized the Al-M interatomic potential [14]. To demonstrate the generality of our results, selected simulations were repeated with two additional potentials: the embedded-atom potential from Ref. [24] (Al-99) and the recently developed

physically-informed neural network (PINN) potential [25] referred to here as Al-PINN. The latter is computationally much slower than the Al-M and Al-99 potentials but provides the most accurate description of Al properties. An Arrhenius diagram summarizing the diffusion coefficients in the $\Sigma 3$ and $\Sigma 17$ GBs computed with these potentials is shown in Supplementary Fig. 3a. All three potentials display similar diffusion behaviors, with a comparable degree of diffusion anisotropy and similar temperatures of premelting. More importantly, the existence of the collective diffusion mechanisms in the $\Sigma 3$ and $\Sigma 17$ GBs is reproduced with all three potentials. In particular, the Al-PINN simulations predict string-like displacement geometries visually indistinguishable from those obtained with the Al-M potential. Furthermore, simulations with the Al-99 potential revealed the same type of diffusion intermittency as observed with the Al-M potential (see example in Supplementary Fig. 3b). The intermittent diffusion behavior and its disappearance with increasing system size were also confirmed for the (100) twist and HAIC boundaries, as illustrated in Fig. 3. Although these boundaries are crystallographically and structurally different from the $\Sigma 3$ and $\Sigma 17$ GBs, they exhibit the same correlation between the avalanche time periods on the MSD plots and the bursts of point-defect activity as in the $\Sigma 3$ and $\Sigma 17$ GBs.

To further demonstrate the generic character of our main results and conclusions, we performed additional diffusion simulations for the $\Sigma 3$ GB in FCC Ni and $\Sigma 17$ GB in BCC Fe, see Supplementary Table 1. We again observed the diffusion intermittency on the 10 nm scale at intermediate temperatures, with the avalanche periods associated with bursts of point defect generation (see Supplementary Figure 4). We note that collective diffusion mechanisms were previously studied in BCC Fe GBs in [26], although diffusion intermittency was not documented. The observation of diffusion avalanches across multiple GB structures and chemistries provides strong evidence that the avalanche-mediated diffusion behavior reported here is generic to metallic GBs.

Discussion

The previous paradigm of GB diffusion has been that this process is continuous in time and uniform across the GB area. Contrary to this idealistic picture, we have shown that there is a temperature-size domain in which GB diffusion is discontinuous in both time and space. For the metallic GBs studied here, the time and space scales of the diffusion intermittency are several nanoseconds and several nanometers, respectively, although the exact numbers are system-dependent. The physical origin of the GB diffusion intermittency is the dynamic heterogeneity of the diffusion process. The atomic displacements are not distributed uniformly along the boundary but cluster together into large groups of mobile

atoms undergoing a collective rearrangement. Spontaneous formation of a mobile cluster is triggered by a local atomic rearrangement that spreads like an avalanche by the dynamic facilitation mechanism. The avalanche region is characterized by a drastically increased defect population and enhanced atomic mobility. If the avalanche size is comparable to the GB size in at least one direction, a spike in the GB diffusivity arises. This is the cause of the system-size dependence of GB diffusion and the reason why the size effect vanishes when the GB area becomes large.

To put our findings in perspective with the literature, dynamic heterogeneity has been studied for years, but mostly in disordered bulk systems such as supercooled liquids and glasses [9–12]. The concept of dynamic facilitation was introduced more recently [22, 23, 27] but again in the context of bulk disordered systems. Zhang et al. [8] have shown that GB migration and diffusion processes exhibit dynamic heterogeneity similar to that in supercooled liquids. They also observed string-like atomic displacements on time and length scales similar to those in supercooled liquids. However, their work was focused primarily on GB migration rather than diffusion. Dynamic heterogeneity and collective diffusion mechanisms were also investigated in highly disordered, premelted copper GBs [7]. Intermittent diffusion behavior was seen in MD simulations of low-angle twist GBs, but no explanation was attempted [28]. None of the prior work [7, 8, 28] investigated the physical origin of the GB diffusion intermittency or its size effect. On the other hand, avalanche-mediated dynamics were investigated by MD simulations of several processes, such as crystallization of glasses (see, e.g, [29] and references therein), but not for GB or even bulk diffusion. It should also be noted that the avalanches during glass crystallization occur in a metastable state as the system gradually transitions to a more stable state. By contrast, the avalanches discussed in this work occur in a fully equilibrium system and are caused by thermal fluctuations away from equilibrium. Thus, although some of the individual components of this work pre-existed, they were expanded and integrated into a coherent mechanistic explanation of the previously unknown effects reported in this article.

One lesson from this work for future atomistic simulations is that the system size effect is important. If the GB size is comparable to or smaller than the avalanche size and the simulation time is too short, the MSD-vs-time curve can represent either an avalanche or a locked state. In either case, the GB diffusivity extracted from the Einstein relation will be far from the real value. Multiple simulations with different system sizes and diffusion times are required to ensure averaging over multiple avalanche-locked cycles to obtain the converged GB diffusivity. In experiments, a nano-scale GB can exhibit intermittent mass transport, creating an additional source of noise in electronic devices. The situation can, for example, be relevant to mass diffusion and/or electromigration in conductor lines in

integrated circuits. Assuming a nanosecond time scale of the avalanches, the respective fluctuation frequency could be in the GHz range.

In addition to the practical aspects mentioned above, this work raises many fundamental questions. In contrast to the homogeneously disordered matter such as 2D or 3D supercooled liquids and glasses, GBs are partially ordered quasi-2D systems with a tunable structure and structural anisotropy. They can support a broad spectrum of local structural excitations (defects) with diverse sizes, energetics, and geometries. The effects of this partial order and the structural richness on the dynamic heterogeneity require further investigations. The exact mechanism of the dynamic facilitation in GBs remains unknown but could be different from that in homogeneously disordered systems. For example, we found a much larger avalanche length scale (up to $\sim 70r_0$) compared to that in supercooled liquids and glasses (below $\sim 10r_0$) [30] (r_0 being the first nearest neighbor distance). Furthermore, this work only studied GBs in single-component systems. Adding segregating solutes to the GB core will add a new level of complexity but will also provide a means to control the GB dynamics. While the segregation effect on GB diffusion has been studied [31], the underlying microscopic mechanisms remain unknown.

Finally, even though most GB diffusion measurements are performed on time and space scales far exceeding the avalanche scales, one should explore alternative methods capable of extracting at least some mechanistic information. For example, isotope effect measurements provided evidence for collective diffusion mechanisms in metallic glasses [32]. Although such measurements do not give detailed information about specific mechanisms and are limited to elements with available isotopes, their application to GB diffusion could still be attempted to confirm the existence of collective atomic rearrangements predicted by the simulations. Dielectric spectroscopy methods have also been used in specific glasses and supercooled liquids to resolve the characteristic frequencies of slow and fast processes during glassy dynamics [33–35]. They, too, could potentially be used to gain at least some insights into the GB diffusion dynamics on the atomic level.

Methods

The Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) [36] was used to conduct molecular statics and MD simulations. The software package OVITO [37] was used for visualization and analysis of the collective diffusion mechanisms. The interatomic potentials were downloaded from the LAMMPS potential library. The GitHub codes from [38] were used for LAMMPS simulations with the AI-PINN potential.

Unrelaxed AI GB structures were created by joining two grains in a simulation box

with periodic boundary conditions in the GB plane (x - y coordinate plane) and free-surface boundary conditions normal to the GB (z -direction). The GB cross-section was chosen with dimensions at least 10 nm by 10 nm in the x and y directions, and each grain had a thickness of at least 6 nm. To study finite-size effects on diffusion, several GB cross-sections were tested up to 32 nm by 32 nm. For the commensurate GBs (Table 1), the lateral bicrystal dimensions were chosen with integer repeats of the coincident site lattice (CSL) unit cell. For the incommensurate GB, the misfit strain was minimized within the maximum interface size (30 nm by 30 nm) and applied to the upper grain only. The minimization procedure was repeated at different temperatures for lattice constants expanded by the precomputed bulk thermal expansion coefficients. The maximum absolute value of the misfit strain used in this work was 1.001.

The initial GB structures were optimized by a standard grid search that seeks to find a deep local energy minimum [39, 40]. Several hundred initial unrelaxed GB structures were prepared with different rigid shifts applied to the upper grain relative to the lower. Translations were chosen within a unit cell of the reciprocal lattice of the CSL (known as the displacement shift complete lattice) and included overlaps of the two grains. For each initial structure, pairs of closely spaced atoms were identified and one atom was deleted at random if the overlap radii were in the range 0.7 - $0.95r_0$, where $r_0 = 0.28$ nm is the first nearest neighbor distance in FCC Al. Conjugate gradient minimization was performed at 0 K to relax the atoms in the GB core of each candidate structure. The lowest energy structure was used as input for the subsequent diffusion simulations. This optimization procedure recovered the well-known structures of the $\Sigma 3$ and $\Sigma 17$ GBs, but it did not sample different GB densities as in more sophisticated optimization routines [41–43].

Wigner-Seitz analysis as implemented in OVITO was used to analyze the point defect content of GBs. This method identifies point defects in a finite-temperature GB structure relative to the Voronoi tessellation of a defect-free reference structure. As the reference state, we used the 0 K GB structure homogeneously expanded by the thermal expansion coefficient at the chosen temperature.

GB diffusion was studied by canonical (NVT) and microcanonical (NVE) MD simulations. A multi-step equilibration procedure was performed before production runs. First, the bicrystal was homogeneously expanded by the precomputed bulk thermal expansion strain at the chosen temperature. Next, a 1 nm thick rigid slab at the top of the upper grain was allowed to float in z -direction during a short (0.1 ns) NVT anneal. Combined with the pre-expansion, this step reduced the pressure in the grains to near zero. Then, the rigid slabs at the top and bottom of the bicrystal were fixed and an NVT anneal was performed for 1 ns. The fixed boundary conditions suppressed spontaneous GB sliding

events allowing us to clearly identify the diffusion mechanisms. After the equilibration, production NVT runs were performed for up to 40 ns and several hundred dump files were output for the subsequent calculation of the diffusion coefficients. NVE simulations were then performed starting from the end of each NVT run to analyze the diffusion mechanisms. The NVE ensemble was chosen to eliminate any possible effect of the thermostat on spontaneous diffusive events. For selected calculations, including diffusion measurements at low temperatures, additional statistics were obtained by performing multiple runs with different velocity seeds.

The GB self-diffusion coefficients were measured by tracking atoms within a 2 nm thick layer centered at the GB. The current GB position was determined as the average z -coordinate of non-FCC atoms identified by the polyhedral template matching modifier in OVITO [44]. The diffusion coefficients within the layer were calculated from the Einstein relations $D_x = \langle x^2 \rangle / 2t$ and $D_y = \langle y^2 \rangle / 2t$, where $\langle x^2 \rangle$ and $\langle y^2 \rangle$ are the MSDs of atoms in the respective directions parallel to the GB plane and t is the simulation time. Bootstrap resampling was employed as in [45] to compute error estimates associated with the diffusion coefficient. The hyper-parameters chosen for this method include a smoothing window of 5 ps, a block length of 20 ps, and the number of resampled trajectories equal to 100. Note that using a fixed-width layer can underestimate the diffusion coefficient because of the possible inclusion of some of the immobile atoms from the perfect lattice regions next to the GB core. This underestimation was corrected by rescaling the diffusion coefficients by the average inverse fraction of the mobile atoms in the layer at long times. The convergence of diffusion calculations in time was verified by checking that the slope of the $\log(\text{MSD})$ - $\log(t)$ plot was equal to one. All diffusion coefficients reported here satisfied this condition.

At high temperatures (typically, $T > 0.85T_m$) and depending on the GB, random interface displacements were observed in addition to diffusion. When the average interface position changed by more than 0.5 nm, the diffusion calculation was reset from the new GB position.

To compute the liquid diffusion coefficients, an initial 32,000-atom liquid structure was created in a periodic box by heating a perfect Al crystal in the isothermal-isobaric (NPT) ensemble to 1500 K and holding it for 200 ps. Next, a set of liquid samples was generated in the temperature range from 1050 to 1450 K by quenching the high-temperature structure at a rate of 50 K/100 ps and holding it at the set temperature for 200 ps. A further stepwise quenching was performed from 1050 K to 600 K at a rate of 25 K/ns with a hold time of 2 ns every 50 K. These times were sufficient for liquid equilibration at the chosen temperatures as evidenced by converged total potential energy and linear MSD vs time behavior. Crystallization was observed at and below 650 K, and these temperatures were

not used for the diffusion calculations. Production NVE anneals were performed for all liquid structures for 0.1 ns. The diffusivity was computed from the 3D Einstein relation $D = \langle r^2 \rangle / 6t$ and averaged over 20 independent runs with different velocity seeds.

The following algorithm was used to reveal string-like displacements in GB diffusion. First, mobile atoms were identified within the GB core such that the net displacement of an atom Δr during a preset time interval Δt lay within the range $0.4r_0 < \Delta r < 1.2r_0$. Here, the upper bound was chosen to eliminate atoms that had undergone multiple hops, and the lower bound was chosen to eliminate immobile atoms. Next, mobile atomic pairs (i, j) were found that remained nearest neighbors at the times $t = 0$ and $t = \Delta t$ and satisfied the criterion $\min(|r_i(t) - r_j(0)|, |r_j(t) - r_i(0)|) < 0.43r_0$. This criterion captures atomic pairs with string-like motion in which one atom jumps into the previous position of the other. The algorithm has three hyper-parameters: the lower and upper bounds for the displacement and the substitution distance (the numbers 0.4, 1.2 and 0.43 above). These parameters were chosen based on prior studies of diffusion in glass-forming supercooled liquids [8, 11] and were fixed across all GBs studied in this work.

All mobile pairs containing common atoms were then joined into larger string-like clusters, and each cluster was assigned a unique ID. Cluster statistics were then computed over all clusters, including the number of atoms and the gyration tensor. The string identification algorithm was repeated for a range of time intervals Δt with multiple start times. The average string length, measured by the average number of atoms in the string-like cluster, typically exhibits a single maximum as a function of Δt at a characteristic time $\Delta t = t_s^*$.

The analysis of diffusion avalanches required a more flexible definition of mobile clusters. The input to this method is the space-time trajectory consisting of atomic displacement fields computed at a fixed time interval (Δt) and stacked in time. Here, Δt is a hyper-parameter taken to be approximately $0.02t_s^*$. First, the string clustering step was performed in space-time with no upper bound on the displacement length and all other hyper-parameters as above. The absence of an upper bound allows the strings to incorporate atoms executing multiple jumps. Next, the string connectivity criterion was relaxed: neighboring strings were combined in space if at least two atoms in adjacent strings (either in time or space) were no more than $1.2r_0$ apart. This hyper-parameter can be interpreted as a cutoff distance for the interaction range in dynamic facilitation. It also provides a good visual segmentation of the data. If the cutoff distance is too large, or the trajectories in space-time are too dense, then all atoms are part of the same mobile cluster and the algorithm loses its meaning. In the space-time trajectories, the same atom can be included multiple times in the same mobile cluster if it executes multiple jumps. The mobile clusters often form elongated, anisotropic shapes in space-time. Their size was quantified as the

number of unique atoms in the cluster. The dynamic length scale of a given mobile cluster was quantified as its maximum width along a given direction in the GB plane, and its timescale as the maximum width along the time axis.

Immobile clusters are apparent in space-time diagrams as empty regions (“bubbles” [23]) separating the mobile clusters. In principle, their length and time scales can be computed in a similar manner as for the mobile clusters. However, in practice a single percolating immobile cluster in space-time is often found with this method. An alternative method used here defines and computes the immobility time by considering individual square ($l \times l$) GB patches in space. The immobility time in each patch is then computed as the time between mobility events. The immobility time scale is obtained in the limit of l approaching zero, while the immobility time distribution can be computed at $l = r_0$. The ratio of the immobility and mobility times can also serve as a measure of diffusion intermittency. Considered as a function of the patch size l , this ratio is used in the virtual size-effect tests as shown in Supplementary Fig. 2.

Data availability. The data supporting the findings of this study are available in the Supplementary Information file or from the corresponding authors upon reasonable request. The computer simulation part of this research used the publicly available codes LAMMPS and OVITO. The routine computer scripts controlling the execution of the calculations are not central to this work but are available from the corresponding authors upon reasonable request.

Table 1: Crystallography and 0 K energies (γ) of GBs studied in this work. The Cartesian x , y and z axes are aligned with edges of the rectangular simulation box. The GB plane is normal to the z -direction. For each GB, the two lines indicate crystallographic directions parallel to the Cartesian axes in the upper and lower grains. The GB energy was computed with the interatomic potential from Ref. [14].

GB description	Direction	E (eV)	D_0 (m ² /s)
$\Sigma 3$ $\langle 110 \rangle$ tilt 70.5°	tilt axis	1.31 ± 0.03	$(3.89 \pm 7.8) \times 10^{-3}$
	⊥ tilt axis	1.45 ± 0.03	$(1.17 \pm 2.24) \times 10^{-2}$
$\Sigma 17$ $\langle 100 \rangle$ tilt 61.9°	tilt axis	0.72 ± 0.01	$(5.53 \pm 1.59) \times 10^{-6}$
	⊥ tilt axis	0.81 ± 0.01	$(2.09 \pm 0.74) \times 10^{-5}$
Supercooled liquid		0.227 ± 0.001	$(9.69 \pm 0.24) \times 10^{-8}$
FCC crystal:			
Experiment [46]		1.32	1.79×10^{-5}
DFT calculations [20]		1.25–1.35	$5.42 \times 10^{-6} - 2.42 \times 10^{-5}$

Table 2: Activation energies (E) and prefactors (D_0) calculated in this work. The reference data for diffusion in FCC Al is taken from experiments [46] and first-principles density functional theory (DFT) calculations with several different DFT functionals [20].

Figure 1 Atomic structure and diffusion coefficients in the Al $\Sigma 3$ and $\Sigma 17$ GBs. Panels (a) and (b) show the optimized GB structures as viewed parallel (left column) and normal (right column) to the tilt axis. Atoms identified with perfect FCC coordination via common neighbor analysis are colored grey and all other atoms are colored red. (c) Arrhenius diagram of GB diffusion coefficients parallel (D_{\parallel}) and perpendicular (D_{\perp}) to the tilt axis. The vertical dashed line indicates the melting point predicted by the interatomic potential. Shown for comparison are the computed diffusivities in liquid Al and the experimental (dashed stripe) [46, 47] and computed (lower stripe) [20] literature data for self-diffusion in FCC Al.

Figure 2 Intermittent diffusion in the $\Sigma 3$ GB for a typical GB cross-section ($10 \text{ nm} \times 10 \text{ nm}$). (a) Example of atomic MSD as a function of time at 710 K ($0.77 T_m$). (b,c) Typical atomic displacement diagrams during the (b) avalanche and (c) locked time periods corresponding to the blue and red regions in (a). The arrows represent net displacements during time intervals of 1.2 ns and 3 ns and are colored by the displacement magnitude. Note the enhanced atomic mobility in the avalanche regime and only a few displaced atoms in the locked regime. (d) Typical collective diffusion event involving Frenkel pairs. The arrows represent string-like displacements during the time $\Delta t = 80 \text{ ps}$ colored in dark grey and light grey for displacements smaller and larger than the first-neighbor distance r_0 . (e) Peaks in the numbers of vacancies and interstitials correlate with the locked and avalanche time periods seen in (a). (f) Peaks in the number of mobile atoms also correlate with the locked and avalanche time periods. (g) Correlation between the point-defect population and the number of mobile atoms in the GB core with the correlation factor of $R^2 = 0.83$.

Figure 3 Size dependence of diffusion in the Al Σ 3 GB. (a) Atomic MSD versus time at the temperature of 700 K for the (10 nm \times 10 nm) and (30 nm \times 30 nm) GB cross-sections. Note that the diffusion intermittency disappears with increasing cross-section. (b) Size dependence of GB diffusivity for several different cross-sections with a fixed 13 nm size perpendicular to the tilt axis and a varied size from 6 nm to 38 nm along the tilt axis. The points represent independent MD runs with different velocity seeds. The red points represent the average values. (c) Locked-state probability (fraction of plateau portions in (a)) as a measure of intermittency plotted as a function of temperature. The error bars are obtained by using up to ten velocity seeds at each temperature. The sigmoidal fit is only meant to guide the eye. Note the suppression of intermittency with increasing temperature.

Figure 4 Space-time diagrams showing dynamic facilitation of GB diffusion. (a) Space-time atomic mobility diagram for the $\Sigma 3$ GB at 700 K computed with the time interval of $\Delta t = 40$ ps and viewed perpendicular to the tilt axis. The GB structure is shown on the left with light grey FCC atoms and dark grey non-FCC atoms. The immobile clusters are evident as voids (“bubbles”) [23] between the mobile atom trajectories. The arrows show examples of mobile and immobile cluster dimensions in time. (b) Cross section of the same diagram with all time data projected onto the GB plane. The rectangular box indicates the 6 nm scale of the GB structure shown in (a) relative to the GB area. (c) Probability distribution of lifetimes of mobile and immobile clusters. Note that immobile clusters persist on a longer time scale than mobile clusters. (d) Avalanche size distribution at 720 K as measured by the maximum avalanche size perpendicular and parallel to the tilt axis. The avalanches are elongated along the tilt axis and exhibit a cutoff behavior with large avalanches becoming increasingly unlikely with increasing size. Note that the cutoff size along the tilt axis is larger than 10 nm.

Figure 5 Intermittent diffusion behavior in the (a,b) $\Sigma 85$ $\{100\}$ low-angle twist Al GB at 500 K and (c,d) $\{100\} \parallel \{111\}$ HAIC Al GB at 700 K. The twist GB is composed of a square network of dislocations displayed in the top left corner of the MSD plot. Panels (b) and (d) are atomic displacement maps using the same color coding as in Fig. 2 and representing the avalanches shown as blue stripes in (a) and (c). In (b), the GB structure constrains the collective atomic displacements to the dislocation cores, resulting in string-like and ring-like trajectories.

SUPPLEMENTARY INFORMATION

Point-defect avalanches mediate grain boundary diffusion

Ian Chesser and Yuri Mishin

Figure 1 Mobile atoms in the $\Sigma 3$ Al GB core have a signature in the free volume distribution relative to immobile atoms. Most atoms in the GB core are in tension relative to the perfect crystal, but the mobile atoms exhibit larger compressive and tensile tails in the probability distribution relative to immobile atoms. This is consistent with string-like displacements having a compressive head with interstitial character and a tensile tail with vacancy character. The example distribution is shown for 710 K but is generic to all temperatures surveyed up to 750 K.

Figure 2 Average avalanche size as a function of temperature for the $\Sigma 3$ and $\Sigma 17$ Al GBs. The avalanche size was extracted from the virtual system-size analysis by selecting $(l \times l)$ GB patches and measuring the ratio of time spent in locked (immobile) versus avalanche-like (mobile) states in the space-time trajectories. The average avalanche size is defined as one corresponding to $t_{\text{immobile}}/t_{\text{mobile}} = 1$, i.e., when the avalanches and locked states occur with equal probability. The plots demonstrate the decrease in the avalanche size with temperature.

Figure 3 (a) Arrhenius diagram of GB diffusion in the $\Sigma 3$ and $\Sigma 17$ Al GBs computed with three interatomic potentials: Al-M [14] (blue), Al-99 [24] (black), and Al-PINN [25] (red). The system size is (10 nm \times 10 nm). Due to the slow computational speed, the Al-PINN calculations only cover a limited temperature range for the $\Sigma 17$ GB and only one temperature ($0.9 T_m$) for the $\Sigma 3$ GB. To save computational time, the GB structures were first equilibrated with the Al-M potential before switching the atomic interactions to the Al-PINN with an adjustment of atomic coordinates according to the Al-PINN thermal expansion. (b) Example of atomic MSD as a function of time at $T = 0.82 T_m$ (point marked by arrow in (a)) computed with the Al-99 potential for two different GB cross-sections. Note the intermittent behavior for the smaller cross-section and its disappearance for the larger cross-section.

GB description	x	y	z	γ (mJ/m ²)
FCC Ni, $\Sigma 3$ $\langle 110 \rangle$ tilt 70.5°	$[-1, 1, 1]$ $[1, -1, -1]$	$[0, 1, -1]$ $[0, -1, 1]$	$[2, 1, 1]$ $[2, 1, 1]$	879
BCC Fe, $\Sigma 17$ $\langle 100 \rangle$ tilt 61.9°	$[5, -3, 0]$ $[-5, 3, 0]$ $[1, 1, -2]$	$[0, 0, -1]$ $[0, 0, 1]$ $[1, -1, 0]$	$[3, 5, 0]$ $[3, 5, 0]$ $[1, 1, 1]$	1096

Table 1: Crystallography and 0 K energies (γ) of the FCC Ni and BCC Fe GBs studied in this work. The Cartesian x , y and z axes are aligned with edges of the rectangular simulation box. The GB plane is normal to the z -direction. For each GB, the two lines indicate crystallographic directions parallel to the Cartesian axes in the upper and lower grains. The GBs were simulated with the EAM interatomic potentials for FCC Ni [48] and BCC Fe [49]. The initial optimized GB structures were taken from the GB structure databases in [50] and [51].

Figure 4 Size dependent intermittent diffusion behavior in the (a,b) $\Sigma 3$ $\langle 110 \rangle$ tilt 70.5° GB in FCC Ni at 1200 K ($0.77 T_m$) and (c,d) the $\Sigma 17$ $\langle 100 \rangle$ tilt 61.9° in BCC Fe at 1050 K ($0.59 T_m$). Panels (b) and (d) show atomic displacement maps using the same color coding as in Fig. 2 of the main text and demonstrating the avalanches occurring in the blue highlighted regions in (a) and (c).
