(Dated: June 30, 2022)

Transition amplitudes and transition probabilities are relevant to many areas of physics simulation, including the calculation of response properties and correlation functions. These quantities are also closely related to solving linear systems of equations in quantum linear algebra. Here we present three related algorithms for calculating transition probabilities with respect to arbitrary operators and states. First, we extend a previously published short-depth algorithm, allowing for the two input quantum states to be non-orthogonal. The extension comes at the cost of one ancilla qubit and at most only a constant four additional two-qubit gates. Building on this first procedure, we then derive a higher-depth approach based on Trotterization and Richardson extrapolation that requires fewer circuit evaluations. Third, we introduce a tunable approach that in effect interpolates between the low-depth method and the method of fewer circuit evaluations. This tunability between circuit depth and measurement complexity allows the algorithm to be tailored to specific hardware characteristics. Finally, we implement proof-of-principle numerics for toy models in physics and chemistry and for use a subroutine in variational quantum linear solving (VQLS). The primary benefits of our approaches are that (a) arbitrary non-orthogonal states may now be used with negligible increases in quantum resources, (b) we entirely avoid subroutines such as the Hadamard test that may require three-qubit gates to be decomposed, and (c) in some cases fewer quantum circuit evaluations are required as compared to the previous state-of-the-art in NISQ algorithms for transition probabilities.

I. INTRODUCTION

If breakthroughs in hardware design continue, quantum computers will be able to simulate quantum systems that are classically intractable, including those from condensed matter physics [1], nuclear structure [2], high-energy physics [3], and chemistry and materials [4, 5]. As theoretical and algorithmic work progresses, it is imperative to continue improving quantum computational primitives and subroutines so that calculations can be available on the earliest possible hardware.

One important subroutine is the calculation of transition amplitudes and probabilities, quantities closely related to the Fermi golden rule, response functions, and correlation functions more generally. These are required for calculating intensities in various areas of spectroscopy [6–11] and for response functions in scattering experiments and condensed matter [12–15]. Additionally, as vector-matrix-vector products $\vec{a}^t \mathbf{A} \vec{b}$ (or $\vec{a}^t \mathbf{A} \vec{a}$) are often relevant to classical linear algebra problems, transition probability subroutines may be useful in quantum linear algebra [16–21], including for classical partial differential equations [22–24], finance [25, 26], and quantum machine learning [27–29].

In this work we introduce three algorithms for calculating transition probabilities. We refer to our algo-

rithm framework as NOTraP, for non-orthogonal transition probabilities.

First, we show how to extend an existing short-depth quantum subroutine to allow for non-orthogonal states, at resource costs of just one additional qubit and at most four additional two-qubit gates. This short-depth algorithm (NOTraP-SD) allows for a broader class of states and applications. As with previous related methods [10], an important feature is that controlled unitaries (meaning known state preparation unitaries and unitaries for Pauli string exponentials) are not required for any algorithms in this work.

Second, we demonstrate a higher-depth method (NOTraP-HD) that greatly reduces the number of distinct quantum circuits that must be simulated. Third, we show how one may tune (NOTraP-T) between low circuit depths and a low number of distinct quantum circuits. This allows one to tailor the algorithm to a given set of hardware. For example, if one is given access to a quantum computer allowing for larger maximum circuit depth than before, one may modify the algorithm to use deeper circuits with the trade-off of having fewer circuit evaluations.

There are many problems for which states $|a\rangle$ and $|b\rangle$ are non-orthogonal, for example the calculation of Franck-Condon factors in molecules [6, 7], arbitrary correlation functions in condensed matter systems, or comparing two states in classical linear algebra. Other than this expansion of the types of states that may be used as input, the algorithms of this work still also provide the

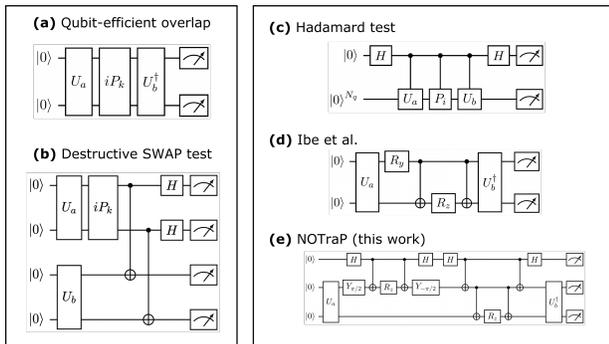

FIG. 1. Left panel: Circuits for calculating quantities $|\langle a|P_k|b\rangle|^2$ with respect to a single Pauli string P_k . (a) Qubit-efficient overlap circuit, given state preparation unitaries $U_a|0\rangle = |a\rangle$ and $U_b|0\rangle = |b\rangle$. (b) Use of the shorter-depth destructive SWAP test [32], requiring twice the qubits. Right panel: Circuits indirectly used in determining cross-terms between Pauli strings, using different methods. For illustrative purposes the bottom two circuits implement the cross-terms in operators $A = k_1 Y_1 + k_2 Z_1 Z_2$ and $\hat{A} = k_1 X_0 Y_1 + k_2 X_0 Z_1 Z_2$. (c) The Hadamard test for determining $\Re\langle a|P_i|b\rangle$; a similar circuit yields $\Im\langle a|P_i|b\rangle$ [33, 34]. Because the Hadamard test retains phase information, cross-terms $\langle a|P_i|b\rangle\langle b|P_j|a\rangle$ and $\langle b|P_j|a\rangle$. This circuit uses controlled state preparation unitaries, and therefore is considerably deeper if gate decomposition to one- and two-qubit gates is required. (d) Circuits used by Ibe *et al.* [10] to calculate terms W_2 , W_3 , and W_4 of equation (5). This method requires that $|a\rangle$ and $|b\rangle$ be orthogonal. (e) Circuits for implementing NoTraP-SD, after transforming $\{A, |a\rangle, |b\rangle\} \rightarrow \{\hat{A}, |\hat{a}\rangle, |\hat{b}\rangle\}$ via equations (20) and (21). Importantly, NoTraP allows for transition probabilities to be calculated (i) for arbitrary non-orthogonal states $|a\rangle$ and $|b\rangle$, and (ii) without controlled state preparation unitaries nor controlled Pauli rotations.

benefits of tunable circuit depths and general applicability to linear algebra.

This work should be considered in the context of recent efforts to derive algorithms that eliminate the use of controlled-unitary circuits [10, 16, 30, 31], especially the Hadamard test. Since the native gate set of many quantum computers will consist solely of one- and two-qubit gates, such controlled state preparations require many three-qubit gates to be decomposed into simpler gates. Controlled state preparation unitaries thus would have lead to circuits several times deeper, making algorithms with many (decomposed) three-qubit gates prohibitive on most near-term quantum hardware.

II. THEORY

The quantity of interest is the transition probability

$$|\langle a|A|b\rangle|^2 \quad (1)$$

Method	3-qubit gates?	Works if $\langle a b\rangle \neq 0$	Tunable depth & meas?
Hadamard test [15, 33]	Yes	Yes	No

TABLE II. Circuit depths and distinct quantum circuit evaluations for calculating transition probabilities with respect to A_{loc} and A_{nonloc} . The asterisk (*) denotes methods that require three-qubit gates and hence longer depths upon decomposition. While this table does not consider depth for the state preparation unitaries of $|a\rangle$ and $|b\rangle$, we stress that the Hadamard test is the only method in the table that requires controlled versions of the state preparation circuits for $|a\rangle$ and $|b\rangle$, greatly increasing the overall circuit depth on most current hardware. cPR signifies that Pauli rotations are controlled while state preparation unitaries are not, for example in one formulation of VQLS [16].

where $|a\rangle$ and $|b\rangle$ are arbitrary states and A is a Hermitian operator that may be expressed as

$$A = \sum_k^{N_P} g_k P_k \quad (2)$$

where g_k is a real constant, P_k is a Pauli string $P_k \in \{I, X, Y, Z\}^{\otimes n_q}$, N_P is the number of Pauli strings in the decomposition, n_q is the number of qubits, I is the identity and $\{X, Y, Z\}$ are the Pauli matrices. As previously mentioned, A may come from a quantum problem (such as chemistry) or may be the quantum representation of a matrix from a classical problem. In the latter case, the goal may be to determine formula (1) in order to solve a linear system variationally [16, 18–21].

In order to study scaling behavior of local and nonlocal operators, we will consider the following two simple operators. On n_q qubits, they are the operators

$$A_{loc} = \sum_{i=0}^{n_q-1} X_i \quad (3)$$

and

$$\begin{aligned}
A_{nonloc} &= \sum_{i=0}^{n_q-1} X^{\otimes n_q} X_i \\
&= \sum_{i=0}^{n_q-1} X^{\otimes i} I_i X^{\otimes n_q-i-1}
\end{aligned} \tag{4}$$

where X_i is the Pauli-X operator on qubit i , I is the identity, and n_q is the number of qubits. Considering these two operators will allow us to study some general trends in scaling, including circuit depths and number of distinct circuit evaluations.

A. Previous methods

This subsection reviews the following previously reported methods for transition probabilities: the use of the Hadamard test [15, 33] to determine each individual cross-term between Pauli strings of (2), a related approach that does not require controlled unitaries but does require controlled Pauli rotations [16], and the method of Ibe *et al.* [10] that (assuming state orthogonality) eliminated the need for the Hadamard test in this context. We focus primarily on the latter method as it is similar in spirit to the approach of this work. Circuits for each method are shown in Figure 1.

We begin by summarizing how to use the more expensive Hadamard test. We define unitaries $U_a|0\rangle = |a\rangle$ and $U_b|0\rangle = |b\rangle$, where $|0\rangle$ is some reference state. Established near-term algorithms exist for determining these circuit unitaries for states of interest [35–42]. In this work we assume that these state preparation unitaries are already known.

An obstacle in calculating quantity $|\langle a|A|b\rangle|^2$ is that A is Hermitian but not unitary, meaning it cannot be trivially implemented with a unitary quantum circuit (though the longer-depth linear combination of unitaries approach may be used [43]). However, each individual unitary P_k may be implemented up to global phase with a simple circuit [44]. Furthermore, an expansion of equation (1) reveals cross-terms such as $g_i g_j \langle a|P_i|b\rangle \langle b|P_j|a\rangle$, for which a naive implementation would use the Hadamard test [30, 33, 34].

Using the Hadamard test one may determine $\langle a|P_i|b\rangle$ by using a controlled state preparation unitary cU , where the unitary to be controlled is $U = U_a^\dagger P_i U_b$. Even though this arguably could be classified as a near-term method, its depth requirements are much larger than the original unitary. Assuming the original unitary was composed only of one- and two-qubit gates, these respectively become two- and three-qubit gates, which in turn have costly decompositions into smaller gates. Hence a major purpose of previous studies [10, 31] and of the current work is to circumvent the Hadamard test.

In variational quantum linear solving (VQLS) [16], as originally proposed, an ancilla control qubit *is* used for

the P_k operators while the state preparation unitaries are implemented directly without control qubits. Hence the original formulation of VQLS does still require the high-depth decomposition of three-qubit gates, albeit fewer than in the case of the Hadamard test.

A notable breakthrough was recently introduced by Ibe *et al.* [10]. Without needing any ancilla control qubits, their method uses measurements from many distinct circuits, before taking a weighted sum of each result to arrive at the desired quantity. We summarize their method here using slightly modified notation.

The algorithm of Ibe *et al.* begins by calculating the following quantities on a quantum computer, each of which is in the form $|\langle a|V_i|b\rangle|^2$ where V_i is a different unitary. We define quantities

$$\begin{aligned}
W_1^{(k)} &= |\langle a|P_k|b\rangle|^2 \\
W_2^{(kl)} &= |\langle a|\frac{1}{2}(I + iP_k)(I + iP_l)|b\rangle|^2 \\
W_3^{(kl)} &= |\langle a|\frac{1}{2}(I - iP_k)(I - iP_l)|b\rangle|^2 \\
W_4^{(kl)} &= |\langle a|P_k P_l|b\rangle|^2,
\end{aligned} \tag{5}$$

each of which is a variable between 0 and 1.

Unitaries involving P_k and P_l may be implemented using known circuits for exponentiating a single Pauli string [44], while the states themselves are prepared using U_a and U_b . Calculating the overlaps squared is possible using the SWAP test [45] or destructive SWAP test [32] between states $U_a|0\rangle$ and $VU_b|0\rangle$, or by implementing $U_a^\dagger VU_b$ before determining the frequency of measured state $|0\rangle^{\otimes n_q}$ [46], as shown in see Figure 1(a) and (b). The former methods require $2n_q$ qubits and the latter requires n_q qubits and at most a doubling of circuit depth.

The transition probability may then be reconstructed as

$$\begin{aligned}
|\langle a|A|b\rangle|^2 &= \sum_k g_k^2 W_1^{(k)} \\
&+ \sum_k \sum_{l < k} g_k g_l [2W_2^{(kl)} + 2W_3^{(kl)} - W_1^{(k)} - W_1^{(l)} - W_4^{(kl)}]
\end{aligned} \tag{6}$$

or equivalently

$$\begin{aligned}
|\langle a|A|b\rangle|^2 &= \\
&\sum_k (2g_k^2 - \sum_{l < k} g_k g_l) W_1^{(k)} \\
&+ \sum_k \sum_{l < k} g_k g_l (2W_2^{(kl)} + 2W_3^{(kl)} - W_4^{(kl)})
\end{aligned} \tag{7}$$

where the equality holds only if $\langle a|b\rangle = 0$, though below we propose a method usable for non-orthogonal states. The number of distinct circuits is $(3N_P^2 - N_P)/2$. The number of measurements required for determining each of formulas (5) is $\mathcal{O}(1/\epsilon_i^2)$, where ϵ_i is the required

precision for each circuit; a full analysis of measurement counts is slightly more involved and is derived in the next subsection.

Throughout this work we assume the available gate-set is CNOT and all arbitrary one-qubit unitaries. The depths will change if a different native gate set is assumed. The maximum depth (excluding the state preparation circuits) for the Ibe *et al.* circuit is

$$D^{\text{Ibe}} = 5 + 4(k - 1) = 4k + 1 \quad (8)$$

where k is the longest Pauli string length in the Hamiltonian. This upper bound comes from having a circuit $e^{-i\frac{\pi}{4}P_k}e^{-i\frac{\pi}{4}P_l}$, which in the worst case operate on the same set of qubits. This leads to 4 CNOT-ladders each with $k - 1$ CNOT gates, two $R_z(\frac{\pi}{4})$ rotations, and 4 layers of basis changes of which the middle two layers may be combine into one layer of single qubit gates. This in turn yields $D^{\text{Ibe}}[A_{\text{nonloc}}] = 4n_q$ and $D^{\text{Ibe}}[A_{\text{loc}}] = 8$.

For the circuits of the original VQLS formalism [16], based on controlled Pauli rotations (cPR), we consider controlled versions of the circuits of the previous paragraph, which leads to deeper circuits after decomposition. In this case we have the previous CNOT gates replaced with Toffoli gates, the $R_z(\frac{\pi}{4})$ gates replaced with controlled- R_z , and the depth-1 layer of basis change replaced by a depth- k layer of controlled rotations. The maximum depth for VQLS is

$$D^{\text{VQLS}} = 4(k - 1)(11) + 4k(4) \quad (9)$$

where we use $D_{\text{Toff}} = 11$ for the depth required to decompose a Toffoli (controlled CNOT) gate and $D_{\text{cR}} = 4$ for depth of a decomposed arbitrary controlled one-qubit rotation [47]. This leads to $D^{\text{VQLS}}[A_{\text{nonloc}}] = 60n_q - 104$ and (performing additional gate cancellations via inspection) $D^{\text{VQLS}}[A_{\text{loc}}] = 8$.

B. Measurement counts for previously published methods

To our knowledge, a resource analysis for required measurement counts has not been performed for the previously published methods. Here we perform such an analysis for Ibe *et al.* and for the cPR formalism.

We begin with an analysis of Ibe *et al.* The number of measurements required for the full calculation of $Q = |\langle a|A|b \rangle|^2$ is dependent on the coefficients in equation (7). There are N_W circuits from which measurements need to be extracted, hence N_W independent variables. Re-indexing all random variables W with i , if the goal is an upper additive error bound of ε_Q , then via standard error propagation we have

$$\varepsilon_Q^2 = \sum_i^{N_W} \left| \frac{\partial Q}{\partial W_i} \right|^2 \varepsilon_i^2. \quad (10)$$

Note that ε_Q has the same units as A^2 , while ε_i is dimensionless as it is simply the error in W_i . Assigning

each summed term to have the same uncertainty leads to

$$\left| \frac{\partial Q}{\partial W_i} \right|^2 \varepsilon_i^2 = \varepsilon_Q^2 / N_W \quad (11)$$

which in turn yields measurement counts of each term as

$$n_i = \frac{1}{\varepsilon_i^2} = \frac{N_W \left| \frac{\partial Q}{\partial W_i} \right|^2}{\varepsilon_Q^2} \quad (12)$$

and total measurements

$$n_{\text{tot}} = \sum_i n_i \quad (13)$$

where

$$N_W = N_P + \frac{3}{2}(N_P - 1)N_P \quad (14)$$

Using equation (7) the general result for arbitrary operator $A = \sum_k g_k P_k$ is

$$n_{\text{tot}} = \frac{N_W}{\varepsilon_Q^2} \left(\sum_k \left(2g_k^2 - \sum_{l < k} g_k g_l \right)^2 + \sum_k \sum_{l < k} (9g_k^2 g_l^2) \right). \quad (15)$$

It is instructive to consider the number of measurements for A_{loc} and A_{nonloc} , in order to obtain an understanding of basic scaling. As all g_k equal unity for these two operators, the measurement counts are

$$\begin{aligned} n_{\text{tot}}[A_{\text{loc}}, A_{\text{nonloc}}] &= \\ \frac{N_W}{\varepsilon_Q^2} \left(\frac{1}{6} N_P (2N_P^2 - 15N_P + 37) + \frac{9}{2} N_P (N_P - 1) \right) & \quad (16) \\ &= \mathcal{O}(N_P^5 / \varepsilon_Q^2) = \mathcal{O}(n_q^5 / \varepsilon_Q^2) \end{aligned}$$

where we have used $N_W = \mathcal{O}(N_P^2)$ from equation (14). The perhaps unexpected fifth-order scaling is a result of the first sum of equations (7) and (16) having a cubic scaling in N_P .

In this work we concern ourselves primarily with relative error $\eta = \frac{\varepsilon}{Q}$. Because $|\langle a|A|b \rangle|^2 = \|A\|^2 \frac{|\langle a|A|b \rangle|^2}{\|A\|^2}$, an order of magnitude estimate for the relative error $\frac{|\langle a|A|b \rangle|^2}{\|A\|^2}$ is $\frac{\varepsilon}{\|A\|^2}$. As $\|A_{\text{loc}}\|^2$ and $\|A_{\text{nonloc}}\|^2$ scale as $\mathcal{O}(n_q^2)$, with respect to relative error the total number of measurements scales as $\mathcal{O}(n_q^3 / \eta_Q^2)$.

Now we do a measurement resource analysis for VQLS, for which the VQLS objective function is optimized when the correct solution $|x\rangle$ to system of linear equations $A|x\rangle = |b\rangle$ is found. Though (unlike the Hadamard test) this approach does not require controlled state preparation unitaries, it does require controlled exponentiated Pauli strings.

Because cross-terms are calculated explicitly, the individual terms are

$$\sum_k g_k^2 [|\langle a|P_k|b\rangle|^2] + \sum_k \sum_{l < k} g_k g_l 2\Re[\langle a|P_l|b\rangle \langle b|P_k|a\rangle] \quad (17)$$

where each term in square brackets is a distinct circuit. The number of circuits is thus $N_W = N_P + (N_P - 1)N_P/2$ and the measurement count is

$$n_{tot}^{VQLS} = N_W \varepsilon_Q^{-2} \left[\sum_k g_k^4 + \sum_k \sum_{l < k} 2g_k^2 g_l^2 \right] \quad (18)$$

which in turn leads to

$$\begin{aligned} n_{tot}^{VQLS}[A_{loc}, A_{nonloc}] &= N_W \varepsilon_Q^{-2} [N_P + (N_P - 1)N_P] \\ &= N_W \varepsilon_Q^{-2} [N_P + (N_P - 1)N_P] \\ &= \mathcal{O}(N_P^4) = \mathcal{O}(n_q^4), \end{aligned} \quad (19)$$

corresponding to approximately $\mathcal{O}(n_q^2/\eta_Q^2)$ measurements. Hence using the VQLS method for direct overlaps leads to superior measurement scaling to Ibe *et al.*, though at the cost of using three-qubit gates that are expensive to decompose on some hardware.

III. NON-ORTHOGONAL STATES, EXTRAPOLATION, AND DEPTH TUNING

In this section we introduce three new tools for calculating transition probabilities. First we extend a previous method to allow for calculating transition probabilities between *non-orthogonal* states, while still avoiding any gates higher than 2-qubit gates. We expect this method to be useful both for calculating transition probabilities between arbitrary quantum states and for more efficiently running VQLS. Second we show how to use exponentiation and extrapolation to greatly reduce the number of measurements required, at the cost of an increase in circuit depth. Finally, we demonstrate how one may tune between higher-depth and higher-measurement, in order to use as much of the limited (due to *e.g.* noise) available circuit depth as possible when calculating transition probabilities. Tables I and II show a comparison of the capabilities of our method compared to previous work.

A. Implementing non-orthogonal states (NOTraP-SD)

Our first algorithmic contribution is a simple modification to the states and to the operator A ; after this modification, any procedure that would have required orthogonal input states can be used on the modified states.

First, one adds a single ancilla qubit to the state space, with opposite bit values for each state of interest,

$$\begin{aligned} |a\rangle &\rightarrow |0\rangle_a \otimes |a\rangle_s \equiv |\acute{a}\rangle \\ |b\rangle &\rightarrow |1\rangle_a \otimes |b\rangle_s \equiv |\grave{b}\rangle \end{aligned} \quad (20)$$

Next one modifies the operator A , multiplying it by a bit-flip operator acting on the new qubit:

$$A \rightarrow X_a \otimes A_s \equiv \acute{A}. \quad (21)$$

The result is that, even if an algorithm for formula (1) requires that the two input states be orthogonal, one may use these new constructs ($|\acute{a}\rangle, |\grave{b}\rangle$, and \acute{A}) to calculate the originally desired quantity $|\langle a|A|b\rangle|^2$. This is proven in the following two lemmas.

Lemma 1. $\langle \acute{a}|\grave{b}\rangle = 0$.

Proof.

$$\begin{aligned} \langle \acute{a}|\grave{b}\rangle &= \langle 0|1\rangle \langle a|b\rangle \\ &= 0 \end{aligned} \quad (22)$$

□

Lemma 2. $\langle a|A|b\rangle = \langle \acute{a}|\acute{A}|\grave{b}\rangle$.

Proof.

$$\begin{aligned} \langle \acute{a}|\acute{A}|\grave{b}\rangle &= \langle 0|\langle a|(X \otimes A)|1\rangle|b\rangle \\ &= \langle 0|X|1\rangle \langle a|A|b\rangle \\ &= \langle a|A|b\rangle \end{aligned} \quad (23)$$

□

This simple extension allows the exact transition probabilities for any two states to be calculated using the previously introduced [10] formula (6), which would otherwise produce the incorrect results if the two input states are non-orthogonal. The additional cost is one extra qubit, as well as *at most* a circuit depth increase of four two-qubit entangling gates (sometimes just 2) and two one-qubit gates; note that adjacent Hadamard gates cancel in Figure 1(e). Thus we still avoid the long depths required of the Hadamard test, but calculate the exact desired quantity. Allowing for non-orthogonal states is important for practical applications, with examples including variational linear systems solvers as well as simulating vibronic spectra. This orthogonalization procedure is also necessary for the subsequent methods in this work.

B. Exponentiation method (NOTraP-HD)

Here we develop another algorithm for calculating transition probabilities, with the goal of reducing the required measurement counts at the cost of an increased circuit depth. The method is based on exponentiating the operator \hat{A} and using Richardson extrapolation. (Extrapolation has been to improve efficiency in quantum linear algebra [48], though this previous algorithm is more amenable to longer-term hardware and is not similar to our approach.) We begin by writing the Taylor expansion

$$e^{-i\tau\hat{A}} = \mathcal{I} - i\tau\hat{A} - \frac{1}{2}\tau^2\hat{A}^2 + \dots \quad (24)$$

We first require the determination of $|\langle \hat{a} | \exp(-i\tau\hat{A}) | \hat{b} \rangle|^2$ for multiple τ . This quantity can be determined by the frequency of all- $|0\rangle$ measurements from implementing the circuit for $U_b^\dagger \exp(-i\tau\hat{A}) U_a | \mathbf{0} \rangle$. One may alternatively use the destructive SWAP test on states $\exp(-i\tau\hat{A}) U_a | \mathbf{0} \rangle$ and $U_b | \mathbf{0} \rangle$, which lowers the depth while doubling the number of qubits (see Figure 1).

The algorithm proceeds by determining the following function for at least two values of τ , before using Richardson extrapolation [49, 50] to determine $|\langle a | A | b \rangle|^2$. The function is

$$f(\tau) = |\langle \hat{a} | e^{-i\tau\hat{A}} | \hat{b} \rangle|^2 + |\langle \hat{a} | e^{+i\tau\hat{A}} | \hat{b} \rangle|^2 \quad (25)$$

$$= 2\tau^2 |\langle a | A | b \rangle|^2 + \tau^4 K_4 + \tau^6 K_6 + \mathcal{O}(\tau^8)$$

where many terms are combined into constants K_n . We note two key insights here. First, the quadratic term's coefficient is proportional to $|\langle a | A | b \rangle|^2$ only because of the transformations (20) and (21); otherwise the quadratic term would have been contaminated with a term $\tau^2 \langle b | A^2 | a \rangle \langle a | b \rangle$. Hence the orthogonalization procedure is strictly necessary for this extrapolation-based algorithm. Second, the cancellation of all odd orders of τ in (25) is due to the summing of results from $+\tau$ and $-\tau$.

An important consideration is the choice of τ values for the extrapolation. A smaller τ leads to a lower error for a given number of extrapolation points, but to a larger total number of required measurements. We leave an in-depth analysis of τ -dependent measurement counts for future work.

As we show presently, it is fortunately not necessary to exactly implement the exponential in order to obtain the transition probability. This is important, as on near-term hardware the exact implementation of $e^{-i\tau\hat{A}}$ will often not be possible. Instead, Suzuki-Trotter decompositions may be used. The approximate exponential is then $\tilde{U}(\tau) \approx \exp(-i\tau\hat{A}) = U(\tau)$. The key is that an n th-order Suzuki-Trotter decomposition yields an error of $\|U(\tau) - \tilde{U}(\tau)\| = \mathcal{O}(\tau^{n+1})$ [51], implying that a simple 1st-order decomposition yields $\tilde{U}(\tau) = 1 - i\tau\hat{A} + \mathcal{O}(\tau^2)$.

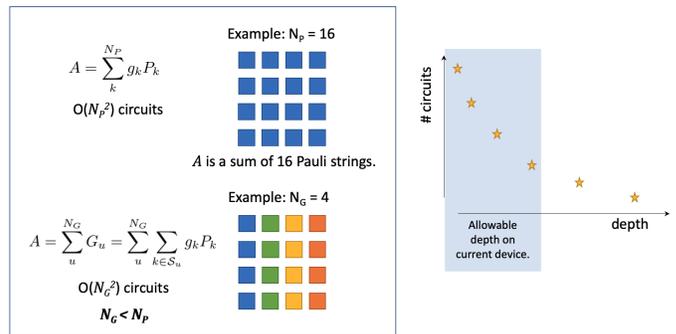

FIG. 2. Schematic of the tunable NOTraP-T algorithm.

Under such a first-order approximation, the resulting extrapolation function takes the form

$$\tilde{f}(\tau) = |\langle \hat{a} | \tilde{U}(\tau) | \hat{b} \rangle|^2 + |\langle \hat{a} | \tilde{U}(-\tau) | \hat{b} \rangle|^2 \quad (26)$$

$$= 2\tau^2 |\langle a | A | b \rangle|^2 + \tau^4 \tilde{K}_4 + \mathcal{O}(\tau^6) + \dots$$

where the leading term is the same as before. Fortunately, all of this implies that there is no immediately obvious reason to think an exact implementation of $\exp(-i\tau A)$ is more useful than a 1st-order Suzuki-Trotter approximation.

C. Tuning between low depth and few circuit evaluations (NOTraP-T)

Different near- and medium-term quantum hardware will have different characteristics—and whatever hardware one uses, one generally would like to take advantage of as much of the circuit depth as possible. This suggests the need for algorithms whereby the circuit depth may be tuned over a wide range, at the cost of another resource like (in this case) total circuit evaluations (see Figure 2).

One of the above methods (NOTraP-SD) uses shorter-depth circuits to implement transition probabilities, while the other (NOTraP-HD) requires deeper circuits but fewer measurements. In this section we introduce a method by which one may interpolate between the short-depth NOTraP-SD and the high-depth NOTraP-HD, which allows for a more fine-tuned trade-off between depth and total circuit evaluations.

Expressing A as a linear combination of N_P Pauli strings, the idea is to first group A into N_G terms instead, with $N_G < N_P$. Write down

$$A = \sum_u^{N_G} G_u = \sum_u^{N_G} \sum_{k \in \mathcal{S}_u} g_k P_k \quad (27)$$

where each G_u is a linear combination of Pauli strings, $\mathcal{S}_u \subset \{0, \dots, N_P - 1\}$, $\bigcup_u \mathcal{S}_u = \{0, \dots, N_P - 1\}$, and $\sum_u |\mathcal{S}_u| = N_P$.

One may choose any arbitrary decomposition for equation (27); there is no requirement, for example, that

members of the set commute. It may appear as though one would want the members of every $\{g_k | k \in \mathcal{S}_u\}$ to commute, as that would allow one to exactly implement $\exp(G_u)$ via first-order Trotterization. However, because it is only fourth-order (τ^4) terms and above that are affected by first-order Trotter error (see Section III B), there is no immediately obvious advantage to having Pauli strings commute. The total number of distinct circuits to run and measure is then reduced to $\mathcal{O}(N_G^2)$, from the previous $\mathcal{O}(N_P^2)$.

Though distinct, our route to the derivation is somewhat inspired by formulas (5) and (6). Define the terms

$$S_+^{(u)} = |\langle \hat{a} | e^{-i\tau \dot{G}_u} | \hat{b} \rangle|^2, \quad (28)$$

$$S_-^{(u)} = |\langle \hat{a} | e^{+i\tau \dot{G}_u} | \hat{b} \rangle|^2, \quad (29)$$

$$\begin{aligned} S_-^{(uv)} &= |\langle \hat{a} | e^{-i\tau \dot{G}_u} e^{-i\tau \dot{G}_v} | \hat{b} \rangle|^2 \\ &= |\langle \hat{a} | [1 - i\tau \dot{G}_u + \mathcal{O}(\tau^2)] [1 - i\tau \dot{G}_v + \mathcal{O}(\tau^2)] | \hat{b} \rangle|^2, \end{aligned} \quad (30)$$

$$\begin{aligned} S_+^{(uv)} &= |\langle \hat{a} | e^{+i\tau \dot{G}_u} e^{+i\tau \dot{G}_v} | \hat{b} \rangle|^2 \\ &= |\langle \hat{a} | [1 + i\tau \dot{G}_u + \mathcal{O}(\tau^2)] [1 + i\tau \dot{G}_v + \mathcal{O}(\tau^2)] | \hat{b} \rangle|^2. \end{aligned} \quad (31)$$

For a single G_u ,

$$S_+^{(u)} + S_-^{(u)} = 2\tau^2 |\langle a | G_u | b \rangle|^2 + \mathcal{O}(\tau^4). \quad (32)$$

It is instructive to first consider the case of $N_G = 2$. We write

$$\begin{aligned} S_+^{(uv)} + S_-^{(uv)} &= 4\tau^2 \Re \langle a | G_u | b \rangle \langle b | G_v | a \rangle \\ &+ 2\tau^2 |\langle a | G_u | b \rangle|^2 \\ &+ 2\tau^2 |\langle a | G_v | b \rangle|^2 + \mathcal{O}(\tau^4) \end{aligned} \quad (33)$$

which upon rearrangement (when $N_G = 2$) yields $|\langle a | A | b \rangle|^2 = \frac{1}{2\tau^2} (S_+^{(uv)} + S_-^{(uv)}) + \mathcal{O}(\tau^4)$.

Turning to the general case of $N_G \geq 2$, it can be shown that

$$\begin{aligned} |\langle a | A | b \rangle|^2 &= \\ &\sum_u^{N_G} (S_+^{(u)} + S_-^{(u)}) / 2\tau^2 + \sum_u^{N_G} \sum_{v < u} [S_+^{(uv)} + S_-^{(uv)} \\ &- S_+^{(u)} - S_+^{(v)} - S_-^{(u)} - S_-^{(v)} +] / 2\tau^2 + \mathcal{O}(\tau^4) / \tau^2 \end{aligned} \quad (34)$$

or

$$\begin{aligned} |\langle a | A | b \rangle|^2 &= |\langle a | \sum_u G_u | b \rangle|^2 \\ &= \sum_u^{N_G} \sum_{u < v} (S_+^{(uv)} + S_-^{(uv)}) / 2\tau^2 \\ &- \sum_u (N_G - 2) (S_+^{(u)} + S_-^{(u)}) / 2\tau^2 \\ &+ \mathcal{O}(\tau^2). \end{aligned} \quad (35)$$

This method (NOTraP-T) is tunable via changing the number of subsets N_G . As before, the orthogonalization procedure of Lemmas 1 and 2 is strictly necessary for the above expressions to yield the correct result. Note that the main mathematical way in which NOTraP-T differs from NOTraP-SD is that the former formulas do not explicitly use coefficients of the Pauli matrices. This difference is what leads to the $\frac{1}{2\tau^2}$ factor.

Finally, the algorithm proceeds by evaluating formula (35) for multiple values of τ and then extrapolating. We leave an analysis of the error to future work, as our primary goal in this work is to introduce the three NOTraP algorithms.

There are N_G circuits each for types $S_+^{(u)}$ and $S_-^{(u)}$, and $\frac{1}{2}(N_G^2 - N_G)/2$ circuits each for types $S_+^{(uv)}$ and $S_-^{(uv)}$. Hence the number of circuits required to estimate the transition probability is $n_\tau(N_G^2 + N_G)$ where n_τ is the number of points used in the extrapolations. As mentioned in the previous section, the relationship between choice of τ and the overall total number of measurements is nontrivial, and we leave a detailed analysis of this relationship to future work.

In this section we have provided an algorithm with tunable circuit depth, where the availability of more circuit depth allows one to evaluate expectation values from fewer circuits. The tunability comes in the choice of the number of groups N_G in which to place the Pauli terms of operator A . This approach is conceptually a mix between the low-depth method of Section III A and the high-depth method of Section III B, allowing the user to make use of any circuit depth available on a particular quantum device.

IV. APPLICATIONS AND NUMERICAL SIMULATIONS

Here we implement numerical experiments for calculating transition probabilities via the NOTraP algorithms. Our primary focus is on the high-depth NOTraP-HD method, whose viability we wish to demonstrate using very few extrapolation points. Additionally, we study the tradeoffs between circuit depth and the number of circuit evaluations for all algorithms introduced in this work. These experiments should be viewed as proofs of principle; additional algorithmic considerations and detailed error analysis would often be desired when using

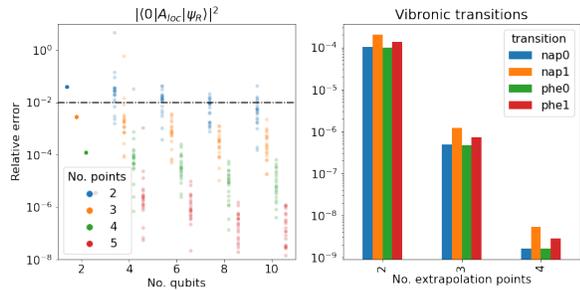

FIG. 3. Errors via the exponentiation- and extrapolation-based method NOTraP-HD using n_τ values of 2 through 5, for A_{loc} and for selected vibronic transitions in naphthalene and phenanthrene. The labels nap $\{N\}$ and phe $\{N\}$ refer to transitions from the ground state of naphthalene and phenanthrene, respectively, to the N th vibrational excited state of the electronic excited state.

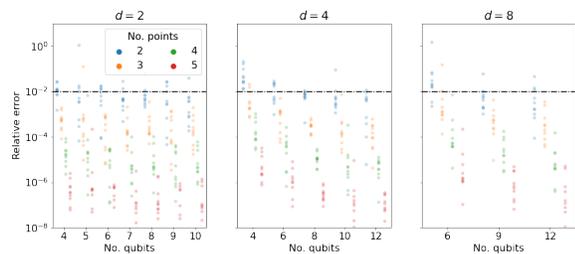

FIG. 4. Using NOTraP-HD of Section IIIB to estimate $|\langle x|A|b\rangle|^2$ for 20 random instances using A as defined in equation (41), relevant to classical linear algebra. The number of extrapolation points n_τ is varied from 2 to 5.

NOTraP algorithms in real-world problems. We consider simple models from three application areas: spin chains, vibronic transitions in molecules, and linear systems solving. We prepared and executed the numerics using primarily Scipy [52], mat2qubit [53], and OpenFermion [54]. In Section IV A we summarize the applications and numerical methods and in Section IV B we present and discuss the results.

A. Applications and numerical methods

Toy spin model. We implement both the one-local operator A_{loc} and the $(N_q - 1)$ -local operator A_{nonloc} defined in Section II. While A_{nonloc} is a contrived operator introduced mainly to study a highly non-local toy case, A_{loc} has a straight-forward physical interpretation as the total magnetism in the transverse direction. For up to ten qubits, we use the extrapolated algorithm NOTraP-HD to calculate $|\langle 0^{\otimes N_q} | A_{loc} | \psi_R \rangle|^2$ where $|\psi_R\rangle$ is a random quantum state. The extrapolation points τ were arbitrarily chosen to be centered around $\frac{1}{\|A\|}$ with spacing between points of $\frac{0.1}{\|A\|}$, where $\|A\|$ is the spectral norm.

In analyzing NOTraP-HD, we analyze the circuit depth versus distinct quantum circuits required for both A_{loc} and A_{nonloc} . As before, we assume a native gate set of CNOT and all arbitrary one-qubit gates. For NOTraP-T, we group the Pauli terms into N_G equally sized sets.

Vibronic transitions in molecules. In the general case, vibrational degrees of freedom in molecules are hard to simulate on classical computers; there has been theoretical work towards developing general quantum approaches for treating vibrations [11, 55, 56]. The more specific problem of calculating vibronic spectra involves the calculation of light-absorption cross sections for coupled vibrational-electronic transitions [6, 7, 57, 58]; here, the goal is to determine both the frequencies and the absorption intensities of each transition. The transition occurs between two electronic eigenstates, each associated with a different vibrational Hamiltonian. Though highly accurate vibrational Hamiltonians must include anharmonic terms, here we approximate naphthalene and phenanthrene using harmonic potential energy surfaces. The transformation between the ground and excited vibrational normal mode coordinates is described by the Duschinsky transformation,

$$\vec{q}' = \mathbf{S}\vec{q} + \vec{d} \quad (36)$$

where q' and q are vibrational normal mode coordinates respectively for the excited and ground electronic potential energy surface (PES), \mathbf{S} is a unitary matrix, and d is a displacement vector. The transition intensity is described by $|\langle \psi | \mu | \psi' \rangle|^2$, where $|\psi\rangle$ is a vibrational eigenstate of the ground PES and $|\psi'\rangle$ is a vibrational eigenstate of the excited PES. When the so-called Condon approximation is used, $\mu = I$ and one simply calculates the overlap of the two states. Non-Condon effects must be included in order to qualitatively capture the correct spectrum in many molecules, including those considered here. An analog photonic-based algorithm for the inclusion of non-Condon effects has been previously described [59]; the current work can be used as a digital version.

We use the following parameters[59] for naphthalene,

$$\begin{aligned} S^{(\text{nap})} &= \begin{pmatrix} .98 & -.20 \\ .20 & .98 \end{pmatrix} \\ \omega_g^{(\text{nap})} &= (509, 938) \\ \omega_e^{(\text{nap})} &= (438, 912) \\ d^{(\text{nap})} &= (0, 0) \\ \mu^{(\text{nap})} &= I + q_0 - q_1, \end{aligned} \quad (37)$$

and the following for phenanthrene,

$$\begin{aligned} S^{(\text{phen})} &= \begin{pmatrix} .9055 & -.4240 \\ .4240 & .9055 \end{pmatrix} \\ \omega_g^{(\text{phen})} &= (700, 800) \\ \omega_e^{(\text{phen})} &= (679, 796) \\ d^{(\text{phen})} &= (.1650, .0780) \\ \mu^{(\text{phen})} &= I + 1.5q_0 - 0.5q_1. \end{aligned} \quad (38)$$

In both problems, we consider only the two normal modes most relevant to the spectra. We map the problem to a binary representation [60] using a truncation of 16 energy levels, leading to 4 qubits per mode and hence 8 qubits overall. We deliberately chose molecules for which vibrational eigenstates on different PESs are not orthogonal, in order to highlight the utility of NOTraP.

Linear systems. A ubiquitous problem in science and engineering is solving the linear system

$$A|x\rangle = |b\rangle \quad (39)$$

where A and $|b\rangle$ are known (or in the quantum case, it is at least known how to prepare $|b\rangle$). The first quantum algorithm for solving linear systems [61] uses the quantum phase estimation algorithm. Variational approaches to solve (39) have been developed [16, 18–21], based on the notion that one may vary $|x\rangle$ using the objective function

$$F_{LS} = \langle x|A|b\rangle. \quad (40)$$

or $\|F_{LS}\|^2$, where the correct answer is reached when this quantity is maximized. Note that the original VQLS paper uses a slightly modified definition of the cost function that not qualitatively affect the results of the current work.

Equation 40 is simply a transition amplitude, and so any method for calculating either transition amplitudes or transition probabilities may be used. The methods of the current work may be used to solve for $|x\rangle$, using $|\langle x|A|b\rangle|^2$ as an objective function instead of equation (40). Using our approach for calculating the objective function has one major advantage over previous work: as previously mentioned, NOTraP does not require the controlled versions of the state preparation circuit nor the controlled versions of the exponentials of P_k and G_u . Though previous work on variational linear systems solvers [16] eliminated the need for controlled versions of state preparation circuits, controlled versions of exponentiation P_k were required. (An alternative approach is to minimize $\langle x|H|x\rangle$ where $H = A^\dagger(1 - |b\rangle\langle b|)A$, though in the general case this H may have many terms, leading to many more measurements being required to reconstruct the expectation value.) Note that the original [10] formulas (6) would not work for optimizing the objective function because it requires $|b\rangle$ to be orthogonal to the candidate for $|x\rangle$.

In order to study the use of our subroutines in variational quantum linear systems (VQLS) solving, we consider random classical matrices that can be expressed as *tensor trains* [62, 63]. Commonly used in machine learning and other fields, tensor train decompositions are a linear combination of matrix tensor products. We use the simple structure

$$A = \sum_{i=1}^{N_{\text{train}}-1} R_i^{(i)} \otimes R_{i+1}^{(i')} \quad (41)$$

where the size of each local subspace is d , hence each “local” matrix R is of size $d \times d$. The subscripts denote

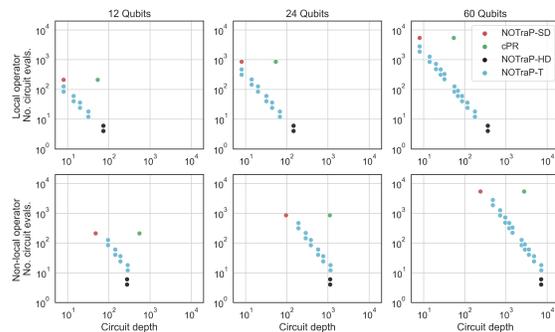

FIG. 5. Pareto fronts demonstrating the trade-off between circuit depth and distinct quantum circuits to evaluate, for the short-depth NOTraP-SD, the tunable NOTraP-T, the high-depth NOTraP-HD, and controlled Pauli rotations (cPR) [16]. Two operators, the local A_{loc} and the non-local A_{nonloc} , are considered.

the position in the tensor network train (identities I are implicit on other subspaces), and we include superscripts to clarify that all R are unique. We consider local tensor sizes $d = 2, 4, 8$, corresponding to local qubit counts of 1, 2, and 3, respectively. The number of qubits required to represent each full classical matrix A is thus $N_{\text{train}} \times \log_2 d$. We consider the error in calculating $|\langle b|A|x\rangle|^2$, where $|b\rangle$ is the zero vector, for 20 random vectors $|x\rangle$. Though we constrain A to be Hermitian, it is well known that any non-Hermitian matrix can be made Hermitian using one additional qubit, as shown in Appendix A.

B. Results and Discussion

The left panel of Figure 3 shows the relative error of using NOTraP-HD for the spin operator A_{loc} , for several qubits counts and values of n_τ . The right panel of Figure 3 shows vibronic transitions discussed in the previous section. In both applications, we observe a trend of the error decreasing exponentially with the number of extrapolation points used, demonstrating the viability of NOTraP-HD for even very few extrapolation points. It is also notable that just 2 extrapolation points is often sufficient for a sub-1% error, while 3 or more extrapolation points is almost always sufficient. In the case of A_{loc} , the average error scaling shows an improvement as the number of qubits increases; determining the generality of this fortuitous finding would require more research.

Figure 4 shows relative error in calculating $|\langle b|A|x\rangle|^2$ for a classical A defined by formula (41). We observe similar trends as before: errors decrease exponentially with increasing n_τ , and there is a modest trend of error reduction as the qubit count increases. The value of the local tensor size d does not appear to have a strong effect on error.

Figure 5 shows Pareto fronts with respect to circuit depth and number of circuit evaluations for several meth-

ods, with the purpose of comparing resource counts and especially demonstrating the resource trade-offs for the tunable NOTraP-T method. We consider both A_{loc} and A_{nonloc} ; the latter leads to larger circuit depths as the operator is highly non-local. NOTraP-T and NOTraP-HD show two values per circuit depth, as we include n_τ values of both 2 and 3. We stress again that these plots show circuit depths only for the calculation of $|\langle a|A|b\rangle|^2$ (depths of the required state preparation unitaries are excluded) and that the relationship between number of circuit evaluations and total number of measurements is non-trivial.

The plots show that NOTraP-T may be continuously tuned between high circuit depth and high number of circuit evaluations. As previously stated, this allows for the NOTraP methods to be tailored to the particular limited depth requirements of a particular quantum device. The values for the controlled Pauli operations (cPR) [15, 16] are shown as well. These circuit depths are based on the gate decompositions discussed in Section II A, and highlight the fact that NOTraP allows for shorter depth circuits than the methods (*e.g.* former formulations of VQLS) that require controlled unitaries. Note that once the available circuit depth is larger than the depth required for NOTraP-HD, there is no benefit to using NOTraP-T.

V. CONCLUSIONS

In this work we made three contributions to quantum algorithms for calculating transition probabilities. First, building on previous work [10] we introduced a method (NOTraP-SD) that can be used to calculate transition probabilities between two non-orthogonal states, while still not requiring any controlled state preparations nor controlled Pauli rotations. Second, we introduced an extrapolation-based method (NOTraP-HD) that needs higher circuit depths but requires far fewer measurements. Third, we show how to tune (NOTraP-T) between these short- and high-depth methods in order to make the most of available quantum hardware. That these methods do not require the above-mentioned controlled unitaries is useful for physics simulation but also for linear systems solving, we we can calculate a VQLS cost function without three-qubit gates and with fewer circuit evaluations.

In principle this method might be combined with shadow tomography [64], which especially for local Hamiltonians may show large reductions in measurements required per circuit evaluation. Though we derived measurement counts for previously proposed methods, for most of this work we left unspecified the method

used for each circuit evaluation.

There are several other promising directions for future work. One can imagine using methods here for calculating linear combinations of higher-order operators $\langle A^K \rangle$ [65]. Further, there may be modifications to our methods that allow for fewer measurement counts when calculating expectation values [37, 66–68] as opposed to transition probabilities.

In conclusion, we expect these quantum subroutines to be useful on near- and mid-term quantum computers for a range of problems in chemistry, materials, condensed matter physics, and quantum linear algebra, especially when circuit depth is the limiting resource.

Appendix A: non-Hermitian matrices

If A is not Hermitian, for example if it was lifted from a classical matrix problem instance, it can be made Hermitian by

$$A \rightarrow \begin{bmatrix} 0 & A \\ A^\dagger & 0 \end{bmatrix} \quad (\text{A1})$$

which is done by first decomposing the operator into Hermitian and anti-Hermitian parts,

$$A = A_H + A_{AH} \quad (\text{A2})$$

where $A_H = (A + A^\dagger)/2$ and $A_{AH} = (A - A^\dagger)/2$. Adding one qubit and the following transformation yields a Hermitian operator:

$$A \rightarrow X \otimes A_H + Y \otimes (-i)A_{AH}. \quad (\text{A3})$$

State vectors are modified as

$$\begin{aligned} |b\rangle &\rightarrow |0\rangle \otimes |b\rangle \\ |x\rangle &\rightarrow |1\rangle \otimes |x\rangle. \end{aligned} \quad (\text{A4})$$
