(Dated: July 12, 2022)

We attempt to simultaneously explain the neutrino oscillation data and the observed $(g-2)_{e,\mu}$ in a hidden gauge $U(1)_X$ model where all the Standard Model(SM) fields are $U(1)_X$ singlets. The minimal version of this model calls for four exotic scalars and two pairs of vector fermions, and all are charged under $U(1)_X$. We carefully consider the experimental limits on charge lepton flavor violation without assuming any flavor symmetry and explore the viable model parameter space. The model can accommodate the neutrino oscillation data for both the normal and the inverted mass ordering while explaining the central value of Δa_e by adopting the fine structure constant determined by using either Cesium or Rubidium atoms. However, mainly constrained by the current experimental bound on $\mathcal{B}(\tau \rightarrow \mu\gamma)$, this model predicts $\Delta a_\mu < 5.5(8.0) \times 10^{-10}$ for the normal(inverted) neutrino ordering. Moreover, while the muon Yukawa coupling is close to the SM one, we find the magnitude of the electron Yukawa coupling could be one order of magnitude larger than the SM prediction. This abnormal electron Yukawa could be probed in the future FCC-ee collider and plays an essential role in testing flavor physics.

I. INTRODUCTION

In the SM of particle physics, the charged fermions acquire their masses after the spontaneous breaking of the $SU(2)_L \times U(1)_Y$ symmetry via the Higgs mechanism. The fermion masses, M_F , are fixed by their Higgs Yukawa couplings, y_F , and $M_F = y_F v_0 / \sqrt{2}$, where $v_0 \sim 246\text{GeV}$ is the SM Higgs vacuum expectation value(VEV). The determination of the Higgs Yukawa couplings of top[1], bottom[2, 3], tau[4, 5], and muon[6, 7] are consistent with the predicted relationship within the errors, typically around a few $\times 10\%$ [8–10]. The consistency suggests that the origin of masses of the second and the third generation charged fermions can be well accounted by the SM Yukawa interaction. Although theoretically economic and technically natural, the SM does not explain the origin of the observed puzzling mass hierarchy among the charged fermions. Meanwhile, the measurements of Yukawa couplings of other light charged fermions are very challenging due to their

* wfchang@phys.nthu.edu.tw

smallness or(and) colossal experimental backgrounds. The current upper limit on electron-Yukawa $|y_e/y_e^{SM}| < 260$ [11, 12], obtained from the branching ratio of $\mathcal{B}(h \rightarrow e^+e^-)$, is relatively poor, and it leaves considerable room for the signal of new physics, see for example[13–17], which might shed light on the origin of flavor.

The flavor puzzle is not limited to the charged fermion sector only: with undoubtful evidence, at least two out of the three active neutrinos are massive[10]. The observed neutrino masses are about twelve orders of magnitude more diminutive than the electroweak scale. Except for the Dirac CP phase and whether the neutrino mass spectrum ordering is normal or inverted, the neutrino oscillation parameters, three mixing angles and two mass squared differences, have been determined to the precision at the percent level[18]. Despite the tremendous success of the minimal SM¹, the origin of neutrino masses calls for new degrees of freedom beyond the SM, and we do not know what they are yet. Regardless of the neutrino mass generation mechanism, the well-measured neutrino oscillation parameters are invaluable guides in exploring the unknown territory of flavor physics.

Moreover, the recently measured $(g - 2)_{e,\mu}$ appear to deviate from the SM predictions². Combining data from BNL E821 and the result of FNAL gives [20]

$$\Delta a_\mu^{FNAL} \simeq (25.1 \pm 5.9) \times 10^{-10}. \quad (1)$$

A new measurement at the J-PARC[21] is expected to improve the experimental uncertainty in the near future. Two recent lattice estimations[22, 23] on the hadronic vacuum polarization contribution to Δa_μ suggest a result consistent with the experimental data. However, these lattice estimations differ significantly from those based on the dispersion relation[19]. More theoretical studies, see, for example, [24–26] and references therein, are needed to understand this discrepancy and its consequences.

As for the electron, Δa_e can be deduced with the input of fine-structure constant α_{em} . By adapting α_{em} determined by using Cesium atoms[27], Δa_e takes the value

$$\Delta a_e^{Cs} \simeq (-8.7 \pm 3.6) \times 10^{-13}. \quad (2)$$

However, the measurement of α_{em} by using Rubidium atoms[28] yields a result

$$\Delta a_e^{Rb} \simeq (+4.8 \pm 3.0) \times 10^{-13}, \quad (3)$$

which differs from Δa_e^{Cs} by $\sim 4\sigma$. It is unclear how to resolve those theoretical and experimental discrepancies associated with $\Delta a_{e,\mu}$ mentioned above. More investigations are needed to settle

¹ Namely, there is no extra DOF beyond the three generations of quarks and leptons, gauge bosons of $SU(3)_c \times SU(2)_L \times U(1)_Y$, and the SM Higgs.

² See [19] for a comprehensive review of the SM prediction of $(g - 2)_\mu$.

down the issues. In this work, we try to accommodate Δa_e^{Cs} and Δa_e^{Rb} separately and scan our model parameter space to see the prediction of Δa_μ .

Aiming for a unified explanation for the neutrino mass generation and the anomalous magnetic moments of muon and electron, we consider a dark gauge $U(1)_X$ model for the one-loop radiative neutrino mass mechanism. For recent attempts to explain both $\Delta a_{e,\mu}$ and neutrino mass generation, see for example, Refs.[29–42]. Although we focus on the flavor physics in this work, the potential connection to dark matter is another motivation for us to consider the hidden gauge $U(1)_X$. With proper arrangement, the residual parity after spontaneous breaking of $U(1)_X$ [43] can be utilized to ensure the stability of the dark matter candidate(s). See [42, 44–62] for the example implementations of the residual gauge parity on dark matter and neutrino mass generation.

As we will show, the new physics responsible for the neutrino mass generation and $(g - 2)_{e,\mu}$ might leave a footprint in the electron-Yukawa. The radiative mechanism for M_ν and $\Delta a_{e,\mu}$ could also lead to sizable charged lepton flavor violation (CLFV) couplings and contradict the stringent experimental constraints, $\mathcal{B}(l_i \rightarrow \gamma l_{j \neq i})$. To avoid introducing further ad hoc assumptions on the flavor pattern, we take a bottom-up approach to investigate what the data say on the model parameter space. We should show that the resulting electron-Yukawa coupling, even its sign, may differ significantly from the SM prediction. Also, the model predicts that $\Delta a_\mu \sim 5.5(8.0) \times 10^{-10}$ at most by saturating the current upper limit of $\mathcal{B}(\tau \rightarrow \mu\gamma)$ (and $\mathcal{B}(\mu \rightarrow e\gamma)$), for normal ordering (inverted ordering) neutrino mass. If the experimental limits on CLFV processes get improved, this model predicts a even smaller Δa_μ .

This paper is organized as follows. Our model is detailed in Sec.II, and we also consider the $(g - 2)_{e,\mu}$, neutrino mass generation, and the effective Higgs-Yukawa couplings. Sec.III is devoted to the numerical study in that we scan the model parameter space to accommodate the neutrino oscillation data while all the experimental constraints are taken care. Four benchmark configurations and our findings are given therein. In Sec.IV, we discuss some phenomenological considerations with brief comments on the possible dark matter candidates and the prospect of detecting the new gauge boson. Finally, we conclude in Sec.V.

II. MODEL

On top of the SM, our model employs two pairs of vector fermions $N_{1,2}$ and four scalars, D, C, S_1, S_2 . The new degrees of freedom (DOF) are charged under a hidden gauge $U(1)_X$ symmetry. The detailed quantum numbers of the new DOFs are listed in Tab.I. On the other hand, all the

SM DOF's are singlet under the $U(1)_X$ such that the $U(1)_X$ is “dark”.

	New Fermion	New Scalar
Symmetry \ Fields	$N_{1L} \ N_{1R} \ N_{2L} \ N_{2R}$	$D = \begin{pmatrix} D^0 \\ D^- \end{pmatrix} \ C \ S_1 \ S_2$
$SU(2)_L$	1	2 1 1 1
$U(1)_Y$	0	$-\frac{1}{2}$ -1 0 0
$U(1)_X$	1	-1 -1 -1 -2

TABLE I. New field content and quantum number assignment under the SM gauge symmetries $SU(2)_L \otimes U(1)_Y$, and the gauge $U(1)_X$.

The $U(1)_X$ -invariant renormalizable Yukawa interactions and couplings involving new fermions are

$$\mathcal{L} \supset y_{ij}^L \bar{L}_i D N_{jR} + y_{ij}^R \bar{e}_{Ri} C N_{jL} - \sum_i \frac{1}{2} [\xi_{iL} \bar{N}_{iL}^c N_{iL} + \xi_{iR} \bar{N}_{iR}^c N_{iR}] S_2 - \sum_{ij} \mathfrak{D}_{ij} \bar{N}_{iR} N_{jL} + H.c. \quad (4)$$

where \mathfrak{D}_{ij} are the new dimensionful Dirac couplings among N 's. Here we adopt a convention that L_i and e_{Ri} are in the charged lepton flavor(mass) basis. Note that one can choose the diagonal ξ 's without losing any generality. The new Yukawa sector enjoys the conventional global lepton number symmetry $U(1)_L$ if $\{N, D, C, S_2\}$ carry lepton number $\{1, 0, 0, -2\}$, respectively³.

For the scalar sector, the Lagrangian is

$$\begin{aligned} \mathcal{L} \supset & (D_\mu H)^\dagger (D^\mu H) + \mu_H^2 H^\dagger H - \lambda_H (H^\dagger H)^2 - V_{NP} \\ & + (D_\mu D)^\dagger (D^\mu D) + (D_\mu C)^* (D^\mu C) + (D_\mu S_1)^* (D^\mu S_1) + (D_\mu S_2)^* (D^\mu S_2), \end{aligned} \quad (5)$$

where the new scalar potential is

$$\begin{aligned} V_{NP} = & -\mu_2^2 |S_2|^2 + M_D^2 D^\dagger D + M_C^2 |C|^2 + M_{S_1}^2 |S_1|^2 \\ & + \lambda_D (D^\dagger D)^2 + \lambda_C |C|^4 + \lambda_1 |S_1|^4 + \lambda_2 |S_2|^4 + \bar{\lambda}_{HD} (D^\dagger H) (H^\dagger D) \\ & + H^\dagger H \left(\lambda_{HD} D^\dagger D + \lambda_{HC} |C|^2 + \lambda_{H1} |S_1|^2 + \lambda_{H2} |S_2|^2 \right) \\ & + D^\dagger D \left(\lambda_{DC} |C|^2 + \lambda_{D1} |S_1|^2 + \lambda_{D2} |S_2|^2 \right) \\ & + |C|^2 \left(\lambda_{C1} |S_1|^2 + \lambda_{C2} |S_2|^2 \right) + \lambda_{12} |S_1|^2 |S_2|^2 \\ & + \sqrt{2} \mu_{DC} H^\dagger D C^* + \sqrt{2} \mu_{DS} H^\dagger \tilde{D} S_1 + 2\lambda_4 H^\dagger \tilde{D} S_2 S_1^* + \frac{\mu_{12}}{\sqrt{2}} S_1^2 S_2^* + H.c. \end{aligned} \quad (6)$$

³ See [63–67] for the discussion if $U(1)_L$ is gauged.

The global $U(1)_L$ is now explicitly broken by λ_4 and μ_{12} , which are crucial for generating the neutrino Majorana masses. Moreover, since $U(1)_L$ is explicitly broken, there is no massless Majorana associated with the SSB of $U(1)_X$ ⁴. However, with the presence of λ_4 or $\bar{\lambda}_{HD}$, no simple analytic expression is available for the scalar potential to be bounded from below. In general, one needs to check the positivity condition numerically. For simplicity while keeping the essential physics, we will set $\lambda_4 = 0$ and $\bar{\lambda}_{HD} > 0$ in our numerical study.

We assume a 2-stage symmetry breaking. At an energy scale higher than the SM electroweak scale, the $U(1)_X$ is broken spontaneously as S_2 acquires a VEV $\langle S_2 \rangle = v_2/\sqrt{2}$. The new gauge boson Z_X acquires a mass $M_X = 2g_X v_2$, where the gauge coupling g_X is a free parameter and we assume $v_2 \gg M_W$. The imaginary part of S_2 is the would-be-Goldstone eaten by the Z_X boson. In between the $U(1)_X$ breaking scale and the SM electroweak scale, the remaining gauge symmetry is the SM $SU(3)_c \times SU(2)_L \times U(1)_Y$.

The mass term of new fermions becomes $\mathcal{L} \supset \frac{1}{2} \bar{N}^c M_N N + H.c.$ where $N = (N_{1L}, N_{1R}^c, N_{2L}, N_{2R}^c)^T$, and

$$M_N = \begin{pmatrix} \frac{v_2 \xi_{1L}}{\sqrt{2}} & \mathfrak{D}_{11} & 0 & \mathfrak{D}_{12} \\ \mathfrak{D}_{11} & \frac{v_2 \xi_{1R}}{\sqrt{2}} & \mathfrak{D}_{21} & 0 \\ 0 & \mathfrak{D}_{21} & \frac{v_2 \xi_{2L}}{\sqrt{2}} & \mathfrak{D}_{22} \\ \mathfrak{D}_{12} & 0 & \mathfrak{D}_{22} & \frac{v_2 \xi_{2R}}{\sqrt{2}} \end{pmatrix}. \quad (7)$$

The symmetric mass matrix M_N can be diagonalized by a transformation, $O^T M_N O$ with eigenvalues $M_{\chi_i} (i = 1..4)$, and $OO^\dagger = O^\dagger O = 1$. We write the mass eigenstates as $\chi_L = (\chi_{1L}, \chi_{2L}, \chi_{3L}, \chi_{4L})$ with $N = O \cdot \chi_L$. From χ_L , one can construct four Majorana states

$$\chi_i = \chi_{iL} + \chi_{iL}^c = \chi_i^c \quad (8)$$

such that $\mathcal{L} \supset \frac{i}{2} \bar{\chi}_i \not{D} \chi_i - \frac{1}{2} M_{\chi_i} \bar{\chi}_i \chi_i$. Reversely, the interaction states can be expressed in terms of the physical Majorana states

$$N_{1L} = O_{1i} \hat{L} \chi_i, \quad N_{2L} = O_{3i} \hat{L} \chi_i, \quad N_{1R} = O_{2i}^* \hat{R} \chi_i, \quad N_{2R} = O_{4i}^* \hat{R} \chi_i, \quad (9)$$

where $\hat{L}/\hat{R} = (1 \mp \gamma^5)/2$ is the chiral projection operator. And the Yukawa coupling becomes

$$\mathcal{L} \supset \bar{\chi}_k \left(Y_L^{ik} D^+ \hat{L} + Y_R^{ik} C^+ \hat{R} \right) l_i + \bar{\chi}_k \left(Y_L^{ik} (D^0)^* \hat{L} \right) \nu_i + H.c., \quad (10)$$

where

$$Y_L^{ik} = \sum_{j=1}^2 (y_{ij}^L)^* O_{(2j)k}, \quad Y_R^{ik} = \sum_{j=1}^2 (y_{ij}^R)^* O_{(2j-1)k}^*. \quad (11)$$

⁴ In some case, the massless Majorana can play the role of dark radiation, see [68, 69].

In the limit that $\mathfrak{D}_{12}, \mathfrak{D}_{21} \ll \mathfrak{D}_{11}, \mathfrak{D}_{22}, \xi v_2$, the mass eigenstates $\chi_{1,2}(\chi_{3,4})$ are mainly composed by $N_{1L,1R}(N_{2L,2R})$. For simplicity, we shall set $\mathfrak{D}_{12,21} = 0$ in our numerical study and the physics is more transparent. For a more general case, the full four by four mixing matrix O can be obtained numerically.

Below the SM electroweak symmetry breaking scale, the neutral component of SM Higgs acquires a VEV, $\langle H_0 \rangle = v_0/\sqrt{2}$. Working in the unitary gauge, $H = [0, (v_0 + h)/\sqrt{2}]^T$, the mixing between D^- and C^- can be described as a term in Lagrangian

$$\mathcal{L} \supset -(D^+, C^+) \mathcal{M}_C \begin{pmatrix} D^- \\ C^- \end{pmatrix}, \quad \mathcal{M}_C = \begin{pmatrix} \widetilde{M}_D^2 & v_0 \mu_{DC} \\ v_0 \mu_{DC} & \widetilde{M}_C^2 \end{pmatrix} \quad (12)$$

where $\widetilde{M}_D^2 = M_D^2 + \frac{1}{2}(\lambda_{HD} + \bar{\lambda}_{HD})v_0^2 + \frac{1}{2}\lambda_{D2}v_2^2$, and $\widetilde{M}_C^2 = M_C^2 + \frac{1}{2}\lambda_{HC}v_0^2 + \frac{1}{2}\lambda_{C2}v_2^2$. The charged scalars can be diagonalized by a two-by-two rotation

$$U_C = \begin{pmatrix} \cos \alpha_c & \sin \alpha_c \\ -\sin \alpha_c & \cos \alpha_c \end{pmatrix} \quad (13)$$

with an angle satisfying

$$\sin 2\alpha_c = \frac{2v_0 \mu_{DC}}{M_{C2}^2 - M_{C1}^2}, \quad (14)$$

where $M_{C1, C2}$ are the physical mass eigenvalues, and $M_{C2} > M_{C1}$.

The λ_{H2} term in Eq.(6) induces a mixing between h and the real part of S_2 . We assume the observed 125GeV Higgs is the lighter physical scalar h_{SM} , and the mass of heavier h_2 is undetermined and not important in this study. The h - $\Re(S_2)$ mixing results in a universal suppressing factor to the SM 125GeV Higgs couplings. Then the Higgs signal strength becomes $\mu = \cos^2 \theta_0$ with θ_0 the mixing angle between h and $\Re(S_2)$. From $\mu = 1.02^{+0.07}_{-0.06}$ obtained by CMS[70] and $\mu = 1.06 \pm 0.06$ by ATLAS[71], we obtain $\mu = 1.042^{+0.047}_{-0.044}$ following the suggestion of [72]. Therefore, one has $\sin^2 \theta_0 < 0.046$ at 2σ C.L. This amounts to $\left| \frac{\lambda_{H2} v_2 v_0}{M_{h_2}^2 - M_{h_{SM}}^2} \right| < 0.21$ which can be easily satisfied with the model parameters, for example $M_{h_2}, v_2 \simeq \mathcal{O}(\text{TeV})$ and $|\lambda_{H2}| < 1$, without much fine-tuning.

Next, the mixings among the neutral components of D and S_1 can be described by

$$\mathcal{L} \supset -(\Re D^0, \Re S_1) \mathcal{M}_R \begin{pmatrix} \Re D^0 \\ \Re S_1 \end{pmatrix} - (\Im D^0, \Im S_1) \mathcal{M}_I \begin{pmatrix} \Im D^0 \\ \Im S_1 \end{pmatrix}, \quad (15)$$

where

$$\mathcal{M}_R = \begin{pmatrix} \overline{M}_D^2 & -\mu_{DS}v_0 - \lambda_4 v_0 v_2 \\ -\mu_{DS}v_0 - \lambda_4 v_0 v_2 & \overline{M}_S^2 + \mu_{12}v_2 \end{pmatrix}, \quad \mathcal{M}_I = \begin{pmatrix} \overline{M}_D^2 & -\mu_{DS}v_0 + \lambda_4 v_0 v_2 \\ -\mu_{DS}v_0 + \lambda_4 v_0 v_2 & \overline{M}_S^2 - \mu_{12}v_2 \end{pmatrix}, \quad (16)$$

FIG. 1. The Feynman diagram, in the interaction basis, for $(g-2)_l$ and the CLFV $l \rightarrow l'\gamma$ process. The photon attaches to the charged scalar in the loop.

$\overline{M}_D^2 = \widetilde{M}_D^2 - \frac{1}{2}\bar{\lambda}_{HD}v_0^2$, and $\overline{M}_S^2 = M_{S_1}^2 + \frac{1}{2}\lambda_{H1}v_0^2 + \frac{1}{2}\lambda_{12}v_2^2$. Note the sign differences in some mass matrix elements for scalar and pseudoscalar, also the mass splitting between \overline{M}_D and \widetilde{M}_D is about the electroweak scale. Similarly, the real parts and imaginary parts mixing can be diagonalized by the two-by-two rotations U_R and U_I with angles $\alpha_{R,I}$, and

$$\sin 2\alpha_R = -\frac{2(v_0\mu_{DS} + \lambda_4 v_0 v_2)}{M_{R2}^2 - M_{R1}^2}, \quad \sin 2\alpha_I = -\frac{2(v_0\mu_{DS} - \lambda_4 v_0 v_2)}{M_{I2}^2 - M_{I1}^2}, \quad (17)$$

where $M_{R2,R1}$ and $M_{I2,I1}$ are the physical masses of scalars and pseudo scalars made from D and S_1 , respectively. Again, we adopt the convention that $M_{R2} > M_{R1}$ and $M_{I2} > M_{I1}$.

A. $\Delta a_{e,\mu}$ and $l_i \rightarrow l_j \gamma$

In this model, the charged lepton $(g-2)$ receives 1-loop contribution, see Fig.1. Ignoring the charged lepton mass and summing over all physical states in the loop, the anomalous magnetic dipole moment can be calculated to be[38]

$$\Delta a_l = -\frac{m_l \sin(2\alpha_c)}{16\pi^2} \sum_{k=1}^4 \frac{\Re[Y_L^{lk}(Y_R^{lk})^*]}{M_{\chi_k}} \mathcal{J}(\beta_H^k, \beta_L^k), \quad (18)$$

where $\beta_H^k = (M_{C_2}/M_{\chi_k})^2$, and $\beta_L^k = (M_{C_1}/M_{\chi_k})^2$. And the loop function is given as

$$\mathcal{J}(x, y) = \mathcal{J}_0(x) - \mathcal{J}_0(y), \quad \mathcal{J}_0(x) = \frac{1 - x^2 + 2x \ln x}{2(1 - x)^3}. \quad (19)$$

The function \mathcal{J}_0 has limits $\mathcal{J}_0(0) = 1/2$ and $\mathcal{J}_0(1) = 1/6$. On the other hand, the electric dipole moment will be proportional to $\Im[Y_L^{lk}(Y_R^{lk})^*]$ and stringently limited by the experimental bounds. For simplicity, we should assume there is no extra CP violation phases beyond the SM in the work.

Similarly, the $L(p+q) \rightarrow l(p) + \gamma(q)$ dipole transition amplitude can be read as

$$i\mathcal{M}_{Ll}^\mu = -ie \overline{u_l(p)} \left[\left(d_L^{Ll} \hat{L} + d_R^{Ll} \hat{R} \right) \left(\frac{i\sigma^{\mu\alpha} q_\alpha}{2} \right) \right] u_L(p+q), \quad (20)$$

where

$$\begin{aligned} d_L^{Ll} &= \frac{\sin(2\alpha_c)}{16\pi^2} \left\{ \sum_{k=1}^4 \frac{\mathcal{J}(\beta_H^k, \beta_L^k)}{M_{\chi_k}} \left[(Y_R^{lk})^* Y_L^{Lk} \right] \right\}, \\ d_R^{Ll} &= \frac{\sin(2\alpha_c)}{16\pi^2} \left\{ \sum_{k=1}^4 \frac{\mathcal{J}(\beta_H^k, \beta_L^k)}{M_{\chi_k}} \left[(Y_L^{lk})^* Y_R^{Lk} \right] \right\}. \end{aligned} \quad (21)$$

In terms of the two dipole coefficients, the corresponding CLFV transition rate can be calculated to be [73]

$$\Gamma(L \rightarrow l + \gamma) = \frac{\alpha_{em} m_L^3}{16} \left(|d_L^{Ll}|^2 + |d_R^{Ll}|^2 \right), \quad (22)$$

if ignoring the mass of the lighter charged lepton. From the current limits: $Br(\mu \rightarrow e\gamma) < 4.2 \times 10^{-13}$ [74], $\mathcal{B}(\tau \rightarrow e\gamma) < 3.3 \times 10^{-8}$, $\mathcal{B}(\tau \rightarrow \mu\gamma) < 4.4 \times 10^{-8}$ [75], $m_\tau = 1.77686(12)\text{GeV}$, $\tau_\tau = (290.3 \pm 0.5) \times 10^{-15}s$ [10], one has

$$\begin{aligned} |d_L^{\mu e}|^2 + |d_R^{\mu e}|^2 &< 2.35 \times 10^{-25} (\text{GeV})^{-2}, \\ |d_L^{\tau e}|^2 + |d_R^{\tau e}|^2 &< 2.93 \times 10^{-17} (\text{GeV})^{-2}, \\ |d_L^{\tau \mu}|^2 + |d_R^{\tau \mu}|^2 &< 3.91 \times 10^{-17} (\text{GeV})^{-2}. \end{aligned} \quad (23)$$

It is clear that to satisfy the stringent experimental bounds, either some couplings are very small or delicate cancellation among the parameters should be arranged. For simplicity and better understanding the physics, we adopt a simple arrangement $\mathcal{D}_{12,21} = 0$ such that the cross mixing between N_1 and N_2 vanishes. In this scheme, the charged lepton $g-2$ become

$$\begin{aligned} \Delta a_e &= [\cdots] y_{11}^L y_{11}^R + [\cdots] y_{12}^L y_{12}^R, \\ \Delta a_\mu &= [\cdots] y_{21}^L y_{21}^R + [\cdots] y_{22}^L y_{22}^R, \\ \Delta a_\tau &= [\cdots] y_{31}^L y_{31}^R + [\cdots] y_{32}^L y_{32}^R, \end{aligned} \quad (24)$$

where $[\cdots]$ represent the numerical factors depending on M_χ , $M_{C,R,I}$, and the mixings. Moreover, once y^L 's and the relevant physical masses and mixings are fixed, the CLFV dipole transition coefficients have simple dependence on the right-handed Yukawa y^R :

$$\begin{aligned} d_L^{\mu e} &= (\cdots) y_{11}^R + (\cdots) y_{12}^R, \quad d_R^{\mu e} = (\cdots) y_{21}^R + (\cdots) y_{22}^R, \\ d_L^{\tau e} &= (\cdots) y_{11}^R + (\cdots) y_{12}^R, \quad d_R^{\tau e} = (\cdots) y_{31}^R + (\cdots) y_{32}^R, \\ d_L^{\tau \mu} &= (\cdots) y_{21}^R + (\cdots) y_{22}^R, \quad d_R^{\tau \mu} = (\cdots) y_{31}^R + (\cdots) y_{32}^R, \end{aligned} \quad (25)$$

where (\cdots) represent the numerical factors depending on y^L , M_χ , $M_{C,R,I}$, and the mixings. One can set $y_{31}^R = y_{32}^R = 0$ to suppress the CLFV dipole transition, with vanishing Δa_τ , $d_R^{\tau \mu}$, and $d_R^{\tau e}$.

FIG. 2. Some leading Feynman diagrams, in the interaction basis, for generating the neutrino masses.

B. Radiative contributions to the lepton masses

The same Feynman diagram displayed in Fig.1 will generate radiative corrections to the charged lepton mass matrix if the external photon line is removed. A simple calculation gives

$$\delta M_{ij}^{loop} = - \sum_k \frac{M_k (Y_L^{ik})^* Y_R^{jk}}{32\pi^2} \sin 2\alpha_c \left(\frac{\beta_L^k \log \beta_L^k}{\beta_L^k - 1} - \frac{\beta_H^k \log \beta_H^k}{\beta_H^k - 1} \right) \quad (26)$$

where the first (second) index stands for the left (right)-handed lepton.

To be consistent with the working assumption that the Yukawa couplings, $y^{L,R}$ in Eq.(4), are in the charged leptons' mass basis, it is required that the tree-level Yukawa coupling between the charged leptons and the SM Higgs doublet, $\mathcal{L} \supset -y_{ij}^H \bar{L}_i e_{Rj} H + H.C.$, must satisfy the following relationship

$$\frac{v_0}{\sqrt{2}} y_{ij}^H + \delta M_{ij}^{loop} = \delta_{ij} m_i, \quad i = (e, \mu, \tau). \quad (27)$$

Such that the off-diagonal entries of charged lepton mass matrix vanish, and our treatment is self-consistent at the one-loop level.

For neutrino masses, they can be radiatively generated by the 1-loop diagrams shown in Fig.2, in the interaction basis. Summing over all mass eigenstates in the loop, we obtain the neutrino mass matrix element

$$\mathcal{M}_{ij}^\nu = \frac{1}{16\pi^2} \sum_{k=1}^4 M_{\chi_k} Y_L^{ik} Y_L^{jk} \times \sum_{a=1}^2 \left[(U_{1a}^R)^2 \frac{s_{ak} \ln s_{ak}}{s_{ak} - 1} - (U_{1a}^I)^2 \frac{p_{ak} \ln p_{ak}}{p_{ak} - 1} \right], \quad (28)$$

where $s_{ak} = (M_{Ra}/M_{\chi_k})^2$ and $p_{ak} = (M_{Ia}/M_{\chi_k})^2$ are the mass squared ratios of scalar and pseudoscalar to the Majorana fermion- k , respectively.

C. Effective Yukawa coupling of charged lepton

Note that the one-loop $h_{SM}-\bar{l}_i-l_j$ couplings can be generated if replacing the external photon in Fig.1 by the 125GeV SM Higgs, and therefore the tree-level SM prediction $y_l = \frac{m_l}{v_0}$ will be modified. Although the new Yukawa couplings are in the charged lepton mass basis at 1-loop level, the different loop integration involved leads to CLFV Higgs decays $h_{SM} \rightarrow l_i l_j$ in general.

Below the electroweak scale, the dimensionful cubic couplings for $\mathcal{L} \supset -\tilde{\mu}_{ab} h_{SM} C_a^+ C_b^-$ can be read from the scalar potential, Eq.(6), as

$$\begin{aligned}\tilde{\mu}_{11} &= v_0(\lambda_{HD} + \bar{\lambda}_{HD})c_\alpha^2 + v_0\lambda_{HC}s_\alpha^2 - 2s_\alpha c_\alpha \mu_{DC} \\ \tilde{\mu}_{22} &= v_0(\lambda_{HD} + \bar{\lambda}_{HD})s_\alpha^2 + v_0\lambda_{HC}c_\alpha^2 + 2s_\alpha c_\alpha \mu_{DC} \\ \tilde{\mu}_{12} &= \tilde{\mu}_{21} = v_0(\lambda_{HD} + \bar{\lambda}_{HD})s_\alpha c_\alpha - v_0\lambda_{HC}s_\alpha c_\alpha + (c_\alpha^2 - s_\alpha^2)\mu_{DC},\end{aligned}\quad (29)$$

in the mass basis of the charged scalars. If ignoring the charged lepton masses, the dimensionless $h_{SM}-\bar{l}_i-l_j$ Yukawa couplings⁵ can be calculated to be

$$y_{ij}^{loop} = \frac{1}{16\pi^2} \sum_{k=1}^4 (Y_L^{ik})^* Y_R^{jk} \sum_{a,b=1}^2 \frac{\tilde{\mu}_{ab}}{M_{\chi_k}} U_{2a}^C U_{1b}^C \mathcal{I}_3 \left(\beta_k^a, \beta_k^b, \frac{q^2}{M_{\chi_k}^2} \right) \quad (30)$$

where q is the momentum carried by h_{SM} , and

$$\mathcal{I}_3(z_1, z_2, z_3) = \int_0^1 dx \int_0^{1-x} dy (1 - x - y + xz_1 + yz_2 - xyz_3)^{-1}. \quad (31)$$

The analytic expression for $\mathcal{I}_3(a_1, a_2, 0)$ can be easily obtained and will not be shown here.

Combining with the tree-level Higgs Yukawa, Eq.(27), we obtain the effective Yukawa

$$y_{ij}^{eff} = \frac{y_{ij}^H}{\sqrt{2}} + y_{ij}^{loop} = \frac{1}{v_0} (\delta_{ij} m_i - \delta M_{ij}^{loop}) + y_{ij}^{loop}. \quad (32)$$

For $i \neq j$, the CLFV decay width of $h_{SM} \rightarrow l_i l_j$ is given by

$$\Gamma(h_{SM} \rightarrow l_i^+ l_j^-) = \Gamma(h_{SM} \rightarrow l_i^- l_j^+) \simeq \frac{M_h}{16\pi} \left(|y_{ij}^{eff}|^2 + |y_{ji}^{eff}|^2 \right) \quad (33)$$

at tree-level if ignoring the charged lepton masses. And for the diagonal ones, it is convenient to define the normalized Yukawa

$$\zeta_l \equiv \frac{y_l^{eff}}{y_l^{SM}} = 1 - \frac{1}{m_l} \left(\delta M_{ll}^{loop} - v_0 y_{ll}^{loop} \right). \quad (34)$$

⁵ We adopt the convention that $\mathcal{L} \supset -y_{ij}^{loop} \bar{l}_i \hat{R} l_j h_{SM} + h.c.$

III. NUMERICAL STUDY

First, we comment on the number of exotic vector fermions N 's. For the three active neutrinos, one needs six independent parameters to describe the symmetric neutrino mass matrix. Thus, the minimal setup of our model calls for two pairs of exotic fermions, with six y^L 's parameters. However, it is easy to see from Eq.(28) that the resulting neutrino mass matrix has rank 2. Namely, the neutrino mass matrix possesses only five independent parameters. One of the y^L 's is redundant and must be fixed first⁶ so the rest five can be uniquely determined by data. And the remaining six y^R 's are used to yield $\Delta a_{e,\mu}$ while satisfying all the experimental CLFV constraints.

With three pairs of exotic fermions, the rank of the neutrino mass matrix is 3. Hence, three out of the nine y^L free parameters are redundant. Moreover, with nine y^R 's parameters, one can always find a viable solution such that all the CLFV limits are satisfied and both central values of Δa_μ and $\Delta a_e^{Cs[Rb]}$ are accommodated. Such scenario has more free parameters than experimental constraints and lacks predictability. Therefore, we focus on the minimal model with two pairs of N 's.

As we only consider the CP-conserving scenario in this work, there is no Dirac nor Majorana CP violation phases in the U_{PMNS} matrix. The case of $\delta_{CP} = 0$ is still allowed in the current 3σ range of global fit of neutrino oscillation data[18], see Tab.II. From the global fit, the pattern of a rank-2 neutrino mass matrix is roughly

$$M_\nu^{NO} \sim \begin{pmatrix} 0.1 & 0.1 & 0.1 \\ 0.1 & 1 & 1 \\ 0.1 & 1 & 1 \end{pmatrix} \times (0.03)\text{eV} \quad (35)$$

for Normal Ordering(NO), and

$$M_\nu^{IO} \sim \begin{pmatrix} 1 & -0.1 & -0.1 \\ -0.1 & 1 & -1 \\ -0.1 & -1 & 1 \end{pmatrix} \times (0.03)\text{eV} \quad (36)$$

for Inverted Ordering(IO).

Note that Δa_l , $d_{L,R}^{Ll}$, δM^{loop} and y^{loop} are linearly proportional to y^R in our model. Moreover, the physical masses of χ 's and the exotic scalars can be scaled up or down by a common factor r while the mixing angles retain if one performs the following scaling

$$M \rightarrow rM, \mu_{DS,DC} \rightarrow r^2\mu_{DS,DC}, \Lambda \rightarrow r^2\Lambda, \quad (37)$$

⁶ For example, one can generally require that the value of one of the y^L 's must lay within a reasonable range, say, from -1.0 to 1.0 .

	$\theta_{12}[^{\circ}]$	$\theta_{23}[^{\circ}]$	$\theta_{13}[^{\circ}]$	$\Delta m_{21}^2 [10^{-5} \text{eV}^2]$	$\Delta m_{3l}^2 [10^{-3} \text{eV}^2]$
Normal Ordering	$31.27 \rightarrow 35.87$	$39.7 \rightarrow 50.9$	$8.25 \rightarrow 8.98$	$6.82 \rightarrow 8.04$	$+2.430 \rightarrow +2.593$
Inverted Ordering	$31.27 \rightarrow 35.87$	$39.8 \rightarrow 51.6$	$8.24 \rightarrow 9.02$	$6.82 \rightarrow 8.04$	$-2.574 \rightarrow -2.410$

TABLE II. The 3σ ranges of the neutrino oscillation parameters from global fit[18]. For NO(IO), $\Delta m_{3l}^2 \equiv m_3^2 - m_{1(2)}^2$.

where $M \supset \{\bar{M}_{D,S}, \widetilde{M}_{D,C}, \mathcal{D}, v_2, \mu_{12}\}$, and $\Lambda \supset \{\lambda_{HD}, \bar{\lambda}_{HD}, \lambda_{HC}, \lambda_{H1}\}$. Moreover, the resulting \mathcal{M}^ν , $d_{L,R}^{Ll}$, and Δa_l will be the same if

$$y^L \rightarrow r^{-1/2} y^L, \quad y^R \rightarrow r^{3/2} y^R, \quad (38)$$

such that both radiative mass corrections and the one-loop effective Yukawa coupling scale like:

$$\delta M^{loop} \rightarrow r^2 \delta M^{loop}, \quad y^{loop} \rightarrow r^2 y^{loop}, \quad (39)$$

while M_ν and $\Delta a_{e,\mu}$ remain unchanged. Therefore, starting from an available solution, one can obtain infinite other possible viable solutions by using this scaling as long as the perturbability and positivity requirements are met.

To avoid multiple counting of the same solution related by the above mentioned scaling, we adopt the following procedures to find the numerical solutions: we first scan the relevant model parameter space spanned by $\mathcal{M}_{C,R,I}$ and M_N . As discussed earlier, we set $\lambda_4 = 0$ and $\bar{\lambda}_{HD} > 0$ to simplify the positivity condition. We also set $\mathcal{D}_{12,21} = 0$ to speed up the numerical scan⁷. Explicitly, it is a 13-dimensional parameter space spanned by $\mathcal{D}_{11,22}$, $(v_2 \xi / \sqrt{2})$, $M_{C1,C2,\alpha_C}$, $\bar{\lambda}_{HD}$, \bar{M}_S , μ_{DS} , and $(\mu_{12} v_2)$. We scan the parameters in the ranges: $(v_2 \xi / \sqrt{2}) \in [10, 1000] \text{GeV}$, $\mathcal{D}_{11,22} \in [0.1, 10] \text{TeV}$, $\bar{M}_S \in [0.3, 10] \text{TeV}$, $\sqrt{\mu_{DS} v_0} \in [3.0, 2000] \text{GeV}$, $\sqrt{\mu_{12} v_2} \in [3.0, 3000] \text{GeV}$, $\bar{\lambda}_{HD} \in [3.3 \times 10^{-5}, 0.93]$, $M_{C1} \in [0.5 - 10] \text{TeV}$, $M_{C2}/M_{C1} \in [1, 10]$, and $\alpha_C \in [0.01, \pi/2]$. Our random samplings are evenly distributed in the logarithmic scale.

After mass diagonalization of χ and the relevant scalar sector, we obtain the mixing angles and physical masses needed for calculating neutrino masses, Eq.(28). Then the neutrino mass matrix is fixed by a set of neutrino oscillation parameters randomly picked within the 3σ range[18] shown in Tab.II. Because one of the active neutrino is massless, there are only five independent parameters in the symmetric neutrino mass matrix. To proceed, we assign y_{11}^L to a value randomly picked between $\pm[10^{-5}, 1.0]$. Then we look for the unique solution of the other five y^L 's in Eq.(4) to the neutrino mass matrix.

⁷ We have checked that our main conclusions do not change in the case that $\mathcal{D}_{12,21} \neq 0$.

Only the points which satisfy positivity conditions are kept. We also require that the resulting physical masses are in the range of $0.5 - 5\text{TeV}$, and the magnitudes of all dimensionless parameters to be less than 1.0.

Finally, the six Yukawa couplings y^R 's in Eq.(4) are determined by finding the minimum of the weighted chi-squared

$$\chi_{\Delta a}^2 = \left(\frac{\Delta a_e - \Delta a_e^{Cs[Rb]}}{\delta \Delta a_e^{Cs[Rb]}} \right)^2 + \left(\frac{\Delta a_\mu - \Delta a_\mu^{FNAL}}{\delta \Delta a_\mu^{FNAL}} \right)^2, \quad (40)$$

while complying the experimental bounds on $\mathcal{B}(l_i \rightarrow l_j \gamma), (i \neq j)$. After that, two more model parameters, $\lambda_{HD,HC}$, are required for calculating the effective Higgs Yukawa couplings. They only associate with the effective Higgs Yukawa couplings and independent of the other observables. We randomly choose $\lambda_{HD,HC}$ from the conservative range $[-1.0 \rightarrow 1.0]$ which is within the lower(upper) bound imposed by the positivity(perturbability) condition.

A. Benchmark points

Here we present four viable benchmark points with detailed model parameters.

1. Benchmark points–Normal Ordering

The relevant model parameters are:

$$\begin{aligned} \{\theta_{12}, \theta_{23}, \theta_{13}, \Delta m_{21}^2, \Delta m_{31}^2\} &= \{32.13^\circ, 48.49^\circ, 8.71^\circ, 7.362 \times 10^{-5} \text{eV}^2, 2.539 \times 10^{-3} \text{eV}^2\}, \\ \frac{v_2}{\sqrt{2}} \times \{\xi_{1L}, \xi_{1R}, \xi_{2L}, \xi_{2R}\} &= \{44.354, 57.795, 12.301, 27.742\} \text{ GeV}, \\ \{\mathcal{D}_{11}, \mathcal{D}_{22}, \mathcal{D}_{12}, \mathcal{D}_{21}\} &= \{2.18072, 2.41526, 0, 0\} \text{ TeV}, \\ \{\widetilde{M}_D, \widetilde{M}_C, \overline{M}_D, \overline{M}_S\} &= \{1.08449, 1.10508, 1.08446, 1.10210\} \text{ TeV}, \\ \{\mu_{DC}, \mu_{DS}, \mu_{12}\} &= \left\{ 2961.99, 33.722, 0.67863 \times \left(\frac{\text{TeV}}{v_2} \right) \right\} \text{ GeV}, \\ \{\overline{\lambda}_{HD}, \lambda_{HD}, \lambda_{HC}\} &= \{2.284 \times 10^{-3}, 0.1, 0.2\}. \end{aligned} \quad (41)$$

From the parameters listed above, the exotic fermions, $N_{1,2}$, can be diagonalized by the rotation matrix

$$O = \begin{pmatrix} 0 & 0 & 0.76016 & -0.708196i \\ 0 & 0 & 0.708196 & 0.706016i \\ 0.705976 & -0.708236i & 0 & 0 \\ 0.708236 & 0.705976i & 0 & 0 \end{pmatrix}$$

with mass eigenvalues $M_\chi = \{2.43529, 2.39525, 2.23181, 2.12966\}$ TeV. The physical masses and mixings of the exotic scalar relevant to m_ν and $\Delta a_{e,\mu}$ are:

$$\begin{aligned} M_{R1} &= 1.08369 \text{ TeV}, \quad M_{R2} = 1.10317 \text{ TeV}, \quad \alpha_R = -0.19998, \\ M_{I1} &= 1.08366 \text{ TeV}, \quad M_{I2} = 1.10258 \text{ TeV}, \quad \alpha_I = -0.20637, \\ M_{C1} &= 0.68533 \text{ TeV}, \quad M_{C2} = 1.38841 \text{ TeV}, \quad \alpha_C = 0.76993. \end{aligned}$$

From the above given parameters, the LH Yukawa couplings, y^L , can be solved. On the other hand, $y_{Cs[Rb]}^R$ is determined by the best-fit solution to $(\Delta a_e^{Cs[Rb]}, \Delta a_\mu)$. The Yukawa couplings are found to be:

$$y^L = \begin{pmatrix} -0.045143 & 0.252272 \\ -0.300581 & 0.370544 \\ -0.309633 & -0.143563 \end{pmatrix}, \quad y_{Cs[Rb]}^R = \begin{pmatrix} -3.124[+1.724] & -2.918[+1.610] \\ -5.4584 & -1.1237 \\ 0 & 0 \end{pmatrix} \times 10^{-2}, \quad (42)$$

The predictions of these two benchmark points are listed in Tab.III.

$\Delta a_\mu = +4.617 \times 10^{-10}, \Delta a_\tau = 0$	$\frac{y_{SM}^{eff}}{y_e^{eff}} = -1.773[+2.530]$	$\frac{y_\mu^{eff}}{y_\mu^{SM}} = +1.031$
$\mathcal{B}(\mu \rightarrow e\gamma) = 4.2 \times 10^{-13}$	$\mathcal{B}(\tau \rightarrow e\gamma) = 2.32[0.717] \times 10^{-8}$	$\mathcal{B}(\tau \rightarrow \mu\gamma) = 4.4 \times 10^{-8}$
$\mathcal{B}(h \rightarrow e\mu) = 3.55[1.24] \times 10^{-10}$	$\mathcal{B}(h \rightarrow e\tau) = 1.25[0.379] \times 10^{-7}$	$\mathcal{B}(h \rightarrow \mu\tau) = 2.286 \times 10^{-7}$

TABLE III. Benchmark point predictions for NO and $\Delta a_e = -8.7[4.8] \times 10^{-13}$.

2. Benchmark points–Inverted Ordering

For IO neutrino masses, the variables take the following values:

$$\begin{aligned} \{\theta_{12}, \theta_{23}, \theta_{13}, \Delta m_{21}^2, \Delta m_{32}^2\} &= \{33.13^\circ, 43.67^\circ, 8.31^\circ, 7.318 \times 10^{-5} \text{ eV}^2, -2.469 \times 10^{-3} \text{ eV}^2\}, \\ \frac{v_2}{\sqrt{2}} \times \{\xi_{1L}, \xi_{1R}, \xi_{2L}, \xi_{2R}\} &= \{34.175, 89.898, 168.230, 253.529\} \text{ GeV}, \\ \{\mathcal{D}_{11}, \mathcal{D}_{22}, \mathcal{D}_{12}, \mathcal{D}_{21}\} &= \{2.4416, 2.3928, 0, 0\} \text{ TeV}, \\ \{\widetilde{M}_D, \widetilde{M}_C, \overline{M}_D, \overline{M}_S\} &= \{1.15705, 1.01073, 1.15702, 1.40638\} \text{ TeV}, \\ \{\mu_{DC}, \mu_{DS}, \mu_{12}\} &= \left\{ 3469.71, 67.306, 3.3332 \times \left(\frac{\text{TeV}}{v_2} \right) \right\} \text{ GeV}, \\ \{\overline{\lambda}_{HD}, \lambda_{HD}, \lambda_{HC}\} &= \{2.1959 \times 10^{-3}, 0.1, 0.2\}. \end{aligned} \quad (43)$$

From the parameters listed above, the $N_{1,2}$ can be diagonalized by the rotation matrix⁸

$$O = \begin{pmatrix} 0 & 0.70306 & 0.71113i & 0 \\ 0 & 0.71113 & -0.70306i & 0 \\ 0.70078 & 0 & 0 & 0.71338i \\ 0.71338 & 0 & 0 & -0.70078i \end{pmatrix}$$

with mass eigenvalues $M_\chi = \{2.60403, 2.50388, 2.37981, 2.18227\}\text{TeV}$. The physical masses and mixings of the exotic scalar are:

$$M_{R1} = 1.15684\text{TeV}, M_{R2} = 1.40772\text{TeV}, \alpha_R = -0.02575,$$

$$M_{I1} = 1.15683\text{TeV}, M_{I2} = 1.40535\text{TeV}, \alpha_I = -0.02602,$$

$$M_{C1} = 0.55858\text{TeV}, M_{C2} = 1.43199\text{TeV}, \alpha_C = 0.87725.$$

The Yukawa couplings can be found to be:

$$y^L = \begin{pmatrix} 6.5398 \times 10^{-4} & 8.2975 \times 10^{-2} \\ 0.19400 & -8.099 \times 10^{-3} \\ -0.18533 & -9.022 \times 10^{-3} \end{pmatrix}, y_{Cs[Rb]}^R = \begin{pmatrix} -0.2344[0.1294] & -5.399[+2.979] \\ 9.241 & -0.07156 \\ 0 & 0 \end{pmatrix} \times 10^{-2} \quad (44)$$

for $\Delta a_e^{Cs[Rb]}$. And the resulting predictions are listed in Tab.IV.

$\Delta a_\mu = +6.92 \times 10^{-10}, \Delta a_\tau = 0$	$\frac{y_e^{eff}}{y_e^{SM}} = -3.366[+3.409]$	$\frac{y_\mu^{eff}}{y_\mu^{SM}} = +1.083$
$\mathcal{B}(\mu \rightarrow e\gamma) = 4.2[4.2] \times 10^{-13}$	$\mathcal{B}(\tau \rightarrow e\gamma) = 1.33[0.405] \times 10^{-10}$	$\mathcal{B}(\tau \rightarrow \mu\gamma) = 4.4 \times 10^{-8}$
$\mathcal{B}(h \rightarrow e\mu) = 2.33[0.710] \times 10^{-13}$	$\mathcal{B}(h \rightarrow e\tau) = 2.07[0.632] \times 10^{-9}$	$\mathcal{B}(h \rightarrow \mu\tau) = 7.032 \times 10^{-7}$

TABLE IV. Benchmark point predictions for IO and $\Delta a_e = -8.7[4.8] \times 10^{-13}$.

B. Numerical results and discussion

From the benchmark points, we observe the follows:

- $\mu_{DC} \sim \mathcal{O}(\text{TeV})$, $v_2\xi \lesssim v_0$, and $\mu_{DS}, \mu_{12} \ll v_0$. This is expected because from Fig.1, we have a ball-park estimation

$$\Delta a \sim \frac{y^L y^R}{16\pi^2} \frac{m_l \mu_{DC} v_0 \mathcal{D}}{M^4} [\dots], \quad (45)$$

⁸ The rotation matrix is not block-diagonal because we reorder the eigenstates such that $M_{\chi_1} > M_{\chi_2} > M_{\chi_3} > M_{\chi_4}$.

where M represents the relevant mass scale and $[\dots]$ represent the order one numerical factor of the loop function. Note that the Dirac mass \mathcal{D} is called for the necessary chiral flipping on the internal fermion. So roughly we have

$$\Delta a_l \sim 10^{-10} \left(\frac{m_l}{m_\mu} \right) \left(\frac{\mu_{DC}}{\text{TeV}} \right) \left(\frac{y^R y^L}{0.001} \right) \left(\frac{(\text{TeV})^3}{M^4/\mathcal{D}} \right), \quad l = (e, \mu), \quad (46)$$

and $\mu_{DC} \sim \mathcal{O}(\text{TeV})$ is about right to reproduce the observed $\Delta a_{e,\mu}$.

Similarly, from Fig.2, the back-of-the-envelope estimation for neutrino mass is

$$m_\nu \sim \frac{(y^L)^2 (v_0 v_2)^2 \xi \mu_{DS}^2 \mu_{12}}{16\pi^2 M^6} [\dots]. \quad (47)$$

Here, both μ_{12} and $v_2 \xi$, the Majorana mass insertion on the heavy fermion, are required to break the global lepton number. Plugging in the reasonable values, we have

$$m_\nu \sim 0.4\text{eV} \times \left(\frac{y^L}{0.1} \right)^2 \left(\frac{v_2 \xi}{100\text{GeV}} \right) \left(\frac{\mu_{DS}^2 \mu_{12}}{(10\text{GeV})^3} \right) \left(\frac{(\text{TeV})^5}{M^6/v_2} \right), \quad (48)$$

which agrees with the numerical result that $\sqrt{\mu_{DS} \mu_{12}} \ll v_0$. The consequences are: (1) the χ 's are pseudo-Dirac fermions, (2) $|\alpha_C| \sim \mathcal{O}(1)$, and (3) M_R and M_I are nearly degenerate with $|\alpha_{R,I}| \ll 1$.

- Both Δa_e^{Cs} and Δa_e^{Rb} can be easily fitted by only adjusting y_{11}^R and y_{12}^R while all other parameters kept unchanged. In fact, by tuning up $|y_{11,12}^R|$, $|\Delta a_e|$ can be as large as $\sim \mathcal{O}(10^{-11})$ without affecting Δa_μ and M^ν nor upsetting the current experimental limits in the benchmark points.
- Both $\mathcal{B}(\tau \rightarrow \mu\gamma)$ and $\mathcal{B}(\mu \rightarrow e\gamma)$ nearly saturate the current experimental bounds.
- The resulting $\Delta a_\mu \sim 6 \times 10^{-10}$ is roughly 3σ away from Δa_μ^{FNAL} . This is because Δa_μ is tightly bounded by $\mathcal{B}(\tau \rightarrow \mu\gamma)$ (and $\mathcal{B}(\mu \rightarrow e\gamma)$).
- Also note that $y_{31,32}^R = 0$ which minimizes the CLFV $\mathcal{B}(l_i \rightarrow \gamma l_{j \neq i})$ and it predicts $\Delta a_\tau = 0$ and $y_\tau^{eff} = y_\tau^{SM}$ at one-loop level.
- Since $y_{11,12}^R$ have little constrain from experiment, the effective electron-Higgs Yukawa coupling can be very different from the SM one. On the contrary, the muon-Higgs Yukawa is close to the SM one because the relevant parameters are stringently constrained by $\mathcal{B}(\tau \rightarrow \mu\gamma)$ (and $\mathcal{B}(\mu \rightarrow e\gamma)$).

FIG. 3. The probability histogram of Δa_μ . The yellow(blue) bar is for normal(inverted) hierarchy.

- Comparing with the current limits[10],

$$\mathcal{B}(h_{SM} \rightarrow \tau\mu) < 2.5 \times 10^{-3}, \mathcal{B}(h_{SM} \rightarrow \tau e) < 4.7 \times 10^{-3}, \mathcal{B}(h_{SM} \rightarrow e\mu) < 6.1 \times 10^{-5}, \quad (49)$$

the branching ratios of CLFV Higgs decays $h_{SM} \rightarrow l_i l_{j \neq i}$ are small, $\lesssim 10^{-7}$, and experimentally insignificant.

Besides the displayed four benchmark points, we have generated 3000 viable points for each neutrino mass hierarchy according to the stated scan strategy to better explore the model. In the followings, we present more results and distribution plots extracted from the data sets found in our numerical study.

Fist of all, by using $y_{11,12}^R$ both central values of Δa_e^{Cs} and Δa_e^{Rb} can be well fitted in our model, as have been demonstrated in the benchmark points. On the other hand, the histogram of predicted Δa_μ of our model is shown in Fig.3. The distribution of Δa_μ peaks at around $\sim 4(6) \times 10^{-10}$ for NO(IO) neutrino mass. The largest available Δa_μ is about $\lesssim 5(8) \times 10^{-10}$ for NO(IO) neutrino mass. It is clear that our model cannot reproduce Δa_μ^{FNAL} . This can be understood as following: our radiative neutrino mass generation mechanism implies that $M_{ij}^\nu \sim (\cdots) y_i^L y_j^L$. Similarly, $\Delta a_l \sim (\cdots) y_l^L y_l^R$. Here we use (\cdots) to collectedly denote the numerical factors and summing over all the contributions from the relevant physical masses and mixings. So roughly speaking, it is expected that

$$\begin{aligned} \mathcal{B}(\mu \rightarrow e\gamma) &\sim |(\cdots) y_2^R y_1^L|^2 + |(\cdots) y_1^R y_2^L|^2, \\ &\sim \frac{M_{11}^\nu}{M_{22}^\nu} \left[(\cdots) (\Delta a_\mu)^2 + (\cdots) \left(\frac{M_{22}^\nu}{M_{11}^\nu} \Delta a_e \right)^2 \right] \sim \frac{M_{11}^\nu}{M_{22}^\nu} (\cdots) (\Delta a_\mu)^2. \end{aligned} \quad (50)$$

Since $|\Delta a_\mu| \gg |\Delta a_e|$, the second term is dropped in the last approximation. Likewise,

$$\mathcal{B}(\tau \rightarrow \mu\gamma) \sim |(\cdots) y_2^R y_3^L|^2 \sim (\cdots) \frac{M_{33}^\nu}{M_{22}^\nu} (\Delta a_\mu)^2, \quad (51)$$

$$\mathcal{B}(\tau \rightarrow e\gamma) \sim |(\cdots) y_1^R y_3^L|^2 \sim (\cdots) \frac{M_{33}^\nu}{M_{11}^\nu} (\Delta a_e)^2. \quad (52)$$

From the above, we expect that $\Delta a_\mu^{NO} \sim \Delta a_\mu^{IO}$ due to the ratio $M_{33}'/M_{22}' \sim 1$ for both cases. Because of the M_{33}'/M_{11}' factor, the branching ratio of $\mathcal{B}(\tau \rightarrow e\gamma)$ in NO is expected to be larger than that in the IO. For the precise evaluation, we definitely must consult the full numerical study.

As shown in the benchmark points previously, the CLFV branching ratios $\mathcal{B}(\mu \rightarrow e\gamma)$ and $\mathcal{B}(\tau \rightarrow \mu\gamma)$ nearly saturate the current experimental upper bounds. We define two dimensionless variables,

$$L_{\mu e} \equiv \frac{\mathcal{B}(\mu \rightarrow e\gamma)_{c.l.}}{\mathcal{B}(\mu \rightarrow e\gamma)_{f.l.}}, \quad L_{\tau\mu} \equiv \frac{\mathcal{B}(\tau \rightarrow \mu\gamma)_{c.l.}}{\mathcal{B}(\tau \rightarrow \mu\gamma)_{f.l.}}, \quad (53)$$

to characterize the sensitivity improvement of the future experimental bounds, and the subscription “c.l.(f.l.)” stands for the current(future) limit. We use the benchmark points to explore the

FIG. 4. The dependence of Δa_μ (in unit of 10^{-10}) on $L_{\mu e}$ and $L_{\tau\mu}$. The left(right) panel is for the NO(IO) benchmark point. The horizontal dash line represents the projected reach of MEGII[76], $\mathcal{B}(\mu \rightarrow e\gamma) < 6 \times 10^{-14}$ or $L_{\mu e} = 7.0$.

dependence of Δa_μ on $L_{\mu e}$ and $L_{\tau\mu}$ by varying the L values. From Fig.4, it is clear that Δa_μ is mainly controlled by $L_{\tau\mu}$, and $\Delta a_\mu \propto \sqrt{L_{\tau\mu}}$ as expected in Eq.(51). In some parameter space, as in the IO benchmark point, both $L_{\mu e}$ and $L_{\tau\mu}$ place comparable constraint on Δa_μ . The projection limit on $\mathcal{B}(\tau \rightarrow \mu\gamma)$ by Belle II is $\sim 10^{-9}$ [77], or $L_{\tau\mu} \sim 42$. If no CLFV $\tau \rightarrow \mu\gamma$ transition is observed before reaching that sensitivity, our model predicts $\Delta a_\mu \lesssim 1 \times 10^{-10}$.

On the other hand, $\mathcal{B}(\tau \rightarrow e\gamma)$ can be much below the current limit, $< 3.3 \times 10^{-8}$ [10], for IO while it is close to the current experimental constraint for NO. The numerical result, as shown in Fig.5, agrees with our naive expectation, Eq.(52), that $\mathcal{B}(\tau \rightarrow e\gamma)_{NO} > \mathcal{B}(\tau \rightarrow e\gamma)_{IO}$. Therefore, $\mathcal{B}(\tau \rightarrow e\gamma)$ could serve as an indirect probe to determine the type of neutrino mass hierarchy in our model.

In Fig.6, another observed correlation between Δa_μ and θ_{23} is displayed. This correlation can be understood as follows. Note that increasing θ_{23} , while keeping all other neutrino oscillation

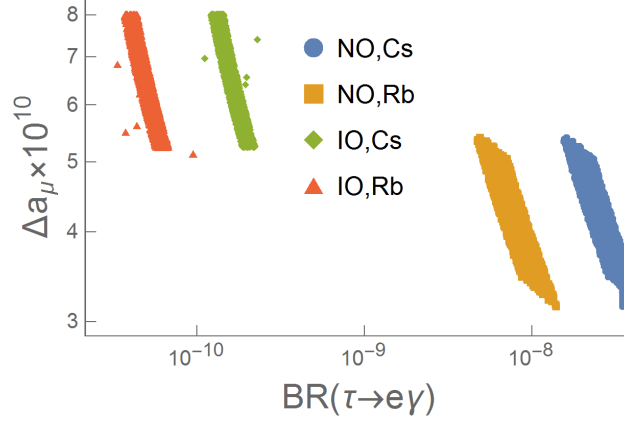

FIG. 5. Correlation between $\mathcal{B}(\tau \rightarrow e\gamma)$ and Δa_μ . The blue, orange, green, and red points stand for NO Δa_μ^{Cs} , NO Δa_μ^{Rb} , IO Δa_μ^{Cs} , and IO Δa_μ^{Rb} respectively.

parameters unchanged, results to a larger(smaller) M_{22}^ν for NO(IO) neutrino masses. On the other hand, since $M_{22}^\nu \propto (y_2^L)^2$ and $\Delta a_\mu \propto y_2^L y_2^R$, the observed correlation follows. Back to

FIG. 6. Correlation between θ_{23} and Δa_μ . The blue(orange) dots stand for NO(IO) viable points.

Fig.5, it is clear that $\mathcal{B}(\tau \rightarrow e\gamma)$ anti-correlates with Δa_μ for both neutrino mass hierarchy. It is because increasing θ_{23} leads to smaller(larger) M_{33}^ν (thus y_3^L) for NO(IO). So together with the positive(negative) correlation between $\Delta a_\mu^{NO[IO]}$ and θ_{23} , Fig.6, $\mathcal{B}(\tau \rightarrow e\gamma) \propto |y_3^L y_1^R|^2$ always anti-correlates with Δa_μ .

From all the viable points we found the effective muon-Higgs Yukawa coupling is close to the SM one. The range of the normalized muon-Yukawa, ζ_μ , is roughly between 0.98 – 1.05. The distribution variance of IO is slightly larger than NO, but both peak at around 1.005, as seen in Fig.7. It is well within the current 2σ constraint, $0.6 \lesssim \zeta_\mu \lesssim 1.5$ [6, 7]⁹. For the future updates of

⁹ Note that the $h_{SM}-g-g$ vertex does not change from the SM prediction at 1-loop level in our model. Therefore, from the signal strength μ_μ for $pp \rightarrow h_{SM} \rightarrow \mu\mu$, the ζ_μ value is simply estimated as $\zeta_\mu \simeq \sqrt{\mu_\mu}$.

FIG. 7. The probability histogram of the predicted normalized Higgs muon-Yukawa.

FIG. 8. The left/right panel is the scattered plot of Δa_μ v.s. $\log_{10}(|\zeta_\mu - 1|)$ for the NO/IO case. The vertical lines, from right to left, indicate the projected sensitivity[78] at CEPC[80], ILC[81]/CLIP[82], HL-HLC(red), and FCC[79](black), respectively.

ζ_μ [78], we also show the scatter plot of Δa_μ vs ζ_μ in Fig.8. It is clear that ζ_μ weakly correlates with Δa_μ , and roughly half of the parameter space can be probed at the future FCC[79] with a projected precision of $\sim 0.4\%$ on muon-Yukawa.

Interestingly, this model predicts a possible unconventional electron-Higgs Yukawa coupling. This is due to $|\delta M_{ee}^{loop}| \gtrsim m_e$, and that can be traced back to the less constrained $y_{11,12}^R$. From Fig.9, it is clear that the magnitude of electron-Higgs Yukawa could be one order of magnitude larger than the SM prediction. The projected sensitivity, $|\zeta_e| < 1.6$ at 95% CL, at FCC-ee[83] is shown as the vertical dashed line. For the case of Δa_e^{CS} , the sign of electron-Higgs Yukawa could even be negative. However, the sign determination requires an interference with the tiny electron-Higgs Yukawa coupling, and thus very challenging in the foreseeable future.

In summary, from our numerical study, the viable model parameter space only requires (1)

FIG. 9. ζ_e v.s. ζ_μ . The vertical dashed lines indicate the projected sensitivity at FCC-ee[83].

Majorana masses \ll Dirac masses \sim TeV, and (2) order 1(0.1) mixings among charged(neutral) scalars. Since we take a bottom-up approach, this model cannot address the pattern of neutrino mass matrix. It is taken as the experimental input. However, we find that the hierarchy among the model parameters y^L 's and y^R 's is less than 5 orders of magnitude for most of the cases. Thus, this model is technically natural, and no extreme fine-tuning is required to accommodate the neutrino oscillation data and $\Delta a_e^{Cs[Rb]}$.

IV. DISCUSSION AND PHENOMENOLOGY

SM Higgs decay

Due to the violation of lepton number, we also have $h_{SM} \rightarrow \nu_i \nu_j^c$ decays generated at one-loop level. By dimensional analysis, the effective $h_{SM}-\nu_i-\nu_j^c$ Yukawa coupling can be estimated to be $\sim \frac{1}{4\pi^2} \frac{m_\nu}{M}$, where M is the typical mass of exotic degrees of freedom. The coupling strength is then $\sim \mathcal{O}(10^{-15})$ if taking $M \sim \mathcal{O}(1\text{TeV})$, and being experimentally insignificant. Since we assume all the exotic DOF's are heavier than 0.5TeV, there is no modification to the SM invisible Higgs decay width either. Because all new fields in our model are color singlet, the ggh_{SM} vertex does not receive any correction at 1-loop level.

However, the two additional charged scalars contribute to di-photon Higgs decay width. The decay width is given by[84, 85]

$$\Gamma_{\gamma\gamma} = \frac{G_F \alpha_{em}^2 M_{h_{SM}}^3}{128\sqrt{2}\pi^3} \left| \frac{4}{3} F_{1/2}(\tau_t) + F_1(\tau_W) + \sum_{a=1}^2 \frac{v_0 \tilde{\mu}_{aa}}{2M_{C_a}^2} F_0(\tau_{C_a}) \right|^2, \quad (54)$$

where $\tilde{\mu}_{aa}$ is the charged scalar-Higgs cubic coupling given in Eq.(29). The $F_{1/2}$ and F_0 terms are the dominate SM 1-loop contributions from top quark and W^\pm boson, respectively. We define

$\tau_i = (M_{h_{SM}}/2M_i)^2$, and the one-loop functions are given by

$$F_0(x) = \frac{f(x) - x}{x^2}, \quad F_{1/2}(x) = \frac{2[x + (x-1)f(x)]}{x^2}, \quad F_1(x) = -\frac{2x^2 + 3x + 3(2x-1)f(x)}{x^2}, \quad (55)$$

with $f(x) = [\arcsin(\sqrt{x})]^2$ for $x < 1$. For $x \ll 1$, $F_0(x) \sim \frac{1}{3} + \frac{8}{45}x$. Plugging in the masses of top, W^\pm , and h_{SM} , we have $F_{1/2}(\tau_t) = 1.38$ and $F_1(\tau_W) = -8.32$. Assuming that $\mu_{DC} \gg v_0$, we have approximately $\tilde{\mu}_{11} \sim -2s_\alpha c_\alpha \mu_{DC}$ and $\tilde{\mu}_{22} \sim +2s_\alpha c_\alpha \mu_{DC}$. So the width becomes

$$\Gamma_{\gamma\gamma} \simeq \frac{G_F \alpha_{em}^2 M_{h_{SM}}^3}{128\sqrt{2}\pi^3} \left| (-6.49)_{SM} - \frac{1}{3} \left(\frac{v_0 \mu_{DC}}{M_{C_1} M_{C_2}} \right)^2 \right|^2. \quad (56)$$

It is clear that $\Gamma_{\gamma\gamma}/\Gamma_{\gamma\gamma}^{SM} > 1$. Assuming $M_{C_1} = 0.5\text{TeV}$ and $\mu_{DC} \simeq M_{C_2}$, then the NP will only modify the di-photon decay width by a magnitude $\sim 2\%$. Comparing to the latest coupling scaling factor $\kappa_\gamma = 1.06 \pm 0.05$ obtained by [86], we expect a weak constraint on this model from the Higgs diphoton decay.

CLFV $\mu \rightarrow e$ conversion, and $\mu \rightarrow 3e$

Concerning on the other CLFV experimental bounds on the model parameter space, we comment on the μ - e conversion on nuclei and $\mu \rightarrow 3e$.

For μ - e conversion on nuclei, the current upper bound of the ratio of $\mu \rightarrow e$ conversion rate normalized to the muon capture rate[87],

$$R_{\mu e} = \frac{\Gamma(\mu + (A, Z) \rightarrow e + (A, Z))}{\Gamma(\mu + (A, Z) \rightarrow \nu_\mu + (A, Z-1))} < 7 \times 10^{-13}, \quad (57)$$

is given by SINDRUM II with gold as target[88]. Since the hidden sector does not couple to the SM quark sector, the $\mu \rightarrow e$ conversion is dominated by the $\mu e \gamma$ dipole. For a given target nuclei N , the $\mu \rightarrow e$ conversion rate can be expressed as

$$\Gamma_{\mu \rightarrow e} \sim \pi D_N^2 \Gamma_\mu \mathcal{B}(\mu \rightarrow e \gamma), \quad (58)$$

where $\Gamma_\mu = 0.45517 \times 10^6 s^{-1}$ [10] is the muon decay rate, and D_N is the lepton-nucleus overlap integral coefficient. For gold and aluminum, $D_{Au} = 0.189$ and $D_{Al} = 0.0362$ [89], while the muon capture rates are $13.07 \times 10^6 s^{-1}$ and $0.71 \times 10^6 s^{-1}$, respectively[89, 90]. Plugging in the values of Γ_μ and the current upper limit of $\mathcal{B}(\mu \rightarrow e \gamma)$, one finds $R_{\mu e} < 10^{-15}$ with Au or Al target, roughly three orders of magnitude below the current experimental limit. In the near future, the model prediction, Eq.(58), could be checked with improved sensitivity[91–94].

FIG. 10. The box diagram for $\mu \rightarrow 3e$ transition, where $a, b \in \{1, 2\}$ and $i, j \in \{1, 2, 3, 4\}$.

In this model, $\mu \rightarrow 3e$ can be induced by the CLFV $\mu e \gamma$ dipole coupling and the box diagram shown in Fig.10. The contribution from the $\mu e \gamma$ dipole can be calculated to be [73, 87, 95]

$$\Gamma(\mu \rightarrow 3e)_{dip} \simeq \frac{2\alpha_{em}}{3\pi} \left[\ln \frac{m_\mu}{m_e} - \frac{11}{8} \right] \Gamma(\mu \rightarrow e\gamma). \quad (59)$$

This part is about three orders of magnitude below the current bound of $\mathcal{B}(\mu \rightarrow 3e) < 10^{-12}$ [96]. In addition to the dipole contribution, the box-diagram gives rise to FCNC 4-fermi interactions [73]:

$$\mathcal{L} \supset -\frac{4G_F}{\sqrt{2}} \left[g_1 (\bar{e} \hat{L} \mu) (\bar{e} \hat{L} e) + g_3 (\bar{e} \gamma^\alpha \hat{R} \mu) (\bar{e} \gamma_\alpha \hat{R} e) + g_5 (\bar{e} \gamma^\alpha \hat{R} \mu) (\bar{e} \gamma_\alpha \hat{L} e) + (\hat{L} \Leftrightarrow \hat{R}) \right] + H.c., \quad (60)$$

and leads to

$$\mathcal{B}(\mu \rightarrow 3e)_{4fermi} \simeq \frac{|g_1|^2}{8} + 2|g_3|^2 + |g_5|^2 + (\hat{L} \Leftrightarrow \hat{R}), \quad (61)$$

if ignoring the interference between the dipole and 4-fermi interactions. By dimension analysis, the dimensionless Wilson coefficients can be estimated as

$$|g| \sim \frac{1}{16\pi^2} \frac{\sqrt{2}}{4G_F} \frac{Y_e^3 Y_\mu}{M^2} \times (0.5), \quad (62)$$

where M is the relevant highest mass in the loop, 0.5 is the typical value from the box-diagram loop integration, and $Y_e^3 Y_\mu$ denotes the product of four relevant LH or RH Yukawa couplings. Thus, $\mathcal{B}(\mu \rightarrow 3e)_{4fermi} \simeq 10^{-15} (2\text{TeV}/M)^4 (Y_e^3 Y_\mu / 0.001)^2$ is also expected to be safely below the current experimental limit. The $\mu \rightarrow 3e$ decay could be a relevant constraint and probed by the planned Mu3e experiment with a sensitivity of 10^{-16} [97] in the near future. For CLFV $\tau \rightarrow l_i l_j l_k$ ($l_{i,j,k} = e, \mu$) decay branching ratios, the current bounds, $(\text{a few}) \times 10^{-8}$ [98], and the future $\sim 10^{-10}$ sensitivity [77, 99, 100] do not post further constraint on this model.

Z_X : The smoking gun of the gauge $U(1)_X$

One robust prediction of gauge $U(1)_X$ is the existence of the gauge boson, Z_X . The direct detection of Z_X will be the smoking gun of the gauge $U(1)_X$. Here we give a brief remark on the

prospects on its discovery. As discussed earlier, after S_2 acquires a VEV v_2 , Z_X also acquires a mass $M_{Z_X} = 2g_X v_2$. But Z_X does not play any role in our flavor physics discussion. So far, both the gauge coupling g_X and M_{Z_X} are unknown free parameters. Although Z_X does not couple to any of the SM fields at tree-level, its couplings to $\gamma Z, ZZ, W^+W^-, h_{SM}h_{SM}, \gamma h_{SM}, Zh_{SM}$, and lepton pairs can be generated at one-loop level. Also, the one-loop vacuum polarization diagrams can generate the Z_X - Z and Z_X - γ mixings. The Z_X - Z and Z_X - γ mixings can also be induced through the tree-level kinematic mixing between the field strengths of $U(1)_X$ and $U(1)_Y$, $\mathcal{L} \supset -\frac{\epsilon}{2} B^{\mu\nu} X_{\mu\nu}$, see [101–103]. Since the kinematic mixing term is gauge invariant and renormalizable, ϵ is not required to be small. The kinematic mixing term can be rotated away by a $GL(2)$ transformation, and the two massive eigenstates couple to SM fields. From electroweak precision measurements, $h_{SM} \rightarrow ZZ_X$, and the Drell-Yan process, the mixing is constrained to be $\epsilon \lesssim 10^{-2}$ for $10 \text{ GeV} \lesssim M_{Z_X} \lesssim 1 \text{ TeV}$ [104]. In the future, the HL-LHC and HE-LHC can probe the effective mixing to the level about $\sim 10^{-3}$ for $10 \text{ GeV} \lesssim M_{Z_X} \lesssim 90 \text{ GeV}$ and $0.2 \text{ TeV} \lesssim M_{Z_X} \lesssim 2 \text{ TeV}$ [104]. In this model, the ϵ parameter is the combination of tree-level and 1-loop contributions. Moreover, the Z_X to lepton pair couplings receive flavor dependent quantum corrections. At the LHC, the Drell-Yan processes $pp \rightarrow Z^* \rightarrow ZZ_X$, or $pp \rightarrow W^* \rightarrow WZ_X$ will be the dominate Z_X production mechanism for $M_{Z_X} \gtrsim 180 \text{ GeV}$. And the decays $Z_X \rightarrow l_i^+ l_j^-$ with di-lepton invariant mass peaked at around $m_{l_i l_j} \simeq M_{Z_X}$ will be the clear signal. Incidentally, in this model the CLFV di-lepton decay connects to the flavor physics that we have discussed. A comprehensive study on this topic is beyond the scope of this paper, and we will leave it to the future works.

Dark matter

Finally, we give a sketchy discussion on DM in this model. After the SSB of $U(1)_X$ by S_2 , the remaining gauge discrete parity[43] stabilizes the the lightest neutral DOF carrying one unit of $U(1)_X$ charge. Apparently, this DOF is a DM candidate. There are two possible candidates in our model: (1) S_D , the lighter of R_1 and I_1 , and (2) χ_4 , the lightest mass eigenstate of the exotic fermions. From our numerical scan, about $\sim 70(30)\%$ of the solutions yield scalar(fermionic) DM candidate. And about $\sim 90\%$ of the potential DM mass is in the range of $[0.5, 1.0] \text{ TeV}$. For a DM in that mass range, the current observational upper limits on the spin-independent DM-nucleon cross section is $\sigma_{SI} \lesssim 10^{-46} (cm)^2$ [105–107]. In our model, both S_D and χ_4 do not couple to the SM quark sector at tree-level and all the new DOFs are color singlets. Hence, for both DM candidates the σ_{SI} can be easily arranged to stay below the direct detection bounds.

If χ_4 is the DM candidate, the relic density is determined mainly by t - and u -channel annihilation $\chi_4\chi_4 \rightarrow l\bar{l}$ ($l = l^-, \nu$), and the s -channel $\chi_4\chi_4 \rightarrow h_2$ or $h_{SM} \rightarrow (SM)(SM)$ processes, where (SM) stands for any SM field coupled to the SM Higgs. On the other hand, for the bosonic DM case, the relic density is mainly controlled by the $S_D S_D \rightarrow h_{SM} h_{SM}$, $S_D S_D \rightarrow h_2$ or $h_{SM} \rightarrow (SM)(SM)$, and $S_D S_D \rightarrow W^+ W^-, ZZ$. One needs to take into account the co-annihilation $R_1 I_1 \rightarrow (SM)(SM)$ when R_1 and I_1 are nearly degenerate.

It should be emphasised that although the DM candidate is stable, phenomenology only demands that its relic density must not exceed the observed DM relic density, $\Omega_{DM} h^2 = 0.120 \pm 0.001$ [108]. However, the full evaluation of the relic density requires more model parameters which are independent of the flavor physics we are focusing on, and the comprehensive analysis of the extended parameter space is beyond the scope of this paper.

V. CONCLUSION

Motivated by the recently measured anomalous magnetic moments of muon and electron, we studied a model with gauge hidden $U(1)_X$ symmetry as the unified framework to accommodate both the radiative neutrino mass generation mechanism and the measured $\Delta a_{\mu,e}$. This UV-complete model employs four exotic scalars and a minimum of two pairs of exotic vector fermions, all charged under $U(1)_X$, as seen in Table-I. The $U(1)_X$ is assumed to be spontaneously broken at an energy scale higher than the SM electroweak scale when one of the exotic singlet bosons gets a non-zero VEV. After the SSB of $U(1)_X$, the new fermions acquire Majorana masses, which are crucial to the radiative neutrino mass generation. Moreover, the new vector fermions admit tree-level Dirac masses which are essential for chirality flipping in explaining Δa_l .

Any mechanism that gives rise to charged lepton anomalous magnetic moments could potentially lead to CLFV which are stringently constrained by experiments. Usually, additional flavor symmetries or assumptions are summoned to suppress the unwanted CLFV. Contrarily, in this work we took a bottom-up approach and asked what restrictions the experimental constraints would impose upon the model parameter space. We have carefully taken into account the neutrino oscillation data and the experimental CLFV limits in our numerical study. We found that the model can explain the observed neutrino oscillation data, either normal or inverted ordering, and the central value of $\Delta a_e^{Cs[Rb]}$ without much fine-tuning on the model parameters. However, in the minimal model, the current experimental CLFV limit on $\mathcal{B}(\tau \rightarrow \mu\gamma) < 4.4 \times 10^{-8}$ [75] results in $\Delta a_\mu \sim (4 - 8) \times 10^{-10}$, which differs from $\Delta a_\mu^{FNAL} \simeq (25.1 \pm 5.9) \times 10^{-10}$ [20] by $\sim 3\sigma$'s, but

agrees with the SM prediction using the recent lattice QCD evaluation on hardronic contribution to a_μ [22, 23]. Of course, more theoretical and experimental investigations are needed to settle down the Δa_μ issue. We pointed out that the future improvement on the CLFV limit will further suppress our predicted Δa_μ because of $(\Delta a_\mu)^2 \propto \mathcal{B}(\tau \rightarrow \mu\gamma)$ in our model.

The unconventional electron-Higgs Yukawa is another intriguing feature of this model. We found that the magnitude of electron-Higgs Yukawa can be one order of magnitude larger than the SM prediction. This unusual electron Yukawa can be probed at the future FCC-ee[83]. More interestingly, if Δa_e^{Cs} is confirmed in the future, a negative electron-Higgs Yukawa could be allowed in this model. Due to the smallness of electron-Higgs Yukawa, the determination of its sign is extremely challenging in the foreseeable future. On the other hand, the muon-Higgs Yukawa is found to be close to the SM prediction with the deviation fraction $\lesssim 10^{-2}$ for most of the viable model parameter space. Although the deviation of muon-Higgs Yukawa is small, it could be probed at the FCC with a projected precision of $\sim 0.4\%$ [78].

Since our approach is bottom-up, the prediction $\Delta a_\mu < \Delta a_\mu^{FNAL}$ is robust and applies to the minimal model with arbitrary add-on flavor symmetry. One has to go beyond the minimal model if the deviation between the experimentally and theoretically improved Δa_μ and the model prediction persists, or a few $\times 10\%$ muon Yukawa deviation is confirmed in the future. If that is the case, a trivial extension of this model by utilizing the third pair of vector fermion will do the job, and an even more enormous electron-Higgs Yukawa coupling strength is possible.

From the exercise, we have demonstrated that due to the smallness of the SM electron Yukawa, the effective electron-Higgs coupling strength is sensitive to new physics and plays a vital role in testing our understanding of flavor physics.
