## Abstract

In crystalline materials, electron-phonon coupling (EPC) is a ubiquitous many-body interaction that drives conventional Bardeen-Cooper-Schrieffer (BCS) superconductivity. Recently, in a new kagome metal CsV<sub>3</sub>Sb<sub>5</sub>, superconductivity that possibly intertwines with time-reversal and spatial symmetry-breaking orders is observed. Density functional theory calculations predicted weak EPC strength,  $\lambda$ , supporting an unconventional pairing mechanism in CsV<sub>3</sub>Sb<sub>5</sub>. However, experimental determination of  $\lambda$  is still missing, hindering a microscopic understanding of the intertwined ground state of CsV<sub>3</sub>Sb<sub>5</sub>. Here, using 7-eV laser-based angle-resolved photoemission spectroscopy and Eliashberg function analysis, we determine an intermediate  $\lambda$ =0.45~0.6 at *T*=6 K for both Sb 5*p* and V 3*d* electronic bands, which can support a conventional superconducting transition temperature on the same magnitude of experimental value in CsV<sub>3</sub>Sb<sub>5</sub>. Remarkably, the EPC on the V 3*d*-band enhances to  $\lambda$ ~0.75 as the superconducting transition temperature elevated to 4.4 K in Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub>. Our results provide an important clue to understand the pairing mechanism in the kagome superconductor CsV<sub>3</sub>Sb<sub>5</sub>.

#### Introduction

The kagome lattice, made of corner-shared triangles, is an exciting platform for emergent quantum phenomena<sup>1-3</sup>. Due to the wavefunction interference, the electronic structure of the kagome lattice features flat band, Dirac fermion, and van Hove singularities that result in a rich interplay between topology, geometry, and correlations<sup>4,5</sup>. For kagome metals near the van Hove singularities, the high density of states combining with the frustrated lattice geometry are predicted to support novel electronic orders<sup>6-8</sup>. Recently, in a topological kagome metal CsV<sub>3</sub>Sb<sub>5</sub>, superconductivity that possibly intertwines with charge density wave (CDW)<sup>9-12</sup> (Fig. 1a), nematicity<sup>13-16</sup> and loop current<sup>17,18</sup> is observed. To date, the origin of superconductivity and its interplay with the other symmetry-breaking orders remain rigorous debate. Angle-resolved photoemission spectroscopy (ARPES) studies<sup>19,20</sup> observed multiple van Hove singularities from V 3*d*-electrons near the Fermi level (*E*<sub>F</sub>), highlighting electronic driven instabilities<sup>6,8</sup> (Fig. 1b). Furthermore, the density functional theory (DFT) calculated EPC strength<sup>21</sup>,  $\lambda$ ~0.25, in CsV<sub>3</sub>Sb<sub>5</sub> fails to support the superconducting transition temperature<sup>9</sup>, *T*<sub>c</sub>~2.6 K, indicating unconventional pairing mechanism. However, a recent ARPES study of a cousin compound KV<sub>3</sub>Sb<sub>5</sub> revealed a clear kink<sup>22</sup> in the

electronic band structure near the van Hove singularity, suggesting a moderate EPC. Therefore, an experimental estimation of orbital- and momentum-dependent  $\lambda$  and its possible connection with superconductivity are highly desired to understand the nature of the superconductivity in CsV<sub>3</sub>Sb<sub>5</sub>. Here we experimentally extract the orbital- and momentum-dependent  $\lambda_{p,d}(\mathbf{k})$  by determining the EPC-induced kinks in the electronic band structure. Our results reveal an intermediate EPC with  $\lambda$ =0.45~0.6 in CsV<sub>3</sub>Sb<sub>5</sub>, which can support a  $T_c$  on the same magnitude of the experimental value. Intriguingly, we find that  $\lambda_d$  is enhanced by about 50% in the isovalentsubstituted Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> with an elevated  $T_c = 4.4$  K. Our results suggest that EPC can play an important role on the superconductivity in CsV<sub>3</sub>Sb<sub>5</sub>.

## Results

Figures 1a and 1c show the crystal structure and Fermi surface (FS) topology of CsV<sub>3</sub>Sb<sub>5</sub>, respectively. In agreement with previous DFT and ARPES studies<sup>12,19-21</sup>, the Sb 5*p*-band forms a circular FS, marked as  $\alpha$ , at the BZ center and the V 3*d*-bands yield hexagonal and triangle FSs, marked as  $\beta$  and  $\delta$  in Fig. 1c, respectively. Figure 1d shows a typical ARPES intensity plot of the  $\alpha$  band corresponding to the black cut shown in Fig. 1c. The coupling between electrons and bosonic modes is manifested by the intensity and dispersion anomalies, known as kink<sup>23,24</sup>, near a binding energy *E*<sub>B</sub>~32 meV. This many-body effect can be quantified by fitting the ARPES momentum distribution curves (MDCs) with a Lorentzian function<sup>25</sup>:

$$I(\boldsymbol{k},\omega) \propto A(\boldsymbol{k},\omega) = \frac{1}{\pi} \frac{\mathrm{Im}\Sigma(\omega)}{(\omega - \varepsilon(\boldsymbol{k}) - \mathrm{Re}\Sigma(\omega))^2 + \mathrm{Im}\Sigma(\omega)^2} \qquad (1),$$

where  $\text{Re}\Sigma(\omega=E-E_F)$  and  $\text{Im}\Sigma(\omega=E-E_F)$  are the real and imaginary parts of the single-particle selfenergy.  $\varepsilon(\mathbf{k})$  is the non-interacting bare band that can be approximated as a liner dispersion crossing  $E_F^{23}$ . Figure 1e demonstrates the extracted self-energy of the  $\alpha$  band. We subtract a linear bare band from the experimentally extracted band to obtain  $\text{Re}\Sigma(\omega)$  (see supplementary note 1). To extract the electron-boson coupling induced  $\text{Im}\Sigma(\omega)$ , the electron-electron and electron-impurity scatterings induced self-energy effects are removed, as suggested by previous practices<sup>23,26</sup> (see supplementary note 2). At  $E_B \sim 32$  meV, a peak near in  $\text{Re}\Sigma(\omega)$  and a step jump in  $\text{Im}\Sigma(\omega)$  prove strong many-body interactions. Since the self-energy anomalies persist above CDW transition temperature  $T_{\text{CDW}}$  (supplementary Fig. S7), we attribute the self-energy anomaly to EPC. Figures 2a-2c compare the EPC-induced kinks on the  $\alpha$  and  $\beta$  bands at 6 K. The ARPES intensity plots of the  $\alpha$  and  $\beta$  bands shown in Fig. 2b correspond to the black cuts in Fig. 2a. While the kink near  $E_B\sim32$  meV is clear on both the  $\alpha$  and  $\beta$  bands, an additional kink is observed at a lower  $E_B\sim12$  meV on the  $\beta$  band (Fig. 2c). The 12-meV kink is also prominent in Re $\Sigma(\omega)$ . As we show in Fig. 2d, Re $\Sigma(\omega)$  of the  $\beta$  band shows a peak near  $E_B\sim12$  meV, proving strong *d*-electron-phonon coupling near 12 meV. In contrast, Re $\Sigma(\omega)$  of the  $\alpha$  band only shows a broad shoulder.

The observation of clear EPC effects on both 5*p* and 3*d* bands points to a non-neglectable role of EPC for superconductivity in CsV<sub>3</sub>Sb<sub>5</sub>. To test the EPC-driven superconductivity, we extract the Eliashberg function,  $\alpha^2 F(\omega)$ , at *T*=6 K, slightly above *T*<sub>c</sub>, using the maximum entropy method<sup>27,28</sup> (see methods). A fit of the Re $\Sigma(\omega)$  and the extracted  $\alpha^2 F(\omega)$  are shown in Fig. 2d and 2e, respectively.  $\lambda$  and the logarithmic mean phonon frequency are obtained via<sup>28,29</sup>:

$$\lambda = 2 \int_0^{\omega_{max}} \left[ \frac{\alpha^2 F(\omega)}{\omega} \right] d\omega \qquad (2),$$
$$\ln \omega_{log} = 2/\lambda \int_0^{\infty} \ln \omega \left[ \frac{\alpha^2 F(\omega)}{\omega} \right] d\omega \qquad (3),$$

where  $\omega_{max}$  is the maximum frequency of the phonon spectrum. As shown in Fig. 2e, the orbital dependence of the EPC is mirrored in the different shapes of  $\alpha^2 F(\omega)$ , where phonon modes near 32 meV are accounted for 70% of the total EPC strength on the  $\alpha$  band,  $\lambda_p$ , but less than 50% for the EPC strength on the  $\beta$  band,  $\lambda_d$ . Interestingly, due to the spectral weight redistribution in  $\alpha^2 F(\omega)$  (shaded area in Fig. 2e), the extracted  $\lambda_p$  and  $\lambda_d$  are similar with  $\lambda_{p,d} \sim 0.45 \pm 0.05$ . We also employed the MEM fits to the extracted Im $\Sigma(\omega)$ , which yields a  $\lambda$  consistent with the Re $\Sigma(\omega)$  fits (see supplementary note 4 and Fig. S2). Theoretically,  $\lambda$  can approximately be derived from a simpler approach<sup>29</sup> following  $\lambda_{dev} = -\partial Re \Sigma(\omega)/\partial \omega|_{\omega=E_F} \cong \lambda$ , when T is far lower than the Debye temperature. At T = 6 K, this method yields a  $\lambda_{dev} \sim 0.6 \pm 0.1$ , qualitatively consistent with Eq. (2) within the experimental uncertainty (Fig. 3f).

Generally, EPC can exhibit momentum dependence. Figure 3 summarizes the momentumdependent kinks on the  $\alpha$  and  $\beta$  bands. The ARPES intensity plots and extracted band dispersions along representative directions are shown in Figs. 3a, 3b and Figs. 3d, 3e, respectively (see supplementary Fig. S3 for complete dataset). The extracted  $\lambda_{dev}(\mathbf{k})$  for the  $\alpha$  and  $\beta$  bands of two independent samples (supplementary Fig. S4) are summarized in Fig. 3f, which shows a nearly isotropic behavior within experimental uncertainties.

The orbital- and momentum-dependent results demonstrate that the EPC strength  $\lambda$  in CsV<sub>3</sub>Sb<sub>5</sub> falls in the intermediate range of 0.45~0.6, which is about 2 times larger than the previous DFT predicted  $\lambda_{DFT}$ ~0.25 (ref<sup>21</sup>). Using McMillan's formula<sup>30</sup> and taking the lower and upper limits of the experimentally estimated  $\lambda$  and the logarithmic mean phonon frequency ~17.1 meV obtained from Eq. (3), we derive  $T_c$  in a range from 0.8 K to 3 K (see supplementary note 6). The upper limit is comparable to the experimentally determined  $T_c$  in CsV<sub>3</sub>Sb<sub>5</sub> (Fig. 4a). We shall note that the CDW gap near the M point<sup>20,31</sup> (supplementary Fig. S6f) flattens the  $\delta$  bands near  $E_F$ , hindering the precise estimation of EPC strength. However, strong self-energy anomalies are observed on the  $\delta$  bands and they have the same energy scales as the  $\alpha$  and  $\beta$  bands (supplementary Fig. S6).

As shown in Figs. 4a and 1a,  $T_c$  of CsV<sub>3</sub>Sb<sub>5</sub> is increased with chemical substitutions or external pressure<sup>32-35</sup>. We thus continue to examine the EPC in a 7% Nb-doped Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> with  $T_c \sim 4.4 \text{ K}^{34}$ . Electronic Kinks are observed on both the  $\alpha$  and  $\beta$  bands as shown in Fig. 4b for the ARPES intensity plots and Fig. 4c for the extracted band dispersions. Figure 4d shows the extracted Re $\Sigma(\omega)$  on the  $\alpha$  and  $\beta$  bands of Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub>. The shaded area corresponds to the Re $\Sigma(\omega)$  of the pristine CsV<sub>3</sub>Sb<sub>5</sub>. Remarkably, we observe that while Re $\Sigma(\omega)$  on the  $\alpha$  band is similar in Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> and CsV<sub>3</sub>Sb<sub>5</sub>, on the  $\beta$  band, it shows a strong enhancement in the Nb-doped sample, especially near  $E_B \sim 10$  meV. Based on the extracted  $\alpha^2 F(\omega)$ , shown in Fig. 4e, we find that  $\lambda_d \sim 0.75 \pm 0.05$  is enhanced by about 50% in Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> (Fig. 4f). Such giant enhancement is also manifested by the slope of Re $\Sigma(\omega)$  near  $E_F$  (Fig. 4d). Consequently, the enhanced  $\lambda_d$  in Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> is expected to elevate  $T_c$  up to 4.5 K (see supplementary note 6), which is comparable to the experimental value of 4.4 K (Fig. 4a). Such synchronous enhancements of  $\lambda_d$  and  $T_c$  may indicate that the V 3*d*-electron-phonon couplings are the main driver of the superconductivity in CsV<sub>3</sub>Sb<sub>5</sub>.

Finally, we discuss the influences of CDW order on the quantitative extraction of  $\lambda$  at  $T < T_{CDW}$ . The formation of a CDW gap will modify the bare band to deviate from a linear dispersion near  $E_{\rm F}$ . As we show in the supplementary Fig. S5, within the experimental resolution, we do not observe a CDW gap on the  $\alpha$  and  $\beta$  bands. Therefore, for the  $\alpha$  and  $\beta$  bands, the CDW modified bare band dispersion below  $T_{\rm CDW}$  is  $\sqrt{\varepsilon_0^2(k) + \Delta_{\rm CDW}^2} \cong \varepsilon_0(k)$ , where  $\varepsilon_0(k) = v_0 \hbar k$  is the linear bare band dispersion above  $T_{\rm CDW}$ . In this case, the linear bare band assumption used in our study is a good approximation. Indeed, the excellent agreement of  $\text{Re}\Sigma(\omega)$  and  $\text{Im}\Sigma(\omega)$  linked by Kramers-Kronig transformation<sup>23,26</sup> validates the linear bare band assumption for the  $\alpha$  and  $\beta$ bands (supplementary Figs. S1c-d). The linear bare band assumption, however, does not apply to the  $\delta$  band that forms a CDW gap comparable to the kink energy<sup>20,31</sup>. We also note that the formation of CDW will also modify the electronic self-energy. As we show in the supplementary Fig. S7e,  $\lambda_{dev}$  shows an inflection point at  $T_{\rm CDW}$ , which may suggest an enhanced EPC strength below  $T_{\rm CDW}$ . However, it can also be a consequence of the CDW-corrected electronic self-energy effect (see supplementary note 8).

In summary, by investigating the electronic kinks, we determined an intermediate EPC that is twice larger than the DFT calculated value in the kagome superconductor  $CsV_3Sb_5$  and  $Cs(V_{0.93}Nb_{0.07})_3Sb_5$ . Our results provide an important clue to understand the pairing mechanism in  $CsV_3Sb_5$ . The orbital, momentum of electronic kinks and their strengthening with the promoted  $T_c$  prove that the EPC in  $CsV_3Sb_5$  is strong enough to support a  $T_c$  comparable to the experiment value and hence cannot be excluded as a possible pairing mechanism. While the exact microscopic pairing mechanism calls for further scrutiny, it is important to point out that the EPC-driven superconductivity is not incompatible with the recently observed pair-density wave (PDW) in  $CsV_3Sb_5^{17}$ . Indeed, PDW has been observed in another conventional superconductor NbSe<sub>2</sub>, where the pair-density modulation is due to the real space charge density modulations<sup>36</sup>. We also note that the EPC-driven superconductivity can coexist with the time-reversal symmetry-breaking (TRSB) orders or fluctuations<sup>18,37,38</sup>, as proposed by theoretical studies<sup>39-41</sup>. In those cases, the superconducting order parameter is expected to intertwine with the TRSB order parameter, which gives rise to an unconventional ground state.

## Methods

## Growth and characterization of single crystals

Single crystals of CsV<sub>3</sub>Sb<sub>5</sub> were grown using CsSb<sub>2</sub> alloy and Sb as flux. Cs, V, Sb elements and CsSb<sub>2</sub> precursor were sealed in a Ta crucible in a molar ratio of 1:3:14:10, which was finally sealed in a highly evacuated quartz tube. The tube was heated up to 1273 K, maintained for 20 hours and then cooled down to 763 K slowly. Single crystals were separated from the flux by centrifuging. The single crystals of Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> were provided by Jinggong New Materials (Yangzhong) Co., Ltd. The growth and characterizations of Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub> were present in ref<sup>34</sup>. The magnetic susceptibility was measured under magnetic field 20 Oe for CsV<sub>3</sub>Sb<sub>5</sub> and 5 Oe for Cs(V<sub>0.93</sub>Nb<sub>0.07</sub>)<sub>3</sub>Sb<sub>5</sub>.

## Laser-ARPES measurements

ARPES measurements were performed for the freshly cleaving surface with a Scienta-Omicron R4000 hemispherical analyzer with an ultraviolet laser (hv = 6.994 eV) at the Institute for Solid State Physics, the University of Tokyo<sup>42</sup>. The energy resolution was set to be 1.3 meV. The sample temperature was set to be 6 K if there is no special announcement. The samples were cleaved in situ and kept under a vacuum better than  $3 \times 10^{-11}$  torr during the experiments.

## **Maximum Entropy Method**

The Eliashberg function  $\alpha^2 F(\omega; \epsilon, \mathbf{k})$  is related to the real part of the self-energy by the integration function

Re 
$$\Sigma(\epsilon, \mathbf{k}; T) = \int_0^\infty d\omega \, \alpha^2 F(\omega; \epsilon, \mathbf{k}) K\left(\frac{\epsilon}{k_B T}, \frac{\omega}{k_B T}\right)$$
 (4)

where  $K(y, y') = \int_{-\infty}^{\infty} dx \frac{f(x-y)2y'}{x^2-y^2}$  and f(x) is the Fermi distribution function. It is an ill-posed problem to obtain the Eliashberg function from Eq. (4). In this work, we adopted the maximum entropy method (MEM)<sup>27,28</sup>, which is frequently used to perform the analytic continuation<sup>43</sup>. By considering the energy resolution of the laser-ARPES, we estimated that the error bar of the real part of the self-energy was 1 meV. MEM requires a model default function to define the entropic prior. Here, we adopted the following model:

$$m(\omega) = \begin{cases} m_0 \left(\frac{\omega}{\omega_D}\right)^2 & \omega \le \omega_D \\ m_0 & \omega_D \le \omega \le \omega_m \\ 0 & \omega > \omega_m \end{cases}$$
(5),

where  $m_0 = 15 \text{ meV}$ ,  $\omega_D = 10 \text{ meV}$ , and  $\omega_m = 80 \text{ meV}$ . This default model was also used in the previous study of the electron-phonon coupling on the Be surface<sup>28</sup>.
