

Antenna Combiner for Periodic Broadcast V2V Communication Under Relaxed Worst-Case Propagation

Chouaib Bencheikh Lehocine, Erik G. Ström, *Fellow, IEEE*, and Fredrik Brännström

Abstract—The performance of a previously developed analog combining network (ACN) of phase shifters for vehicle-to-vehicle communication is investigated. The original ACN was designed to maximize the sum of the signal-to-noise ratios (SNRs) for K consecutive, broadcast, periodic cooperative awareness messages when communication is over a dominant path whose angle of arrival (AOA) is constant over the duration of K packets. In this work, we relax this scenario by allowing the dominant path AOA and path-loss (PL) to be time-variant. Assuming a highway scenario with line of sight (LOS) propagation between vehicles, we use affine approximations to model the time variation of different path quantities, including the PL, the relative distance-dependent phase shift between antennas, and the AOA-dependent far-field function of the antennas. Using these approximations, we analytically derive the ACN sum-SNR as each one of these quantities vary over the duration of K packets. Moreover, we suggest a phase slope design rule that is robust against time variation of the dominant path and optimal under time-invariant conditions. Finally, we validate this design rule using numerical computations and an example of vehicular communication antenna elements.

I. INTRODUCTION

COOPERATIVE intelligent transportation system (C-ITS) rely on the exchange of cooperative awareness messages (CAMs) to increase traffic safety and efficiency on roads. CAMs are all-to-all broadcast, periodic packets carrying status information about the dynamics of the disseminating vehicles. Due to the broadcast nature of these messages, vehicles need to have an antenna system with good gain in all directions. This is challenged by the fact that antenna patterns are distorted by vehicles body, mounting positions, the housing of antennas, etc. These factors cause antennas to have a low gain or even blind spots in certain directions [1]–[3]. In the case that the transmitted and/or received signal coincides with directions where the antenna system has low gain then the cooperative service can be compromised. Therefore, in [4], it is proposed to process multiple antennas using an analog combining network (ACN) of phase shifters to mitigate the vehicle-body distortions, and enable omnidirectional coverage at the receive side. ACN is a low-cost, low-complexity solution that does not rely on channel state information (CSI), unlike the classical digital counterparts,

This research has been carried out in the antenna systems center *ChaseOn* in a project financed by Swedish Governmental Agency of Innovation Systems (Vinnova), Chalmers, Bluetest, Ericsson, Keysight, RISE, Smarteq, and Volvo Cars.

selection combining, equal gain combining, and maximal ratio combining (MRC). In [5], the fully analog ACN combining was enhanced using an MRC-based digital stage, to form a hybrid-combining scheme. Then, a transmit-side counterpart to ACN, namely, an analog beamforming network (ABN) of phase shifters has been developed in [6]. ABN does not rely on CSI either, and is fully analog, and hence has a lower cost than digital schemes, like cyclic delay diversity (CDD) [7], and Alamouti [8].

To assess the performance of the multiple antenna schemes in [4]–[6] burst error probability (BrEP) has been used. BrEP is related to the reliability at a C-ITS application level, where an outage occurs if the available information about a certain vehicle at a receiving end is outdated after a loss of K consecutive CAMs. Using certain assumptions, minimizing BrEP is found [4]–[6] to be equivalent to maximizing the sum-signal-to-noise ratio (SNR) of K consecutive packets, and it is the performance metric used in the design of the schemes. To ensure robust vehicle-to-vehicle (V2V) communication, ACN and ABN have been designed assuming a worst-case propagation environment, corresponding to a single dominant path with an angle of arrival (AOA) and an angle of departure (AOD) that are negligibly varying over the duration of K consecutive packets. Consequently, the distance-dependent relative phase shifts between the antennas, and path-loss (PL) were assumed to be negligibly varying over the same duration. A set of phase slopes that maximize the sum-SNR of K consecutive CAMs when the dominant path direction coincides with the worst-case AOA and AOD of the antenna systems have been derived in [4]–[6].

The negligibly varying single dominant path assumption holds under certain positions and speeds of the transmitter (Tx) and the receiver (Rx), and potential reflecting objects. Therefore, we are interested in investigating the performance of the designed multiple antenna system when the geometries and the mobility of the Tx and Rx result in a time-varying (instead of an unvarying) single dominant path. Namely, we are interested in investigating the performance of the system when the AOA, AOD, the relative phase shifts between the antennas, and the PL are time-varying over the duration of K packets.

The optimal phase slopes under worst-case propagation assumption [4], [6] are available for a generic $L_s \times L_r$ ABN-ACN where L_s , and L_r are the number of transmit and receive antennas, respectively. However, for such a system, it is difficult to model, analytically study, and understand the effects of time variation of the AOA, the AOD, the relative phase shift between antennas, and the

PL. Therefore, we study the effects of these quantities for a 1×2 ACN system (equivalent to 2×1 ABN). In particular, we first approximate, based on a reference highway scenario with a line of sight (LOS) propagation, the time variation of these quantities at medium and large distances between the Tx and Rx using an affine function. Besides distance, antenna separation and speeds are taken into account in the time variation modeling. Note that a dominant path is not necessarily a LOS, it can be a reflected path too. However, we assume a LOS propagation since it simplifies the modeling of the quantities of interest. Second, we analytically derive the loss in sum-SNR incurred on the ACN system for different phase slopes when the dominant path quantities are time-varying. Third, we derive a design rule to choose a robust phase slope that sustains good performance when the AOA, the phase shifts, and the PL vary over the duration of K CAMs. Finally, using numerical computation, we visualize the performance of the ACN and validate the design rule. The investigation of the 1×2 ACN system serves as a guideline for investigating $1 \times L_r$, $L_r > 2$, and $L_s \times L_r$ systems performance. The loss functions in sum-SNR can be numerically evaluated (they seem analytically intractable), then a design rule for robust phase slopes under a time-varying dominant path can be derived.

A summary of the contributions of this paper follows.

- Based on a reference highway scenario, that takes into account distance, speed, and antenna separation, we model the time variation of phase shifts between antennas, PL, and AOA-dependent antenna responses using an affine function at medium to large distances between the Tx and Rx.
- We analytically derive the loss function in ACN sum-SNR when the three quantities vary separately.
- We set a design rule to choose the most robust phase slope against the effects of time variation of the single dominant component quantities.
- Using numerical computation we validate the design rule and illustrate the performance of ACN under time-varying AOA, phase shifts, and PL.

II. PRELIMINARIES

In this section, we briefly reintroduce ACN/ABN, and restate the worst-case propagation assumptions used to design them alongside the obtained optimal phase slopes in [4], [6].

A. Multiple Antenna Scheme

Consider the multiple antenna scheme shown in Fig. 1 with analog time-varying phase shifters that are modeled following

$$e^{j(\alpha_l t + \beta_l)}, \quad 0 \leq l \leq L - 1, \quad (1)$$

where $\alpha_l \in \mathbb{R}$, and $\beta_m \in [0, 2\pi)$ denote the phase slope and the initial unknown phase offset, respectively, and L is the number of antennas. The scheme is referred to as ACN when used at the Rx, and ABN when used at the Tx. A multiplier of $1/\sqrt{L}$ is introduced in (1) to ensure equal transmitted power with respect to a single transmit antenna case when the scheme is used at the transmitter.

Fig. 1. ACN with L receive antennas.

B. Data Traffic Model and Performance Metric

Consider a periodic traffic of CAMs that are broadcasted by vehicular users (VUs) every $0.1 \leq T \leq 1$ s [9]. CAMs carry status information like position, speed, heading, etc. Their repetition interval T depends on how fast the dynamics of a vehicle are changing, the channel load, and the requirements of C-ITS applications [9]. CAMs are short packets with sizes that range between 100 and 500 bytes [10], which correspond to a duration $T_m < 0.7$ ms, assuming IEEE802.11p as an access technology and 6 Mbit/s data rate. (For LTE-V2X technology, the CAM duration corresponds to a subframe duration $T_m = 1$ ms [11].) Observe that the CAM duration is much smaller than the repetition interval T , $T_m \ll T$, and this will be used to assert certain assumptions in the sections to come.

Consider that age-of-information (AoI) [12] is used to assess the reliability of a C-ITS application that relies on the information carried by CAMs. At a receiving VU, if the information available about a certain neighboring vehicle has not been updated within a maximum tolerable AoI, A_{\max} , then the C-ITS application running at the receiving VU is in outage. If latency between the transmission and reception of packets is neglected, an outage occurs if a burst of K consecutive CAMs is lost, implying that $A_{\max} = KT$. The loss of K consecutive packets was defined as BrEP in [4], and used in [4], [6] as a design metric for ACN and ABN. In particular, the multiple antenna schemes were designed to minimize the BrEP. Under the assumption¹ that packet error probability follows an exponential function of SNR, and that packet errors are statistically independent, minimizing BrEP is found to be equivalent to maximizing the sum of SNR of the K consecutive packets [4, Section III], [5, Section III.B]. Therefore, the sum-SNR is the metric used in assessing the ACN/ABN performance in this paper.

C. Channel Model and Worst-Case Propagation Scenario

To ensure robust communication, ACN/ABN was designed under a scarce multipath propagation with a dominant path, and a few diffuse components with small angular spread, which is typical in roads that are not surrounded by buildings, e.g., highways [13]. Such propagation is challenging for the antenna system since if the AOD and the AOA of the dominant path coincide with a direction where the antenna system has low gain, there is a risk to lose a packet. Furthermore, in the cases when the AOD and

¹Motivation and justification can be found in [6, Section III].

the AOA are approximately non-varying over the duration of K consecutive packets, then there is a risk of an outage, i.e., loss of K consecutive packets. Following this, the baseband channel between the transmitter and the receiver was modeled in [4], [6] using the single dominant physical path. Assuming a $1 \times L$ ACN system (this is equivalent to $L \times 1$ ABN), the channel gain is given by [14, Ch. 6]

$$h_l(t) = a(t)g_l(\phi)e^{-j\Omega_l(t)}, \quad l = 0, \dots, L-1, \quad (2)$$

where $a(t)$ is the (complex) path amplitude, ϕ is the AOA, g_l is the far-field function of the receive antenna l in the azimuth plane, and Ω_l is the relative phase shift at antenna l with respect to the reference antenna with index $l = 0$. It is given by

$$\Omega_l(t) = 2\pi/\lambda(d_l(t) - d_0(t)), \quad (3)$$

where $d_l(t)$ is the propagation distance between the receive antenna with index l and the transmit antenna, and λ is the carrier wavelength. Note that $\Omega_0(t) = 0$. The far-field function of the transmit antenna, which can be accounted for by $a(t)$, is assumed for simplicity to be isotropic throughout the paper, and thus $a(t)$ models solely the amplitude of the dominant path.

Since a dominant path with a negligibly varying ϕ results in a higher risk of an outage, in [4], [6] it is assumed that the speed and position of the Tx and the Rx, alongside potential interacting objects, are such that ϕ is approximately constant over the duration of KT s. Consequently, Ω_l and PL are also assumed to be approximately constant over KT s. These are referred to as the worst-case propagation assumptions, and they were used when designing ACN/ABN.

D. Sum-SNR Under Worst-Case Propagation

Given the transmission of a CAM packet, employing (1) and (2), the received signal by a VU after ACN combining (as shown in Fig. 1) is expressed as

$$r(t) = a(t)x(t) \sum_{l=0}^{L-1} g_l(\phi)e^{-j(\Omega_l - \alpha_l t - \beta_l)} + \sum_{l=0}^{L-1} n_l(t), \quad (4)$$

where $x(t) = \tilde{x}(t - \tau(t))$, $\tilde{x}(t)$ is the transmitted baseband signal, $\tau(t) = 2\pi d_0(t)/\lambda$ is the propagation delay, and $n_l(t)$ is an independent zero-mean additive white Gaussian noise over the signal bandwidth with variance σ_n^2 . Let $P_r = \mathbb{E}\{|a(t)x(t)|^2\}$ be the average received power which is approximately the same for the K packets since the PL is assumed to be approximately constant over KT s, and let

$$\psi_l(t) \triangleq \Omega_l(t) - \angle g_l(\phi) - \beta_l, \quad (5)$$

which is non-varying over KT s since $\Omega_l(t)$ is assumed to be non-varying over the same duration. Then, using (4) and (5), we express the SNR of the k^{th} packet as

$$\gamma_k = \frac{P_r}{L\sigma_n^2} \left| \sum_{l=0}^{L-1} |g_l(\phi)| e^{-j(\psi_l - \alpha_l kT)} \right|^2, \quad (6)$$

where the phase variation is assumed negligible over a packet duration since $T_m \ll T$, and thus the approximation $e^{-j(\psi_l - \alpha_l t)} \approx e^{-j(\psi_l - \alpha_l kT)}$ when $kT \leq t \leq kT + T_m$,

is employed when deriving γ_k . Then we can readily express the normalized sum-SNR with respect to P_r/σ_n^2 using the column vectors $\boldsymbol{\alpha} = [\alpha_0, \alpha_1, \dots, \alpha_{L-1}]^T$ and $\boldsymbol{\psi} = [\psi_0, \psi_1, \dots, \psi_{L-1}]^T$, as

$$\begin{aligned} S(\phi, \boldsymbol{\alpha}, \boldsymbol{\psi}) &= \sigma_n^2/P_r \sum_{k=0}^{K-1} \gamma_k \\ &= K \sum_{l=0}^{L-1} \frac{|g_l(\phi)|^2}{L} + J(\phi, \boldsymbol{\alpha}, \boldsymbol{\psi}), \end{aligned} \quad (7)$$

where

$$\begin{aligned} J(\phi, \boldsymbol{\alpha}, \boldsymbol{\psi}) &= \frac{2}{L} \sum_{l=0}^{L-2} \sum_{m=l+1}^{L-1} |g_l(\phi)| |g_m(\phi)| \\ &\times \sum_{k=0}^{K-1} \cos(\psi_m - \psi_l - (\alpha_m - \alpha_l)kT). \end{aligned} \quad (8)$$

To design ACN/ABN an optimization problem is defined in [4], [6] to find the phase slopes that maximize the sum-SNR for the worst-case AOA/AOD, and for the worst-case $\boldsymbol{\psi}$ since it depends on the initial unknown and uncontrollable phase offsets $\{\beta_l\}$. The solution to the optimization problem is found in [4], [6] to be the same for any AOA/AOD, and it is given by

$$S^*(\phi) = \sup_{\boldsymbol{\alpha} \in \mathbb{R}^L} \inf_{\boldsymbol{\psi} \in [0, 2\pi]^L} S(\phi, \boldsymbol{\alpha}, \boldsymbol{\psi}) = K \sum_{l=0}^{L-1} \frac{|g_l(\phi)|^2}{L}. \quad (9)$$

The optimal phase slopes are independent of the far-field functions of the antennas and exist when $L \leq K$ and they satisfy [4], [6]

$$(\alpha_m - \alpha_l)T/2 \in \mathcal{X}^*, \quad 0 \leq l < m \leq L-1, \quad (10)$$

where

$$\mathcal{X}^* \triangleq \{q\pi/K : q \in \mathbb{Z}\} \setminus \mathcal{X}, \quad \mathcal{X} \triangleq \{q\pi : q \in \mathbb{Z}\}. \quad (11)$$

The condition in (10) can be satisfied when $L = 2$ using a single phase shifters, where $\alpha_0 = \beta_0 = 0$, and $\alpha_1 T/2 \in \mathcal{X}^*$, $\beta_1 \in [0, 2\pi)$.

III. TIME-VARYING SINGLE DOMINANT PATH PROPAGATION

The optimal phase slopes for ACN/ABN were designed under the worst-case assumption of a negligibly varying single dominant path over KT s. In the following, we aim to investigate the effects of time variation of the dominant path on ACN/ABN performance. That is done following an investigation of the impact of variation of ϕ , Ω_l , and PL separately. Moreover, we aim to define a design rule

Fig. 2. Two-lane highway scenario with two reference vehicles.

Fig. 3. Time variation of ϕ for different initial distances between the Tx and the Rx, $\Delta_v = -60$ km/h, $d_y = -4$ m.

Fig. 4. Time variation of Ω_1 for different initial distances between the Tx and the Rx, $\Delta_v = -60$ km/h, $d_y = -4$ m.

to pick the most robust choice of phase slopes to the variation of these quantities. To be able to perform an analytical investigation of the variation of ϕ , Ω_l , and PL we resort to the simple scheme of a 1×2 system. It allows us to accurately understand the effects of the quantities and to draw design methodology. These can be used as guidelines when investigating the time variation effects of these quantities on $L_s \times L_r$ ABN-ACN system.

To model the variation of ϕ , Ω_l , and PL and to evaluate the sum-SNR of the multiple-antenna scheme, we consider two reference VUs on a highway as shown in Fig. 2, one employing two antennas $L = 2$ and it is referred to as the receiving VU, and the other is employing a single antenna, and it is referred to as the transmitting VU. We assume a LOS propagation between the two VUs, which corresponds to the dominant component. If the two VU are moving at the same speed, then the worst-case propagation assumptions in Section II-C (non-variation of the channel) are fully satisfied. In addition, if the two vehicles are moving at different speeds but in the same lane, then the

Fig. 5. Time variation of PL following WINNER+B1 pathloss model [15] for different initial distances between the Tx and the Rx, $\Delta_v = -60$ km/h, $d_y = -4$ m.

AOA and Ω_l are fixed, while the PL varies. However, if the vehicles are moving at different speeds and located on different lanes, then the geometries between the Tx and Rx change over time and result in variations of all three quantities of interest. In other words, the accuracy of the aforementioned worst-case scenario assumptions depends on the speed and lane position of vehicles (for this particular scenario). The use of such a scenario allows us to model the variations of the three quantities of interest.

To define certain parameters for the scenario in Fig. 2 we take the initial position of the transmitting VU as the origin $(0, 0)$ of a Cartesian coordinates system. Then, we define the following parameters.

- d_x , the initial longitudinal position of the receiving VU with respect to the transmitting VU (measured from the center of vehicles).
- d_y , the lateral position of the receiving VU with respect to the transmitting VU.
- $\Delta_v = (v_r - v_t)$, the speed difference between the receiving and the transmitting VUs.
- δ_a , the receive antennas separation.

For simplicity, we assume that the antennas of the Rx are mounted along the lateral axis of the vehicle.

The defined parameters d_x , d_y , Δ_v and δ_a can span a wide range of values. However, we limit the range of these parameters to intervals that are large enough to allow us to observe the different effects resulting from changing geometries between the Tx and Rx. In particular, we set $d_x \in [-100, 100]$ m, since for larger distances than 100 m, ϕ , Ω_l and PL are approximately non-varying over KT s. From another aspect, taking into account typical cruising speeds on highways, and assuming a maximum regulatory speed of 100 km/h, we can restrict $\Delta_v = (v_t - v_r) \in [-60, 60]$ km/h, which corresponds to absolute speeds in the range $[70, 130]$ km/h. Furthermore, to cover different lane positions we use $d_y \in [-4, 0, 4]$ corresponding to a lane width of 4 m. Lastly, we consider two cases for δ_a , $\delta_a = \lambda/2 \approx 0.025$ m and $\delta_a = 10\lambda \approx 0.5$ m at carrier frequency $f_c = 5.9$ GHz, corresponding to a small and

large antenna separations, respectively.

In Figs. 3–5 we show examples of the time variation of the three quantities for different d_x when $d_y = -4$ m, and $\Delta_v = -60$ km/h, which is the speed within $[-60, 60]$ km/h that results in the maximum change of the quantities. From the figures, we observe that at $d_x = 100$ m the AOA exhibits negligible change and so does Ω_1 ($\Omega_0 = 0$) and the PL, implying that the worst-case assumptions in Section II-C hold. At a short distance $d_x = 10$ m, ϕ is very rapidly changing. Thus, even if the AOA for a received packet coincides with a low gain of the antenna system, the AOA for the successive packets (e.g., when $T = 0.1$ s) can be coinciding with a high gain of the antenna system, which lowers the risk of consecutive packet losses. More importantly, the PL is very low at such short distances as seen in Fig. 5 which results in a high SNR and a high probability of decoding packets. Thus, this region is not critical for the communication system.

At the medium distance $d_x = 30$ m, the AOA is slowly changing, with an approximate rate of 9 deg/1 s. In this case, if the AOA for a received packet coincides with a low gain of the antenna system, there is a risk that several successive packets (e.g., when $T = 0.1$ s, ϕ changes by 0.9 deg/ T) experience comparably low gain as well. The PL, which is also slowly changing, is neither too high nor too low in this region. Therefore, there is a risk of losing a burst of consecutive packets due to the alignment of the dominant path with a direction of low gain of the antenna system. From another aspect, the change in Ω_1 is fast (greater than 2π rad/1 s for $\delta_a = 10\lambda$), which impacts the ACN/ABN system by introducing a time-varying phase offset to the preset phase shifters. Proper antenna processing is of paramount importance in this region of medium to large distances, and it will therefore be the focus of the coming analytical investigations.

In the coming three sections, we investigate the effects of time variation of ϕ , Ω_l , and PL on ACN/ABN performance. When ϕ changes, there is a change in the channel phase shift which is captured by Ω_l , and a change in antenna far-field functions $g_l(\phi)$, in both phase and amplitude. When we refer to time variation effects of ϕ we mean the far-field functions variation effects. To simplify the analysis, we study the effects of time variation of each quantity separately. We start with Ω_l , followed by PL, and finally ϕ . As mentioned earlier, the focus of the analysis is on medium to large distances. This will be backed up by a numerical assessment of the system performance at short distances in the numerical results section.

IV. CHANNEL PHASE (Ω) VARIATION EFFECTS

In this section, we first model Ω_l based on the reference scenario shown in Fig. 2 when the distance between the two VUs is medium to large. We then derive the sum-SNR of 1×2 ACN system under the effects of time variation of Ω_l . Last, we derive a design rule to pick a robust phase slope under these conditions.

A. Channel Phase Shift (Ω) Model

Given that $L = 2$, and $\Omega_0(t) = 0$, under LOS propagation between the reference VUs shown in Fig. 2,

the relative phase shift at receive antenna $l = 1$ with respect to the reference antenna ($l = 0$), $\Omega_1(t) \triangleq \Omega(t)$ is modeled by

$$\begin{aligned} \Omega(t) &= 2\pi/\lambda(d_1(t) - d_0(t)) \\ &= 2\pi/\lambda \left(\sqrt{(d_x + \Delta_v t)^2 + (d_y - \delta_a/2)^2} - \sqrt{(d_x + \Delta_v t)^2 + (d_y + \delta_a/2)^2} \right). \end{aligned} \quad (12)$$

Observe that as d_x becomes large $\Delta_v/d_x \rightarrow 0$, and Ω becomes approximately constant as seen in Fig. 4. Moreover, the smaller the antenna separation is δ_a , the slower the time variation of Ω . To investigate the effect of this time variation, we resort to the approximation

$$\Omega(t) \approx b_\Omega + a_\Omega t, \quad (13)$$

where a_Ω and b_Ω can be obtained using first-order Taylor series, or the least squares (LS) method. When first-order Taylor expansion around $t = t_0$ is used, a_Ω is given by

$$\begin{aligned} a_\Omega &= \frac{2\pi}{\lambda} \Delta_v \left(\frac{(d_x + \Delta_v t_0)}{\sqrt{(d_x + \Delta_v t_0)^2 + (d_y - \delta_a/2)^2}} \right. \\ &\quad \left. - \frac{(d_x + \Delta_v t_0)}{\sqrt{(d_x + \Delta_v t_0)^2 + (d_y + \delta_a/2)^2}} \right), \end{aligned} \quad (14)$$

and $b_\Omega = \Omega(t_0) - a_\Omega t_0$. Based on Fig. 4, we expect the affine approximation to have good accuracy at medium to large distances with $\Delta_v \in [-60, 60]$ km/h. At short distances, the approximation is not expected to be very accurate, especially when the antenna separation is large (e.g., $\delta_a = 10\lambda$), and the speed difference is high.

B. Sum-SNR

To evaluate the sum-SNR of ACN/ABN taking into account the effects of time variation of Ω only, we assume the use of isotropic antennas at the Rx, i.e., $g_0(\phi) = g_1(\phi) = 1$, $\forall \phi$. Thus, despite that ϕ varies, the gain of the antenna system does not vary. Moreover, we assume that PL is approximately non-varying over KT s. This allows us to disentangle the effects of variations of the channel phase Ω from the effects of variation of AOA and PL. Now, assume that the ACN is implemented using a single phase shifter, implying that $\alpha_0 = \beta_0 = 0$, and $\alpha_1 \triangleq \alpha \in [0, 2\pi)$, $\beta_1 \triangleq \beta \in [0, 2\pi)$. Then, from (5) and (13), we have

$$\begin{aligned} \psi_1(t) &= \Omega(t) - \underbrace{\angle g_1(\phi) - \beta}_{\psi_1} \\ &\approx (b_\Omega - \underbrace{\angle g_1(\phi) - \beta}_{\psi_1}) + a_\Omega t, \end{aligned} \quad (15)$$

while $\psi_0 = -\angle g_0(\phi)$ ($= 0$ when the antenna is isotropic). Assuming that the variation of $\psi_1(t)$ due to a_Ω is negligible over a packet duration $T_m \ll T$, we write

$$\psi_1(t) \approx \psi_1(kT), \quad kT \leq t \leq kT + T_m. \quad (16)$$

Following this, the sum-SNR (7) can be expressed taking into account (15), the isotropic antenna characteristics, and $L = 2$ as

$$S_\Omega(\phi, \alpha, \psi) = \sigma_n^2/P_r \sum_{k=0}^{K-1} \gamma_k = K + J_\Omega(\phi, \alpha, \psi), \quad (17)$$

where J_Ω is given by (8) and it simplifies to

$$\begin{aligned}
J_\Omega(\phi, \alpha, \psi) &= |g_0(\phi)| |g_1(\phi)| \\
&\times \sum_{k=0}^{K-1} \cos(\psi_1(kT) - \psi_0 - (\alpha_1 - \alpha_0)kT) \\
&\approx \sum_{k=0}^{K-1} \cos(\hat{\psi}_1 + a_\Omega kT - \psi_0 - \alpha kT) \\
&= \sum_{k=0}^{K-1} \cos((\hat{\psi}_1 - \psi_0) - (\alpha - a_\Omega)kT) \\
&= \sum_{k=0}^{K-1} \cos(y - 2\alpha k) \\
&\triangleq J_\Omega(x, y), \tag{18}
\end{aligned}$$

where the approximation follows from (15), and where

$$y \triangleq (\hat{\psi}_1 - \psi_0), \quad x \triangleq (\alpha - a_\Omega)T/2. \tag{19}$$

We can write the sum-SNR as

$$S_\Omega(x, y) = K + J_\Omega(x, y). \tag{20}$$

Now, we can evaluate the performance of the system using a similar optimization problem as in (9),

$$\inf_{y \in [0, 2\pi)} S_\Omega(x, y) = K \left(1 + \inf_{y \in [0, 2\pi)} \frac{J_\Omega(x, y)}{K} \right). \tag{21}$$

That is, we account for the worst-case value of y , since it depends on the unknown, uncontrollable, initial phase shift β of the ACN. When the channel phase variations are negligible, $a_\Omega = 0$, we know from (9) that the optimal performance is given by $\inf_y S_\Omega(x, y) = K$, which implies that $\inf_y J_\Omega(x, y) = 0$. Therefore, we define the loss function as

$$L_\Omega(x) \triangleq - \inf_{y \in [0, 2\pi)} \frac{J_\Omega(x, y)}{K}, \tag{22}$$

and we characterize some of its properties in the following lemma.

Lemma 1. *Let $L_\Omega(x)$ be as defined in (22), $x \in \mathbb{R}$, and let \mathcal{X} be as defined in (11), then*

(i) *The loss function is given by*

$$L_\Omega(x) = \begin{cases} 1, & x \in \mathcal{X} \\ |f_1(x)|/K, & x \notin \mathcal{X} \end{cases} \tag{23}$$

where $f_1 : \mathbb{R} \setminus \mathcal{X} \rightarrow \mathbb{R}$, is given by

$$f_1(x) = \frac{\sin(Kx)}{\sin(x)}. \tag{24}$$

(ii) *L_Ω is periodic with period π , and symmetric around $\pi/2$.*

(iii) *The loss function is bounded as*

$$0 \leq L_\Omega(x) \leq 1, \quad x \in [0, \pi), \tag{25}$$

where $L_\Omega(x) = 0$ when $x \in \mathcal{X}^*$, and \mathcal{X}^* is defined in (11).

Proof. See the Appendix. \square

Fig. 6. The sum-SNR loss function $L_\Omega(x)$, $x = (\alpha - a_\Omega)T/2$ when $K = 5, 10$.

Fig. 7. Range of change in Ω as a function of d_x when $\Delta_v \in [-60, 60]$ km/h, and $d_y = \pm 4$. First order Taylor expansion (14) is used to compute a_Ω .

The loss function for $K = 5$ and $K = 10$ is shown in Fig. 6. Since $L_\Omega(x)$ is periodic with period π , we define

$$\mathcal{A}^* \triangleq \left\{ q \frac{2\pi}{KT}; q = 1, 2, \dots, K-1 \right\}, \tag{26}$$

which has $K-1$ elements satisfying $\alpha \in \mathcal{A}^*$, $\alpha T/2 \in \mathcal{X}^*$. These are all the unique elements in \mathcal{X}^* , since for every $x \in \mathcal{X}^*$, we can write $x = \alpha T/2 + q\pi$, where $\alpha \in \mathcal{A}^*$, $q \in \mathbb{Z}$.

Recall that when $a_\Omega = 0$, all $\alpha \in \mathcal{A}^*$ yield the same optimal sum-SNR, and $L_\Omega(x) = 0$. Consider now an example where $a_\Omega T/2 \in [-\pi/K, \pi/K]$, and $\alpha T/2 = \pi/K$ ($\alpha \in \mathcal{A}^*$). It follows that $x = (\alpha - a_\Omega)T/2 \in [0, 2\pi/K]$, and thus, the worst-case loss due to phase deviation a_Ω correspond to $L_\Omega(x) = 1$, as can be seen from Fig. 6. On the other hand, when $\alpha T/2 = 2\pi/K$, ($\alpha \in \mathcal{A}^*$) it follows that $x \in [\pi/K, 3\pi/K]$, and from Fig. 6 we see that the worst-case loss in this case is $L_\Omega(x) \approx 0.25$, and $L_\Omega(x) \approx 0.22$ for $K = 5$, and $K = 10$,

respectively. Hence, under channel phase variation, not all phase slopes $\alpha \in \mathcal{A}^*$ yield the same loss in sum-SNR. Moreover, $\alpha T/2 = 2\pi/K$ is more robust than $\alpha T/2 = \pi/K$ in mitigating phase deviation effects when $a_\Omega T/2 \in [-\pi/K, \pi/K]$. Therefore, in the following, we propose a design rule to choose the most robust phase slope in \mathcal{A}^* under channel phase shift variation.

C. Phase Slope Design Under Time-Varying Ω ($a_\Omega \neq 0$)

To derive a design rule to choose the most robust phase slope in \mathcal{A}^* under channel phase variation, we start by characterizing the trends of the loss function, $L_\Omega(x)$. Let $\alpha \in \mathcal{A}^*$, and assume that $a_\Omega \neq 0$. At the points $x = (\alpha - a_\Omega)T/2 = q\pi$ the loss function is at its maximum value $L_\Omega(x) = 1$. On the other hand, as can be seen in Fig. 6, in the range $[\pi/K, (K-1)\pi/K]$ the loss function exhibits $K-2$ lobes. These lobes have decreasing maxima in the range $[\pi/K, \pi/2]$. That follows since $\sin(x)$ is increasing over the interval, while $|\sin(Kx)|$ is periodic with π/K (which is equal to the lobes width). Due to the symmetry around $\pi/2$, the lobes maxima are increasing as we get far from the symmetry point in the range $[\pi/2, (K-1)\pi/K]$. In addition, the maximum loss within $[\pi/K, (K-1)\pi/K]$ is bounded following

$$L_\Omega(x) \leq \frac{1}{K \sin(\pi/K)}, \quad x \in \left[\frac{\pi}{K}, (K-1)\frac{\pi}{K} \right], \quad (27)$$

since $|\sin(Kx)| \leq 1$ and $\sin(\pi/K) \leq \sin(x)$ where $x \in [\pi/K, (K-1)\pi/K]$. This bound is decreasing with K and it quantifies to $L_\Omega(x) \leq 0.34$ for $K = 5$, and $L_\Omega(x) \leq 0.32$ for $K = 10$. Substituting with the bound in (21) we deduce that the sum-SNR when $x \in [\pi/K, (K-1)\pi/K]$ is at worst -1.8 dB, and -1.7 dB below the zero-loss sum-SNR ($\inf_y S_\Omega(x, y) = K$) for $K = 5$, and $K = 10$, respectively. Hence, in summary, the loss in sum-SNR is moderate within the interval $[\pi/K, (K-1)\pi/K]$ and it gets lower as we approach the point of symmetry $\pi/2$ of the loss function. On the other hand, the loss in sum-SNR is severe in the intervals centered around the points $(\alpha - a_\Omega)T/2 = q\pi$.

Guided by these trends in the loss function $L_\Omega(x)$, we aim to pick the phase slope $\alpha \in \mathcal{A}^*$ that handles a wide range of error due to channel variation a_Ω without resulting in the most severe loss in sum-SNR occurring at $x = (\alpha - a_\Omega)T/2 = q\pi$. This is equivalent to picking the phase slope that has the largest phase distance from the points with the most severe loss, $x = q\pi$, and which is in turn, the phase slope that has the shortest phase distance from the point $x = \pi/2$. We formally define this as

$$\alpha^* \triangleq \arg \min_{\alpha \in \mathcal{A}^*} |\alpha T/2 - \pi/2|. \quad (28)$$

Besides having the largest phase distance from the points with the most severe loss, the ACN with α^* ensures that the effective phase slope $(\alpha^* - a_\Omega)T/2$ is within the region with moderate loss in sum-SNR, $[\pi/K, (K-1)\pi/K]$ for the widest range of a_Ω compared to any other phase slope

in \mathcal{A}^* . Thus, α^* is the most robust phase slope in \mathcal{A}^* when Ω is time-varying. The solutions to (28) are given by

$$\alpha^* \in \begin{cases} \left\{ \frac{K-2\pi}{2KT}, \frac{K+2\pi}{2KT} \right\}, & K \text{ even} \\ \left\{ \frac{K-1-2\pi}{2KT}, \frac{K+1-2\pi}{2KT} \right\}, & K \text{ odd} \end{cases} \quad (29)$$

To get more insight into the design rule (28) we plot in Fig. 7 the range of a_Ω as function of d_x when $\Delta_v \in [-60, 60]$ km/h. **(i)** We observe that for $\delta_a = \lambda/2$ the variation of a_Ω is very limited at medium to large distances. This indicates that the impact of channel phase variation is not severe when the antenna separation is small. **(ii)** For $\delta_a = 10\lambda$, we see that a_Ω has much wider range compared to $\delta_a = \lambda/2$. The interval of a_Ω increases with the increase of speed difference $|\Delta_v|$ or the decrease of distance $|d_x|$. This is an indication that certain choices $\alpha \in \mathcal{A}^*$ can have better properties in mitigating the effects of variation of Ω over a wide range of speed and distances. This supports the proposed design rule in (28). For example, assuming $K = 10$, then $\alpha^* T/2 = \pi/2$. Following that, from Fig. 7 we obtain that when $|d_x| \geq 20$ m, $|a_\Omega T/2| < \pi/2$ for $\Delta_v \in [-60, 60]$. Thus, when $|d_x| \geq 20$, the effective phase slope $(\alpha^* - a_\Omega)T/2$ satisfies $0 < (\alpha^* - a_\Omega)T/2 < \pi$, implying that α^* allows us to avoid severe loss in sum-SNR for any speed when $|d_x| \geq 20$ m. On the other hand, using $\alpha T/2 = \pi/K$, then $0 < (\alpha - a_\Omega)T/2 < \pi$ is satisfied for any $\Delta_v \in [-60, 60]$, only when $|d_x| \geq 35$ m. Hence, for medium distances below 35 m, there exists $\Delta_v \in [-60, 60]$ for which the ACN system with $\alpha T/2 = \pi/K$ experiences the most severe loss in sum-SNR. Thus, α^* is a robust choice that allows us to avoid severe loss in sum-SNR over a wide range of distances.

For short distances $|d_x| \leq 15$ ($\delta_a = 10\lambda$), we see in Fig. 7 that $a_\Omega T/2$ can take any value in $[-\pi/2, \pi/2]$ (recall that L_Ω is periodic with π), which implies that for any $\alpha \in \mathcal{A}^*$ including α^* , there exists $\Delta_v \in [-60, 60]$ for which the most severe loss is experienced. In other words, no choice of phase slope is better than other in mitigating the effects of variation of Ω over the full speed range $\Delta_v \in [-60, 60]$ at short distances $|d_x| \leq 15$ ($\delta_a = 10\lambda$). However, we recall that approximating Ω as an affine function (13) is not very accurate over the full range of speed difference at low distances. Therefore, a numerical quantification of the system performance at such short distances is shown in the numerical results section.

V. PATHLOSS VARIATION EFFECTS

In this section, we investigate the performance of ACN under time-varying PL following the same steps as in the previous section.

A. Pathloss Model

The Pathloss is typically modeled following a power law [16], and so does its inverse, the path gain, which will be the one explicitly used in the analysis to follow. A generic model of the path gain [16] is given by

$$A(t) = A_0 \times \left(\frac{d_{\text{ref}}}{d(t)} \right)^{n_e} 10^{-X_\sigma(d)/10}, \quad d \geq d_{\text{ref}}, \quad (30)$$

where $d(t) = \sqrt{(d_x + \Delta_v t)^2 + d_y^2}$, is the distance between the Tx and Rx, n_e is the path loss exponent, d_{ref} is a reference distance with path gain A_0 , and $X_\sigma(d)$ is a zero-mean Gaussian random process with standard deviation σ_{SH} corresponding to shadowing (large scale fading). Shadowing is a spatially correlated process with autocorrelation $\mathbb{E}\{X_\sigma(d)X_\sigma(d + \Delta d)\}$, that can be modeled using a decaying exponential function with parameter d_c [17]. The decorrelation distance d_c , represents the distance difference at which the autocorrelation is equal to e^{-1} . In context of highway scenario, it is reported to be $23.3 \leq d_c \leq 32.5$ m in [16] and $d_c = 25$ m in WINNER+B1 pathloss model [15]. Taking this into account, and for simplicity, we assume that shadowing is a block-type fading over the duration of KT s,

$$X_\sigma \triangleq X_\sigma(d|_{t=(K-1)T/2}), \quad 0 \leq t \leq KT.$$

Then, assuming that² $d(0) > d_{\text{ref}}$ and $d((K-1)T) > d_{\text{ref}}$, we can approximate the average path gain following

$$\bar{A}(t) = \mathbb{E}\{A(t)\} = \mu_X A_0 \left(\frac{d_{\text{ref}}}{d(t)}\right)^{n_e} \approx b_{\text{PL}} + a_{\text{PL}}t, \quad (31)$$

where $\mu_X = \mathbb{E}\{10^{-X_\sigma/10}\} = e^{(\ln(10)\sigma_{\text{SH}})^2/200}$. Assuming that the variation of path gain is negligible over a packet duration $T_m \ll T$, we reach

$$\bar{A}(t) \approx \bar{A}(kT) = b_{\text{PL}} + a_{\text{PL}}kT, \quad kT \leq t \leq kT + T_m.$$

The approximating affine function parameters can be computed using either first-order Taylor expansion or using the LS method. Since $\bar{A}(kT) > 0$, the coefficients need to satisfy the condition $b_{\text{PL}} + a_{\text{PL}}kT > 0$, $k = 0, 1, \dots, K-1$, for the approximation to be valid. When Taylor expansion at $t = t_0$ is applied, the coefficients are given by

$$a_{\text{PL}} = -\mu_X A_0 d_{\text{ref}}^{n_e} \frac{n_e \Delta_v \times (d_x + \Delta_v t_0)}{d^{n_e+2}(t_0)}, \quad (32)$$

and $b_{\text{PL}} = \bar{A}(t_0) - a_{\text{PL}}t_0$.

B. Sum-SNR

To study the effects of the variation of the average PL on the ACN/ABN system, we assume that the two vehicles are moving in the same lane $d_y = 0$ m. This implies that the AOA and the channel phase shift do not change over KT s ($a_\Omega = 0$). Furthermore, we assume that the antennas have isotropic patterns (i.e., even if ϕ is time-varying, the antenna responses are fixed).

The received power of the k^{th} packet can be expressed as $P_r = \mathbb{E}\{|a(t)x(t)|^2\} = \bar{A}(kT)P_t$, where $\bar{A}(kT) = \mathbb{E}\{|a(t)|^2\}$, and $P_t = \mathbb{E}\{|x(t)|^2\}$ is the transmitted power. Then, the SNR of the k^{th} packet (6) is expressed as

$$\gamma_k = \frac{P_t}{L\sigma_n^2} \bar{A}(kT) \left| \sum_{l=0}^{L-1} e^{-j(\psi_l - \alpha_l kT)} \right|^2, \quad (33)$$

²When $d < d_{\text{ref}}$ the model (30) is not valid. In such case, the path gain can be assumed to be equal to that at d_{ref} as done, for example, in WINNER+B1 model [15, Table A.1.4-1].

since $g_l(\phi) = 1$, $l = 0, 1$. Then, normalizing the SNR with respect to P_t/σ_n^2 and summing over k , we find that

$$\begin{aligned} S_{\text{PL}}(x, y) &= \frac{1}{L} \sum_{k=0}^{K-1} \bar{A}(kT) (2 + 2 \cos(y - 2xk)) \\ &\approx \frac{1}{L} \sum_{k=0}^{K-1} (b_{\text{PL}} + a_{\text{PL}}kT) (2 + 2 \cos(y - 2xk)) \\ &= c_1 K \left(1 + \frac{J_{\text{PL}}(x, y)}{c_1 K} \right), \end{aligned} \quad (34)$$

where the approximation follows from (31), and where x and y are as defined in (19) ($x = \alpha T/2$, since $a_\Omega = 0$), $c_1 = (b_{\text{PL}} + a_{\text{PL}}T(K-1)/2)$, and

$$J_{\text{PL}}(x, y) = \sum_{k=0}^{K-1} (b_{\text{PL}} + a_{\text{PL}}kT) \cos(y - 2xk). \quad (35)$$

As done earlier, we define the loss function as

$$L_{\text{PL}}(x) \triangleq - \inf_{y \in [0, 2\pi)} \frac{J_{\text{PL}}(x, y)}{c_1 K}, \quad (36)$$

where the worst-case sum-SNR is given by

$$\inf_{y \in [0, 2\pi)} S_{\text{PL}}(x, y) = c_1 K (1 - L_{\text{PL}}(x)). \quad (37)$$

We then state certain properties of the loss function in the following lemma.

Lemma 2. *Let $L_{\text{PL}}(x)$ be as defined in (36), $x \in \mathbb{R}$, and $(b_{\text{PL}} + a_{\text{PL}}kT) > 0$, $k = 0, 1, \dots, K-1$, then*

(i) *The loss function is given by*

$$L_{\text{PL}}(x) = \begin{cases} 1, & x \in \mathcal{X} \\ \sqrt{c_1^2 f_1^2(x) + c_2^2 f_2^2(x)} / (c_1 K), & x \notin \mathcal{X} \end{cases} \quad (38)$$

where $c_1 = (b_{\text{PL}} + a_{\text{PL}}T(K-1)/2)$, $c_2 = a_{\text{PL}}T/2$, \mathcal{X} is defined in (11), f_1 is defined in (24), and $f_2 : \mathbb{R} \setminus \mathcal{X} \rightarrow \mathbb{R}$, is given by

$$f_2(x) = \frac{K \cos(Kx)}{\sin(x)} - \frac{\sin(Kx)}{\sin(x)} \cot(x). \quad (39)$$

(ii) *The loss function is periodic with period π and symmetric around $\pi/2$.*

(iii) *L_{PL} can be bounded as*

$$0 < L_{\text{PL}}(x), \quad a_{\text{PL}} \neq 0, \quad L_{\text{PL}}(x) \leq 1. \quad (40)$$

(iv) *If $x \in \mathcal{X}^*$ then*

$$L_{\text{PL}}(x) = \left| \frac{c_2}{c_1 \sin(x)} \right|. \quad (41)$$

(v) *The loss function is bounded when $x \notin \mathcal{X}$ as*

$$\frac{|f_1(x)|}{K} \leq L_{\text{PL}}(x) \leq \frac{\sqrt{(K-1)^2 f_1^2(x) + f_2^2(x)}}{K(K-1)}. \quad (42)$$

Proof. See the Appendix. \square

Fig. 8. The sum-SNR loss function under PL variation, $L_{\text{PL}}(x)$, for $K = 10$, $d_x = 30$ m, $d_y = 0$ m, and $\Delta_v = \pm 60$ km/h. The upper and lower bounds (42) of the loss function are shown in dashed lines.

C. Phase Slope Design Under Time-Varying PL ($a_{\text{PL}} \neq 0$)

We recall that when the PL is approximated as constant ($a_{\text{PL}} = 0$), the phase slopes $x = \alpha T/2 \in \mathcal{X}^*$ ensure identical optimal performance corresponding to $\inf_y S_{\text{PL}}(x, y) = c_1 K$, and $L_{\text{PL}}(x) = 0$. Now, when the PL is time-varying, $a_{\text{PL}} \neq 0$, we see from Lemma 2 (41) that the loss in sum-SNR $L_{\text{PL}}(x) \neq 0$ for $x = \alpha T/2 \in \mathcal{X}^*$, and it is not identical for all the elements of \mathcal{X}^* . Since L_{PL} is periodic with π , there exists $K-1$ unique elements in \mathcal{X}^* , which are represented in \mathcal{A}^* (26). Following that, we can deduce that the phase slope that minimizes the loss in sum-SNR under PL variation among \mathcal{A}^* is also the solution to (28). That is,

$$\arg \min_{\alpha \in \mathcal{A}^*} L_{\text{PL}}(\alpha T/2) = \arg \min_{\alpha \in \mathcal{A}^*} |\alpha T/2 - \pi/2|. \quad (43)$$

This follows from (41) since $1/|\sin(\alpha T/2)|$ is minimized by the phase slope satisfying the right-hand side of (43). These results can be observed in Fig. 8 where the loss function, is plotted for $d_x = 30$ m and $\Delta_v = \pm 60$ km/h. The WINNER+B1 [15], [18] pathloss model is used. Assuming a carrier frequency $f_c = 5.9$ GHz, and antenna heights of 1.5 m, the path gain between the Tx and Rx when $d \leq 177$ m (this distance depends on f_c and the antennas heights) can be modeled using (30), with the parameters, $d_{\text{ref}} = 3$ m, $A_0 = 10^{5.32}$, $n_e = 2.27$, and $\sigma_{\text{SH}} = 3$.

From Fig. 8, and using the bounds in (42), we see that the loss in sum-SNR is low for all $\alpha \in \mathcal{A}^*$ ($x = \alpha T/2 = q\pi/K$). In particular, substituting by the upper bound (42) of the loss function in (37) we can deduce that the phase slopes $\alpha = q2\pi/KT$, where $q = 1, \dots, K/2$, ($\alpha \in \mathcal{A}^*$), respectively achieve a sum-SNR that is at worst, -1.94 , -0.91 , -0.64 , -0.54 , and -0.51 dB, lower than the reference zero-loss sum-SNR, $\inf_y S_{\text{PL}}(x, y) = c_1 K$. Note that due to the symmetry of the loss function with respect to $\pi/2$, the phase slopes $\alpha = q2\pi/KT$, $q = K/2 + 1, \dots, K-1$, achieve identical sum-SNR to their symmetric counterparts.

Thus unlike the effects of variation in Ω , when PL is time-varying over the duration of KT s at medium to large distances, the loss in sum-SNR is much lower than the maximum loss $L_{\text{PL}}(x) = 1$, and thus PL time variation cannot cause severe loss in sum-SNR.

As d_x increases, the loss in sum-SNR decreases for all phase slopes $\alpha \in \mathcal{A}^*$. This can be observed from Lemma 2 (41), where the loss is proportional to c_2/c_1 , which is given by

$$\left| \frac{c_2}{c_1} \right| = \frac{n_e |\Delta_v|}{|d_x + \Delta_v t_0|} T/2, \quad (d_y = 0), \quad (44)$$

assuming the use of (32) with $t_0 = (K-1)T/2$. As d_x becomes large, the loss becomes negligible for all phase slopes $\alpha \in \mathcal{A}^*$.

D. Combined PL and Ω Variation

Consider now the scenario when the two VUs are on different lanes $d_y \neq 0$. Then, besides PL, Ω is also time-varying over KT s, and can be approximated using (13), where $a_\Omega \neq 0$. Despite that ϕ varies too, the isotropic antenna responses are fixed, and do not affect the system. In this scenario, the sum-SNR and the loss function are still modeled by (34) and (36) respectively, where $x = (\alpha - a_\Omega)T/2$. Therefore, at medium to long distances, variation in PL changes the shape of the loss function, in the sense that, for any x , the loss in sum-SNR is greater than the loss under non-varying PL, $L_{\text{PL}}(x) \geq L_{\text{PL}}(x)|_{\Delta_v=0}$, as can be seen in Fig. 8. On other hand, variation in Ω introduces deviation to the ACN/ABN phase slope α with a factor of a_Ω . Using the bounds (42) and from Fig. 8, we see that the loss function under PL variation has similar trends to the loss function under time-varying Ω (23) (which is the lower bound). That is, the maximum loss occurs at the points $x = (\alpha - a_\Omega)T/2 = q\pi$, and the loss function has decreasing maxima within $[\pi/K, \pi/2]$, and increasing maxima in $[\pi/2, (K-1)\pi/K]$. Thus, under both PL and Ω variation, the design rule (28) still leads to the most robust phase slope in \mathcal{A}^* . In other words, the phase slope (28) allows us to avoid the most severe loss in sum-SNR over the widest range of a_Ω when both Ω and PL are time-varying over KT s.

VI. EFFECTS OF AOA VARIATION WITH NON-ISOTROPIC ANTENNAS

So far, we assumed that the antenna patterns are isotropic. Now, consider non-isotropic antennas with far-field functions $g_0(\phi)$, $g_1(\phi)$. When the two reference vehicles are on different lanes ($d_y \neq 0$), the AOA varies depending on the speed and initial distance between the Tx and Rx. That introduces a variation in both the gain and the phase of the far-field functions of antennas. In the following, we investigate the effects of these variations on the performance of ACN at medium to large distances. As done in the previous sections, we study the effects of variation of antenna far-field functions while neglecting the effects of the two other quantities of interest (Ω and PL), by assuming that they are both non-varying over KT s. That is, $\Omega(t) \approx b_\Omega$, $a_\Omega = 0$ in (13), and

$\bar{A}(t) \approx b_{\text{PL}}$, $a_{\text{PL}} = 0$ in (31), when $0 \leq t \leq KT$. Then, we express the SNR of the k^{th} packet (6) in this case as

$$\gamma_k = \frac{P_t b_{\text{PL}}}{L \sigma_n^2} \left| \sum_{l=0}^{L-1} |g_l(\phi_k)| e^{-j(\psi_l(kT) - \alpha_l kT)} \right|^2, \quad (45)$$

where the AOA is assumed to be constant over a packet duration $\phi(t) = \phi_k$, $kT \leq t \leq kT + T_m$, $k = 0, 1, \dots, K-1$, and so is ψ_l , $l = 0, 1$. Recalling that $\alpha_0 = 0$, and $\alpha = \alpha_1 \in \mathbb{R}$, the normalized sum-SNR can be expressed as

$$\frac{\sigma_n^2}{P_t b_{\text{PL}}} \sum_{k=0}^{K-1} \gamma_k = \sum_{k=0}^{K-1} \sum_{l=0}^1 \frac{|g_l(\phi_k)|^2}{2} + \sum_{k=0}^{K-1} |g_0(\phi_k) g_1(\phi_k)| \times \cos(\psi_1(kT) - \psi_0(kT) - \alpha kT). \quad (46)$$

From (5) it follows that at $kT \leq t \leq kT + T_m$

$$\begin{aligned} \psi_1(kT) - \psi_0(kT) &= \Omega(kT) - \angle g_1(\phi_k) + \angle g_0(\phi_k) - \beta \\ &= b_\Omega - \angle g_1(\phi_k) + \angle g_0(\phi_k) - \beta, \end{aligned}$$

since $\Omega_0(t) = 0$, $\Omega_1(t) = \Omega(t) = b_\Omega$ when $0 \leq t \leq KT$, $\beta_0 = 0$ and $\beta_1 = \beta \in [0, 2\pi)$. Unlike the case when antennas were assumed to be isotropic, we see here that the phase responses of non-isotropic antennas change with ϕ_k , and introduce a time-varying phase shift. To analyze its effect we apply an affine approximation taking into account the slow change of the AOA at medium to large distances (e.g., at $d_x = 30$ m, ϕ changes by 9 deg/1 s at most, when $\Delta_v \in [-60, 60]$ km/h), following

$$\angle g_0(\phi_k) - \angle g_1(\phi_k) \approx b_{\text{PH}} + a_{\text{PH}} kT. \quad (47)$$

The coefficients b_{PH} and a_{PH} depend on the antenna patterns used and how fast the AOA changes. They can be obtained using the LS method or using the first-order Taylor series when an analytical formula for the antenna far-field functions is available. Adopting the above approximation, we can express the sum-SNR (46) as

$$S_\phi(x, y) = \sum_{k=0}^{K-1} \sum_{l=0}^1 \frac{|g_l(\phi_k)|^2}{2} + J_\phi(x, y),$$

where

$$J_\phi(x, y) = \sum_{k=0}^{K-1} |g_0(\phi_k) g_1(\phi_k)| \cos(y - 2xk), \quad (48)$$

$x = (\alpha - a_{\text{PH}})T/2$ and $y = (b_\Omega + b_{\text{PH}} - \beta)$. The ACN initial phase shift β can take any value in $[0, 2\pi)$, and so does y . Therefore, we assess the performance according to worst-case sum-SNR

$$\inf_{y \in [0, 2\pi)} S_\phi(x, y) = \sum_{k=0}^{K-1} \sum_{l=0}^1 \frac{|g_l(\phi_k)|^2}{2} + \inf_{y \in [0, 2\pi)} J_\phi(x, y). \quad (49)$$

When developing the ACN system [4], [6] under worst-case propagation assumptions, the signal direction ϕ_k was assumed to be negligibly varying over KT s, and coinciding with worst-case AOA defined as

$$\phi_{\min} = \arg \inf_{\phi \in [0, 2\pi)} \sum_{l=0}^1 \frac{|g_l(\phi)|^2}{2}. \quad (50)$$

Thus, we can straightforwardly establish that when the AOA is varying, we achieve a gain in sum-SNR with respect to the worst-case scenario (i.e., $\phi_k = \phi_{\min}$, $\forall k$) since the first term in (49) satisfies

$$\begin{aligned} \sum_{k=0}^{K-1} \sum_{l=0}^1 \frac{|g_l(\phi_k)|^2}{2} &\geq \sum_{k=0}^{K-1} \sum_{l=0}^1 \frac{|g_l(\phi_{\min})|^2}{2} \\ &= K \sum_{l=0}^1 \frac{|g_l(\phi_{\min})|^2}{2}. \end{aligned} \quad (51)$$

On the other hand, under worst-case assumptions of non-varying ϕ_k for $k = 0, \dots, K-1$ (which implies that $a_{\text{PH}} = 0$), we know that for $x = \alpha T/2 \in \mathcal{X}^*$, $\inf_y J_\phi(x, y) = 0$. To investigate if this holds when the AOA is time-varying, and taking into account the slow change rate of ϕ at medium to large distances, we approximate using the LS or first-order Taylor series

$$|g_0(\phi_k) g_1(\phi_k)| \approx b_\phi + a_\phi kT, \quad (52)$$

where $b_\phi + a_\phi kT > 0$, $k = 0, 1, \dots, K-1$. Following that,

$$\begin{aligned} J_\phi(x, y) &= \sum_{k=0}^{K-1} |g_0(\phi_k) g_1(\phi_k)| \cos(y - 2xk) \\ &\approx \sum_{k=0}^{K-1} (b_\phi + a_\phi kT) \cos(y - 2xk). \end{aligned} \quad (53)$$

From (53) we see that variation in ϕ has identical effects to PL variation effects captured by J_{PL} (35), and therefore they can be represented using the same loss function. Consequently, using the left-hand statement of Lemma 2 (40), and the definition (36), we deduce that

$$\inf_{y \in [0, 2\pi)} J_\phi(x, y) < 0, \quad a_\phi \neq 0, x \in \mathbb{R}.$$

Hence, when the AOA is time-varying we also experience a loss in sum-SNR (49) (unlike the case when ϕ is fixed and where $\inf_y J_\phi(x, y) = 0$). The loss in sum-SNR is due to two factors. The first factor is the variation of the antenna gains $|g_0(\phi_k) g_1(\phi_k)|$, which results in a loss even if $a_{\text{PH}} = 0$, $x = \alpha T/2 \in \mathcal{X}^*$. This is identical to the effects of PL variation. The second factor is due to the variation of the phase response of the antennas (47), which shifts the effective phase slope of ACN to $x = (\alpha - a_{\text{PH}})T/2$, and introduces a loss in sum-SNR that has been studied in Section IV under time variation of Ω .

In summary, the effects of time-varying AOA, with affine approximation of phase and magnitude responses of non-isotropic antennas, have the same model as the combined PL and Ω time variation model that has been discussed in Section V-D. Therefore, we can readily conclude that the phase slope in \mathcal{A}^* that ensure a robust performance under the effects of time-varying far-field functions is given by (28). We recall that these conclusions apply at medium to large distances, where the affine approximations used in evaluating the sum-SNR loss term, $\inf_y J_\phi(x, y)$, are expected to be accurate. At short distances, despite that the characterizations of the loss term made in this section may not be very accurate, the gain term in sum-SNR indicated by (51) is still achieved. Furthermore, this gain is expected to be more noticeable

Fig. 9. Normalized worst-case sum-SNR under Ω variation ($1 - L_{\Omega}(x)$) in dB, for $K = 10$, $\delta_a = 10\lambda$, $d_x = 30$ m. ($\bar{\alpha} = \frac{2\pi}{KT}$)

at short rather than large distances, since the AOA change rate is much higher for the former case. These aspects are highlighted using an example of an antenna pattern in the numerical results section.

VII. NUMERICAL RESULTS

In this section, we present numerical results corresponding to the normalized sum-SNR of a 1×2 ACN system (or equivalently 2×1 ABN) when Ω , PL, and ϕ vary over the duration of a burst of K consecutive CAMs, KT s. Throughout this section, we assume that the CAM broadcast period $T = 0.1$ s, and that the maximum tolerable AoI is proportional to $K = 10$ packets.

A. Sum-SNR Under Variation of Ω

In the following, we visualize the sum-SNR for different choices of $\alpha \in \mathcal{A}^*$, taking into account the time variation of Ω only. That is, the antennas are assumed to be isotropic, and the change in PL is assumed negligible over KT s. The coefficients for the affine approximation of Ω in (13) are computed based on Taylor series expansion (14). The LS-based affine approximation was found to lead to comparable results, and it is therefore omitted in the figures to follow in this subsection.

We recall that the worst-case normalized sum-SNR (21), is given by

$$\inf_{y \in [0, 2\pi)} S_{\Omega}(x, y) = K(1 - L_{\Omega}(x)), \quad (54)$$

where $x = (\alpha - a_{\Omega})T/2$. Since a_{Ω} (14) depends on Δ_v , d_x , δ_a , and d_y , we visualize the sum-SNR as a function of Δ_v for a fixed initial distance d_x , and a fixed antenna separation δ_a . Furthermore, since the effect of lateral distance results in $a_{\Omega}|_{-d_y} = -a_{\Omega}|_{d_y}$ (follows from (12), or (14)), the sum-SNR is minimized over $d_y \in \{-4, 4\}$.

In Fig. 9, we plot the sum-SNR, after further normalization with respect to K , in dB, at a medium distance $d_x = 30$ m, when the antenna separation is $\delta_a = 10\lambda$. We recall that the loss function under variation of Ω ,

Fig. 10. Normalized worst-case sum-SNR under Ω variation ($1 - L_{\Omega}(x)$) in dB, for $K = 10$, $\delta_a = 10\lambda$ at $d_x = 100$ m, and $\delta_a = \lambda/2$ at $d_x = 30$ m. ($\bar{\alpha} = \frac{2\pi}{KT}$)

L_{Ω} is symmetric around $\pi/2$ and therefore, we visualize the results only for $\alpha \in \mathcal{A}^*$, $\alpha = q\frac{2\pi}{KT}$, $q = 1, \dots, 5$. From Fig. 9, we see that the choice of α satisfying (28), i.e., $\alpha^* = 5 \times 2\pi/KT$, exhibits a robust performance to channel phase variation with a low loss over the full range of $\Delta_v \in [-60, 60]$ km/h. Besides α^* , the choice of $\alpha = 4 \times 2\pi/KT$, or $\alpha = 3 \times 2\pi/KT$ results in comparably low loss too, which follows since the phase slopes have, respectively, the second and the third largest phase distances from the points of severe sum-SNR loss $x = q\pi$. The phase slope having the shortest phase distance from these points, $\bar{\alpha} = 2\pi/KT$, exhibits the highest loss, and it is the least robust phase slope in \mathcal{A}^* . In Fig. 9, we also plot the sum-SNR using the exact value of Ω (12), for the most and the least robust choices of phase slopes in \mathcal{A}^* (α^* and $\bar{\alpha}$). We see that the sum-SNR using the linearized model is matching the sum-SNR using the exact value of Ω for most speeds. The maximum loss experienced by α^* when antennas are $\delta_a = 10\lambda$ apart, is approximately 0.5 dB (according to the exact sum-SNR). If the antenna separation is smaller $\delta_a = \lambda/2$, then the ACN experiences a significantly lower loss in sum-SNR for both α^* and $\bar{\alpha}$ as can be seen in Fig. 10. In fact, the loss in sum-SNR of the ACN with $\delta_a = \lambda/2$ at $d_x = 30$ m is comparable to that of the ACN with $\delta_a = 10\lambda$ at a large distance $d_x = 100$ m. This implies that implementing ACN systems with low antenna separation limits the sum-SNR loss incurred due to time variation of Ω . Note that for both the cases shown in Fig. 10, α^* has an advantage compared to $\bar{\alpha}$, yet the loss in sum-SNR is not significant for both phase slopes.

In Section IV-A it was explained that modeling Ω as an affine function holds under medium to large distances. Therefore, we are interested in evaluating sum-SNR under short distances using the exact value of Ω . In Fig. 11 we show the sum-SNR at $d_x = 10$ m, when the antenna separation is $\delta_a = 10\lambda$. As expected we see that at such a short distance the linearized model is accurate only for relatively low speeds $\Delta_v \in [-15, 35]$ km/h. We note that for negative relative speeds the variation in Ω is faster than

Fig. 11. Normalized worst-case sum-SNR under Ω variation ($1 - L_{\Omega}(x)$) in dB, for $K = 10$, $\delta_a = 10\lambda$, $d_x = 10$ m. ($\bar{\alpha} = \frac{2\pi}{KT}$)

for positive speeds since, for the former, the geometries between the Tx and Rx change more dramatically due to decreasing distance between the VUs and potential overtaking movement. For the latter, the distance between the VUs is increasing and thus the change in geometries is less severe. At larger speed differences, the change in Ω is much faster and it cannot be approximated using a first-order polynomial. Following this at the points $x = (\alpha - a_{\Omega})T/2 = q\pi$, as it is the case for the ACN with α^* at $\Delta_v \approx -30, -58$ km/h, the loss in sum-SNR is not as severe as it is predicted using the linearized model. This is also observed at $\Delta_v = -41, -46$ km/h for $\bar{\alpha}$. Thus, when the change in Ω is very fast and cannot be accurately approximated using a first-order polynomial, the ACN/ABN system does not exhibit a severe loss in sum-SNR as predicted using the linearized model. The system exhibits better performance. We note that at this short distance α^* shows advantage compared to $\bar{\alpha}$ mostly when $\Delta_v > -15$ km/h.

To highlight more the advantage of a proper choice of α , in Fig. 12 we show the sum-SNR at $d_x = 10$ m, when $\delta_a = \lambda/2$. We can observe that for such small antenna separation the linearized model is valid over a larger range of speed even at such a short distance. Moreover, the phase slope α^* sustains a performance with low loss over the full speed range compared to $\bar{\alpha}$.

B. Sum-SNR Under PL Variation

To show the effects of PL variation and the performance of the different phase slopes, we plot in Fig. 13 the sum-SNR (37) for the worst-case y as a function of Δ_v at a fixed medium distance $d_x = 30$ m. Both vehicles are on the same lane, $d_y = 0$ m, which results in non-varying Ω , ($a_{\Omega} = 0$). Antennas are assumed to be isotropic. We normalize the sum-SNR with respect to the average path gain at $d_x = 30$ m, and with respect to K , such that it is equal to 0 dB at $\Delta_v = 0$ km/h. We show the results for the affine approximation of the path gain, which is modeled according to WINNER+B1 model, based on both Taylor series (32) and the LS method, since the latter exhibited

Fig. 12. Normalized worst-case sum-SNR under Ω variation ($1 - L_{\Omega}(x)$) in dB, for $K = 10$, $\delta_a = \lambda/2$, $d_x = 10$ m. ($\bar{\alpha} = \frac{2\pi}{KT}$)

Fig. 13. Normalized worst-case sum-SNR under PL variation in dB, for $K = 10$, $d_x = 30$ m, $d_y = 0$ m. The PL model parameters correspond to WINNER+B1 model, and they are $d_{\text{ref}} = 3$ m, $A_0 = 10^{5.32}$, $n_e = 2.27$, and $\sigma_{\text{SH}} = 3$. ($\bar{\alpha} = \frac{2\pi}{KT}$)

more accurate results in this case. From the figure, we observe that the loss due to PL variation is not significant for all phase slopes $\alpha \in \mathcal{A}^*$. In particular, the loss is at most around 0.4 dB, and 1.5 dB, for $\alpha^*T/2 = \pi/2$, and $\bar{\alpha}T/2 = \pi/K$, respectively (based on exact curves at $\Delta_v = -60$ km/h). The loss of the remaining phase slopes within \mathcal{A}^* lies in between. As discussed in Section V, unlike the effects of variation of channel phase, variation in PL does not introduce a shift to the ACN/ABN phase slope, and this explains the non-significant loss in sum-SNR.

C. Sum-SNR Under Antenna Response Variation

In Section VI, we have seen that as ϕ varies, the phase and amplitude responses of antennas vary too. In Fig. 15 we show the sum-SNR (49) under these effects when the antennas employed by the ACN/ABN are the ones shown in Fig. 14. The sum-SNR is plotted as a

Fig. 14. Back-to-back patch antenna pattern. The antennas are designed by Smarteq³ for Vehicular applications.

function of Δ_v for a fixed d_x , and for the worst-case $y \in [0, 2\pi)$, and worst-case $d_y \in \{-4, 4\}$. The received signal is assumed to coincide with the worst-case AOA, ϕ_{\min} (50) at time $t = 0$. Moreover, PL and Ω are assumed to be approximately constant over KT s. The affine coefficients for the approximation of far-field functions phase (47) and amplitude (52) are computed using the LS. For consistency, we normalize the sum-SNR with respect to $(|g_0(\phi_{\min})|^2 + |g_1(\phi_{\min})|^2)$, and with respect to K , such that the sum-SNR equals 0 dB at $\Delta_v = 0$ km/h.

From Fig. 15 we see that at a medium distance $d_x = 30$ m, the loss in sum-SNR is low for $\bar{\alpha}$, and negligible for α^* and the remaining phase slopes in \mathcal{A}^* . Despite that the phase slopes are shifted by a_{PH} , resulting in $x = (\alpha - a_{PH})T/2$, the loss in sum-SNR is not as large as it was the case under time variation of Ω at $d_x = 30$ m and $\delta_a = 10\lambda$. The sum-SNR gain (51) due to variation of ϕ is negligible at $d_x = 30$ m for these antenna patterns, as can be inferred from the reference curve in Fig. 15 ($d_x = 30$ m). However, at $d_x = 10$ m, this gain is higher. On the other hand, the loss in sum-SNR due to $\inf_y J_\phi(x, y)$ is also higher at $d_x = 10$ m compared to $d_x = 30$ m, and it is most noticeable for $\bar{\alpha}$. This loss is mostly attributed to the phase deviation a_{PH} , which causes dips in sum-SNR e.g., at $\Delta_v \approx 38$ km/h, when $x = (\bar{\alpha} - a_{PH})T/2 = q\pi$. This can be concluded by looking at the sum-SNR for $\bar{\alpha}$, when the phase response of the antennas is assumed constant over KT s, ($a_{PH} = 0$). Unlike $\bar{\alpha}$, the phase slopes α^* , and $\alpha \in \{4 \times 2\pi/KT, 3 \times 2\pi/KT\}$, effectively mitigate these effects and exhibit a low loss (approximately less than 0.5 dB) over the full range of Δ_v .

Despite that the linearized model cannot be generally claimed to be accurate at short distances, we see from Fig. 15 that it does predict the actual behavior of the sum-SNR curves, and it allows us to correctly select a robust phase slope within \mathcal{A}^* (28) in mitigating the loss in sum-SNR due to the variation of antenna responses.

D. Combined Effects of the Dominant Path Variation

In this section, we show the sum-SNR taking into account the combined effects of time-varying Ω , PL, and

³Smarteq Wireless AB, Sweden is a company specializing in antenna design and development for vehicle industry and others.

Fig. 15. Normalized worst-case sum-SNR under antenna response variation in dB, for $K = 10$, $d_x = 30$ m, and $d_x = 10$ m. ($\bar{\alpha} = \frac{2\pi}{KT}$)

Fig. 16. Worst-case (unnormalized) sum-SNR under variation of Ω , PL, and AOA in dB, for $K = 10$, $\delta_a = 10\lambda$, $P_t = 23$ dBm, and $\sigma_n^2 = -95$ dBm. The linear approximation coefficients of Ω and PL are computed using Taylor expansion, and those of antenna responses are computed using the LS. ($\bar{\alpha} = \frac{2\pi}{KT}$)

ϕ . The PL is modeled using WINNER+B1 channel model, and the receiver antennas have the patterns shown in Fig. 14. The received signal is assumed to coincide with the worst-case AOA, ϕ_{\min} at time $t = 0$. To be able to compare the sum-SNR for different distances, we plot it without normalization. The transmitted power is set to $P_t = 23$ dBm, and the noise power at the receiver is set to $\sigma_n^2 = -95$ dBm, which correspond to the commercial IEEE802.11p radio values (at 6 Mbit/s) [19]. In Fig. 16 we show the sum-SNR for worst-case $y \in [0, 2\pi)$, and worst-case $d_y \in \{-4, 4\}$, at $d_x \in \{10, 30, 100\}$.

From the figure, we see that the observations made earlier when analyzing the effects of the three quantities separately are valid when taking into account their combined effects. Namely, ACN is impacted by time variation at medium and short distances. The choice of α^* (28) yields a robust performance under time variation of the dominant path. Despite that $\bar{\alpha} = 2\pi/KT$ yields optimal performance under non-time-varying conditions (i.e., under worst-case assumptions), it can exhibit severe loss in sum-SNR, e.g., around 13 dB at $d_x = 30$ m, and around 16 dB at $d_x = 10$ m, when the dominant path is time-varying. Other choices of $\alpha \in \mathcal{A}^*$ are more robust than $\bar{\alpha}$ and less robust than α^* . We recall that the antenna separation is set to $\delta_a = 10\lambda \approx 0.5$ m. Using lower δ_a decreases the loss for all $\alpha \in \mathcal{A}^*$ and vice versa. In this paper, motivated by the low PL at short distances we focused our analysis of ACN/ABN at medium to large distances. In Fig. 16 we see a visual validation of this approach where even under severe loss in sum-SNR, the system performance at $d_x = 10$ m is higher than the performance at $d_x = 100$ m and at $d_x = 30$ m for the major part of the speed interval.

VIII. CONCLUSION AND FUTURE WORKS

ACN [4] and ABN [6] are robust multiple antenna schemes that maximize the sum-SNR of K consecutive broadcast, periodic packets, under a worst-case propagation scenario, of a single dominant path with non-varying AOA, path-loss (PL), and phase shift between antennas Ω , over the duration of K packets. In this work, we investigated the performance of a 1×2 ACN (2×1 ABN) when the three quantities of the dominant component are time-varying instead. The main findings of this work follow.

- The phase slopes that yield identical optimal sum-SNR when the AOA, the path-loss, and Ω are non-varying, yield different sum-SNR when any of these three quantities vary over the duration of K packets.
- Time variation of Ω results in shifting the ACN phase slope, and incurs a loss in sum-SNR that depends on the phase slope used, how fast the time variation of Ω is, and the antenna separation. In particular, the smaller the antenna separation, the less susceptible ACN is to these variations.
- To mitigate the loss in sum-SNR under variation of Ω at medium to large distances, we proposed a design rule (28) that yields a phase slope that is robust against time variations and optimal under time-invariant conditions.

- Time variation of the PL does not induce a shift to the ACN phase slope, but it attenuates the sum-SNR achieved using any phase slope compared to the sum-SNR achieved under time-invariant conditions. The sum-SNR loss incurred is minor compared to the loss incurred due to time variation of Ω . The derived design rule (28) is found to yield a phase slope that is robust against variation of PL at medium to large distances, as well.
- Variation of AOA induces a variation of phase and amplitude of the antenna far-field functions, which has equivalent effects to the combined Ω and PL time variation effects, with an extent that depends on the antennas employed. The design rule (28) yields a robust phase slope in \mathcal{A}^* in this case too.

In this study, we investigated the performance of ACN/ABN after relaxing the worst-case propagation scenario assumed when designing them. The next step is to study the performance of ACN/ABN under rich multipath propagation, which represents a full relaxation of the worst-case propagation assumption and is left for future work.

APPENDIX

A. Preliminaries

Here we present preliminary statements and lemmas that are used in the proof of Lemma 1 and Lemma 2.

Define the sets

$$\mathcal{X} \triangleq \{q\pi, q \in \mathbb{Z}\}, \quad (55)$$

$$\mathcal{X}^* \triangleq \{q\pi/K, q \in \mathbb{Z}\} \setminus \mathcal{X}. \quad (56)$$

It follows that

$$x \in \mathcal{X} \iff x + \pi \in \mathcal{X}, \quad (57)$$

$$(\pi/2 - x) \in \mathcal{X} \iff (\pi/2 + x) \in \mathcal{X}. \quad (58)$$

The first statement follows since if $x \in \mathcal{X}$ then $x = m\pi$, $m \in \mathbb{Z}$ and hence $x + \pi = (m + 1)\pi \in \mathcal{X}$. Similarly, if $(x + \pi) \in \mathcal{X}$ then $x + \pi = m\pi$, $m \in \mathbb{Z}$, and hence $x = (m - 1)\pi \in \mathcal{X}$. To show (58), let $(\pi/2 \pm x) \in \mathcal{X}$, then $\pi/2 \pm x = m\pi$, where $m \in \mathbb{Z}$. Then multiplying both sides by -1 and adding π , we obtain $\pi/2 \mp x = (1 - m)\pi$, hence $(\pi/2 \mp x) \in \mathcal{X}$.

For fixed positive integer $K > 1$ define the functions $f_1 : x \in \mathbb{R} \setminus \mathcal{X} \rightarrow \mathbb{R}$, and $f_2 : x \in \mathbb{R} \setminus \mathcal{X} \rightarrow \mathbb{R}$ following

$$f_1(x) \triangleq \frac{\sin(Kx)}{\sin(x)}, \quad (59)$$

$$f_2(x) \triangleq \frac{K \cos(Kx)}{\sin(x)} - \frac{\sin(Kx)}{\sin(x)} \cot(x). \quad (60)$$

Lemma 3. *Let f_1 be as defined in (59), then $|f_1(x)|$ and $f_1^2(x)$ are periodic with period π , and symmetric around $\pi/2$.*

Proof. From (59), and $\sin(K\pi) = 0$ it follows that

$$f_1(x + \pi) = \frac{\sin(Kx + K\pi)}{\sin(x + \pi)} = -\frac{\sin(Kx) \cos(K\pi)}{\sin(x)}.$$

Hence $|f_1(x + \pi)| = |f_1(x)|$ and $|f_1^2(x + \pi)| = |f_1^2(x)|$, and the periodicity property follows. To prove the symmetry property, we show that

$$|f_1(\pi/2 + x)| = |f_1(\pi/2 - x)|. \quad (61)$$

We have $|f_1(\pi/2 + x)|$ is given by

$$\left| \frac{\sin(K\frac{\pi}{2}) \cos(Kx) + \cos(K\frac{\pi}{2}) \sin(Kx)}{\cos(x)} \right|. \quad (62)$$

On the other hand, $|f_1(\pi/2 - x)|$ is given by

$$\left| \frac{\sin(K\frac{\pi}{2}) \cos(Kx) - \cos(K\frac{\pi}{2}) \sin(Kx)}{\cos(x)} \right|. \quad (63)$$

If K is even, it follows from (62) and (63) that $|f_1(\pi/2 + x)| = |\sin(Kx)/\cos(x)| = |f_1(\pi/2 - x)|$. If K is odd, it follows from the same equations that $|f_1(\pi/2 + x)| = |\cos(Kx)/\cos(x)| = |f_1(\pi/2 - x)|$. Hence $|f_1(x)|$ is symmetric around $\pi/2$. Since f_1 is a real-valued function, $f_1^2(x) = |f_1(x)|^2$, and thus $f_1^2(x)$ is symmetric around $\pi/2$ too, and the lemma follows. \square

Lemma 4. *Let f_2 be as defined in (60), then $f_2^2(x)$ is periodic with period π , and symmetric around $\pi/2$.*

Proof. Employing trigonometric identities and noting that $\sin(K\pi) = 0$, we have

$$\begin{aligned} f_2(x + \pi) &= \frac{K \cos(Kx) \cos(K\pi)}{\sin(x + \pi)} \\ &\quad - \frac{\sin(Kx) \cos(K\pi)}{\sin^2(x + \pi)} \cos(x + \pi) \\ &= -\cos(K\pi) \\ &\quad \times \left(\frac{K \cos(Kx)}{\sin(x)} - \frac{\sin(Kx)}{\sin^2(x)} \cos(x) \right). \end{aligned} \quad (64)$$

Hence, $f_2^2(x + \pi) = (-\cos(K\pi))^2 f_2^2(x) = f_2^2(x)$, and thus $f_2^2(x)$ is periodic with period π . To prove the symmetry property, we first let K be even. Using trigonometric identities and the fact that $\sin(K\frac{\pi}{2}) = 0$, we can express $f_2(\pi/2 + x)$ as

$$\frac{K \cos(K\frac{\pi}{2}) \cos(Kx)}{\cos(x)} + \frac{\cos(K\frac{\pi}{2}) \sin(Kx)}{\cos^2(x)} \sin(x),$$

and that is equal to $f_2(\pi/2 - x)$, when K is even. Second, let K be odd, then $f_2(\pi/2 + x)$ can be expressed as

$$-\frac{K \sin(K\frac{\pi}{2}) \sin(Kx)}{\cos(x)} + \frac{\sin(K\frac{\pi}{2}) \cos(Kx)}{\cos^2(x)} \sin(x),$$

while $f_2(\pi/2 - x) = -f_2(\pi/2 + x)$. Combining the cases, K even and K odd, we can conclude that $f_2^2(\pi/2 + x) = f_2^2(\pi/2 - x)$, and hence the symmetry property holds, and the lemma follows. \square

B. Proof of Lemma 1 and Lemma 2

We demonstrate the results of Lemma 1 and Lemma 2 together. To that end, for a fixed integer $K > 1$, $x \in \mathbb{R}$, and $y \in [0, 2\pi)$, define

$$J(x, y) \triangleq \sum_{k=0}^{K-1} (b + akT) \cos(y - 2xk), \quad (65)$$

where $(b + akT) > 0$, $k = 0, 1, \dots, K-1$, implying that $b > 0$, and $a > -b/(K-1)T$. Moreover, define

$$L(x) \triangleq - \inf_{y \in [0, 2\pi)} \frac{J(x, y)}{c_1 K}, \quad (66)$$

where $c_1 = (b + aT(K-1)/2) > 0$. For $b = b_{\text{PL}}$ and $a = a_{\text{PL}}$, (65) and (66), correspond to the functions J_{PL} (35), and L_{PL} (36), respectively. Similarly, for $b = 1$ and $a = 0$, (65) and (66) correspond to the functions J_{Ω} (18) and L_{Ω} (22), respectively.

To show the claims of Lemma 1 and Lemma 2 it is enough to show that for any $b > 0$ and $a > -b/(K-1)T$,

(i) $L(x)$ is given by

$$L(x) = \begin{cases} 1, & x \in \mathcal{X} \\ \sqrt{c_1^2 f_1^2 + c_2^2 f_2^2} / (c_1 K), & x \notin \mathcal{X} \end{cases} \quad (67)$$

where $c_2 = aT/2$, f_1, f_2 are defined in (59), (60), respectively, and \mathcal{X} is defined in (55).

Note that when $b = 1$ and $a = 0$, $L(x) = |f_1(x)|/K$, $x \notin \mathcal{X}$.

(ii) $L(x)$ is periodic with period π and symmetric around $\pi/2$.

(iii) $L(x)$ can be bounded as

$$\begin{cases} 0 < L(x), & a \neq 0 \\ 0 \leq L(x), & a = 0 \end{cases}, \quad L(x) \leq 1. \quad (68)$$

(iv) If $x \in \mathcal{X}^*$, where \mathcal{X}^* is defined in (56), then

$$L(x) = \left| \frac{c_2}{c_1 \sin(x)} \right|. \quad (69)$$

Note that if $a = 0$, then $c_2 = 0$, ($c_1 \sin(x) \neq 0$) and the lower bound in (68) is achieved, $L(x) = 0$.

(v) For $x \notin \mathcal{X}$, $L(x)$ can be bounded as

$$\frac{|f_1(x)|}{K} \leq L(x) \leq \frac{\sqrt{(K-1)^2 f_1^2(x) + f_2^2(x)}}{(K-1)K}. \quad (70)$$

Note that the lower bound is achievable when $a = 0$.

Proof. We start by deriving a different expression of J that facilitates the proof of the lemmas. Let $x \in \mathcal{X}$, it follows that

$$J(x, y) = \cos(y) \sum_{k=0}^{K-1} (b + akT) = \cos(y) c_1 K. \quad (71)$$

Then, let $x \notin \mathcal{X}$. We can write

$$\begin{aligned} J(x, y) &= b \operatorname{Re} \left\{ e^{jy} \sum_{k=0}^{K-1} e^{-j2xk} \right\} \\ &\quad + aT \operatorname{Re} \left\{ e^{jy} \frac{j}{2} \frac{d}{dx} \sum_{k=0}^{K-1} e^{-j2xk} \right\}. \end{aligned} \quad (72)$$

Using the sum of the geometric series, we obtain

$$\begin{aligned} \sum_{k=0}^{K-1} e^{-j2xk} &= e^{-j(K-1)x} f_1(x), \\ \frac{d}{dx} \sum_{k=0}^{K-1} e^{-j2xk} &= -j(K-1) e^{-j(K-1)x} f_1(x) \\ &\quad + e^{-j(K-1)x} f_2(x), \end{aligned}$$

since $f_2(x) = \frac{d}{dx} f_1(x)$. Substituting in (72) we arrive at

$$J(x, y) = \begin{cases} c_1 K \cos(y), & x \in \mathcal{X} \\ c_1 f_1(x) \cos(y - (K-1)x) \\ -c_2 f_2(x) \sin(y - (K-1)x), & x \notin \mathcal{X} \end{cases} \quad (73)$$

Now we tackle the lemmas claims.

- (i) To show that $L(x)$ is given by (67), we first let $x \in \mathcal{X}$. Then, it follows from (73) that

$$L(x) = - \inf_{y \in [0, 2\pi)} \frac{J(x, y)}{c_1 K} = - \inf_{y \in [0, 2\pi)} \cos(y) = 1.$$

Second, let $x \notin \mathcal{X}$, and write

$$\begin{aligned} c_1 f_1(x) &= R(x) \cos(\varphi(x)), \\ -c_2 f_2(x) &= R(x) \sin(\varphi(x)), \\ R(x) &= \sqrt{c_1^2 f_1^2(x) + c_2^2 f_2^2(x)}, \\ \varphi(x) &= \arctan\left(-\frac{c_2 f_2(x)}{c_1 f_1(x)}\right). \end{aligned}$$

Then, it follows from (73) that

$$J(x, y) = R(x) \cos(y - (K-1)x - \varphi(x)),$$

and thus, when $x \notin \mathcal{X}$

$$- \inf_{y \in [0, 2\pi)} \frac{J(x, y)}{c_1 K} = \frac{R(x)}{c_1 K} = \frac{\sqrt{c_1^2 f_1^2(x) + c_2^2 f_2^2(x)}}{c_1 K}.$$

where the minimizer is given by $y = \text{mod}((K-1)x + \varphi(x) + \pi, 2\pi)$. Hence, (67) holds.

- (ii) To show that L is periodic and symmetric, let $x \in \mathcal{X}$, then from (67) we get $L(x) = 1$, which is a constant. Using (57) and (58) we can conclude that L is periodic with period π , and symmetric around $\pi/2$ when $x \in \mathcal{X}$. The same statement is true when $x \notin \mathcal{X}$, since by (67) $L(x) = \sqrt{c_1^2 f_1^2(x) + c_2^2 f_2^2(x)} / (c_1 K)$, and since both f_1^2 and f_2^2 are periodic and symmetric as shown in Lemma 3 and Lemma 4, respectively.
- (iii) To show (68), we first proof that $L(x) \leq 1$. To that end, observe that $\sum_{k=0}^{K-1} (b + akT) = c_1 K$. Then using (65) we deduce that

$$-c_1 K \leq J(x, y) \leq c_1 K. \quad (74)$$

Then, it follows that $L(x) = - \inf_y J(x, y) / (c_1 K) \leq 1$, which is achievable when $x \in \mathcal{X}$.

Second, to show the lower bounds in (68), we employ (67) and the fact that $c_1 > 0$ to deduce that

$$\begin{aligned} L(x) = 0 &\iff x \notin \mathcal{X} \\ &\iff (f_1^2(x) = 0, c_2^2 f_2^2(x) = 0). \end{aligned} \quad (75)$$

Since $f_1(x) = 0$ if and only if $x \in \mathcal{X}^*$, and since

$$f_2^2(x) = \left(K \frac{\cos(Kx)}{\sin(x)}\right)^2 > 0, \quad x \in \mathcal{X}^*, \quad (76)$$

we conclude that $0 < L(x)$ when $a \neq 0$, (since $c_2 = aT/2$), and $0 \leq L(x)$, when $a = 0$.

- (iv) Let $x \in \mathcal{X}^*$, from the definition (56) we deduce that $x = m\pi/K$, where $m \neq qK$, $q \in \mathbb{Z}$, hence $x \notin \mathcal{X}$.

Substituting in (67), and recalling from the previous argument that $f_1(x) = 0$ we get

$$\begin{aligned} L(x) &= \frac{|c_2 f_2(x)|}{c_1 K} = \left| c_2 K \frac{\cos(m\pi)}{c_1 K \sin(x)} \right| \\ &= \left| \frac{c_2}{c_1 \sin(x)} \right|. \end{aligned} \quad (77)$$

- (v) From (67) it follows that, for $x \notin \mathcal{X}$,

$$L(x) = \frac{1}{K} \sqrt{f_1^2(x) + \left(\frac{c_2}{c_1}\right)^2 f_2^2(x)}. \quad (78)$$

From the definitions of c_1 and c_2 , we deduce that

$$\frac{c_2}{c_1} = \frac{aT/2}{b + a(K-1)T/2} \quad (79)$$

$$= \frac{1}{K-1} \frac{a/b}{a/b + 2/(K-1)T} \quad (80)$$

$$= \frac{1}{K-1} \frac{w}{w + 2A}, \quad (81)$$

where $w = a/b$ and $A = 1/(K-1)T$. From the condition $a > -b/(K-1)T$, we have that (81) is valid for $w > -1/(K-1)T = -A$.

We can now write, for $x \notin \mathcal{X}$,

$$L(x; w) = \frac{1}{K} \sqrt{f_1^2(x) + g(w) \frac{f_2^2(x)}{(K-1)^2}} \quad (82)$$

$$= \frac{\sqrt{(K-1)^2 f_1^2(x) + g(w) f_2^2(x)}}{K(K-1)}, \quad (83)$$

where

$$g(w) = \left(\frac{w}{w + 2A}\right)^2, \quad w > -A. \quad (84)$$

It is easily seen that, for a fixed $x \neq \mathcal{X}$, $L(x; w)$ increases as $g(w)$ increases. Moreover, it is easily verified that

$$\begin{aligned} g(0) &= 0, \\ \lim_{w \rightarrow -A} g(w) &= \lim_{w \rightarrow \infty} g(w) = 1, \\ \frac{d}{dw} g(w) &= \frac{4Aw}{(w + 2A)^3} = \begin{cases} \leq 0, & -A < w \leq 0 \\ > 0, & w > 0 \end{cases} \end{aligned}$$

In other words, $g(w)$ is decreasing for $-A < w \leq 0$, attains its minimum as $w = 0$, and increases for $w \geq 0$. It follows that $\sup_{w > -A} g(w) = 1$ and $\inf_{w > -A} g(w) = 0$, and, therefore,

$$L(x; w) \leq \sup_{w > -A} L(x, w) \quad (85)$$

$$= \frac{\sqrt{(K-1)^2 f_1^2(x) + f_2^2(x)}}{K(K-1)}, \quad (86)$$

and

$$L(x; w) \geq \inf_{w > -A} L(x, w) = \frac{|f_1(x)|}{K}. \quad (87)$$

Hence (70) holds.

All the claims have been shown and thus Lemma 1, and Lemma 2 follow. \square
