Wavelike, bosonic dark matter candidates like axions and dark photons can be detected using microwave cavities commonly referred to as haloscopes. Traditionally, haloscopes consist of tunable copper cavities operating in the TM_{010} mode, but ohmic losses have limited their performance. In contrast, superconducting radio frequency (SRF) cavities can achieve quality factors of $\sim 10^{10}$, perhaps five orders of magnitude better than copper cavities, which would lead to more sensitive dark matter detectors. In this paper, we first derive that the scan rate of a haloscope experiment is proportional to the loaded quality factor Q_L , even if the cavity bandwidth is much narrower than the dark matter halo lineshape. We then present a proof-of-concept search for dark photon dark matter using a nontunable ultrahigh quality SRF cavity. We exclude dark photon dark matter with kinetic mixing strengths of $\chi > 1.8 \times 10^{-16}$ for a dark photon mass of $m_{A'} = 5.37 \mu\text{eV}$, achieving the deepest exclusion to wavelike dark photons by almost an order of magnitude.

Introduction.—There is overwhelming evidence that 84.4% of the matter in the universe is made out of dark matter (DM) [1–7]. The ΛCDM model describes dark matter as feebly interacting, nonrelativistic, and stable on cosmological timescales. Not much else is known about the nature of dark matter, particularly what particles beyond the standard model it is made of.

The dark photon (DP) is a compelling dark matter candidate. It is a spin-1 gauge boson associated with a new Abelian $U(1)$ symmetry and is one of the simplest possible extensions to the Standard Model (SM) [8–10]. The dark photon, having the same quantum numbers as the SM photon, generically interacts with the SM photon through kinetic mixing [11, 12] described by the Lagrangian

$$\mathcal{L} = -\frac{1}{4}(F_1^{\mu\nu}F_{1\mu\nu} + F_2^{\mu\nu}F_{2\mu\nu} - 2\chi F_1^{\mu\nu}F_{2\mu\nu} - 2m_{A'}^2 A'^2), \quad (1)$$

where $F_1^{\mu\nu}$ is the electromagnetic field tensor, $F_2^{\mu\nu}$ is the dark photon field tensor, χ is the kinetic mixing strength, $m_{A'}$ is the DP mass, and A' is the DP gauge field. If both $m_{A'}$ and χ are sufficiently small, then it is stable on cosmological timescales [13]. The dark photon is then an attractive dark matter candidate. If its mass is less than an eV, the DPDM is in the wavelike regime, where it is best described as a coherent wave oscillating at the frequency of its rest mass rather than a collection of particles. The dark matter kinetic energy distribution sets the degree of coherence of wavelike dark matter to be of order $v_{\text{DM}}^2 \sim 10^{-6}$ [14, 15].

Several mechanisms could produce a relic of cosmic dark photons. One simple example is the displacement

of the DP field through quantum fluctuations during inflation [16]. These fluctuations in the DP field serve as the initial displacement for dark photon field oscillations, which commence once the Universe’s expansion rate falls below the DP mass. Other mechanisms are possible and are described in [10, 17].

Dark photon dark matter (DPDM) can be detected through its mixing with the SM photon. If dark photons oscillate into SM photons inside a microwave cavity with a large quality factor, then a feeble EM signal accumulates inside the cavity, which can be read by ultralow noise electronics. This type of detector is called a haloscope and is often deployed to search for axionic DM [18]. The SM photon frequency f is related to the dark photon energy $E_{A'}$ by $f = E_{A'} \approx m_{A'}$.

The dark photon signal power is [9, 19–21]

$$P_S = P_0 \frac{\beta}{\beta + 1} L(f, f_0, Q_L) \quad (2)$$

$$P_0 = \begin{cases} \eta \chi^2 m_{A'} \rho_{A'} V_{\text{eff}} Q_L, & \text{if } Q_L \ll Q_{\text{DM}} \\ \eta \chi^2 m_{A'} \rho_{A'} V_{\text{eff}} Q_{\text{DM}}, & \text{if } Q_L \gg Q_{\text{DM}} \end{cases} \quad (3)$$

$$V_{\text{eff}} = \frac{(\int dV \mathbf{E}(\vec{x}) \cdot \mathbf{A}'(\vec{x}))^2}{\int dV \epsilon_r |\mathbf{E}(\vec{x})|^2 |\mathbf{A}'(\vec{x})|^2} \quad (4)$$

where η is a signal attenuation factor, $\rho_{A'}$ is the local density of dark matter, V_{eff} is the effective volume of the cavity, Q_L is the cavity’s loaded quality factor, Q_{DM} is the dark matter “quality factor” related to the dark matter coherence time, and β is the cavity coupling coefficient. The Lorentzian term is $L(f, f_0, Q_L) = 1/(1+4\Delta^2)$, where $\Delta \equiv Q_L(f - f_0)/f_0$ is a detuning factor that depends on the SM photon frequency f , cavity resonant frequency f_0 , and Q_L . V_{eff} is the overlap between the dark photon field $\mathbf{A}'(\vec{x})$ and the dark photon-induced electric field $\mathbf{E}(\vec{x})$. Equations 2, 3, and 4 assume that the cavity size is much smaller than the DP de Broglie wavelength.

The dark photon mass is unknown, so haloscopes must be tunable to search through the χ vs. $m_{A'}$ parameter space. Thus the scan rate is a key figure of merit for haloscope experiments. Most of the haloscope literature has focused on the case where $Q_L \ll Q_{DM}$ because copper cavities have been traditionally used. However, superconducting niobium cavities with $Q_L \sim 10^{10}$ [28] are readily available for DPDM haloscope searches, and superconducting cavities resistant to multi-Tesla magnetic fields with $Q_L > Q_{DM}$ will soon be readily available [47–50].

This Letter first derives that the haloscope scan rate is proportional to Q_L , even in the case that where $Q_L \gg Q_{DM}$ and the DP signal power saturates (Eq. 2). This conclusion strongly motivates the pursuit of ultrahigh Q haloscopes. This Letter then reports a DPDM search using a nontunable 1.3 GHz cavity with $Q_L \sim 10^{10}$. The search demonstrates superior sensitivity enabled by the ultrahigh quality factor and achieves the deepest exclusion to wavelike DPDM to date by almost an order of magnitude.

The scan rate for an ultrahigh Q haloscope.—The haloscope scan rate is strongly dependent on the SNR, where $\text{SNR} = (P_S/P_n)\sqrt{b\Delta t}$ [22, 23]. P_n is the noise power, b is the frequency bin width, and Δt is the integration time. P_n is the combination of the cavity’s blackbody radiation and the receiver’s Johnson noise. The noise power can be expressed as $P_n = k_b b T_n$, where k_b is the Boltzmann constant, and T_n is the system noise temperature referenced to the cavity.

It is common for a microwave haloscope experiment to implement an isolator at nearly the same temperature as the cavity. For such a system, T_n is constant and independent of the cavity detuning Δ and cavity coupling β [24].

If $Q_L \gg Q_{DM}$, the cavity width is smaller than the dark matter halo lineshape width Δf_{DM} . The resulting dark matter signal will follow the Lorentzian cavity response with bandwidth $\Delta f_c = f_0/Q_L$. Fortunately, a haloscope is sensitive to a distribution of possible dark photon rest masses corresponding to the cavity resonant frequency f_c . In other words, a single cavity tuning step can probe the entire dark matter lineshape bandwidth, and the tuning steps need only to be comparable to Δf_{DM} .

The frequency bin width b is typically chosen to be comparable to the dark matter signal bandwidth. Typical haloscope experiments use copper cavities with $Q_L \ll Q_{DM}$, so $b \sim \Delta f_{DM} = f_0/Q_{DM}$. However, if $Q_L \gg Q_{DM}$, the signal bandwidth is the same as the cavity bandwidth and $b \sim f_0/Q_L$. This means that the noise power is inversely proportional the Q_L , i.e., $P_n \sim k_b (f_0/Q_L) T_n$. The higher Q_L is, the lower the noise power.

An estimate of the integration time can be obtained by rearranging the SNR equation $\Delta t = 1/b (\text{SNR} \times P_n/P_S)^2$. The tuning steps are $\Delta f \sim f_0/Q_{DM}$. Putting all this together, the scan rate for a dark photon haloscope consisting of an ultrahigh

Q microwave cavity, i.e., $Q_L \gg Q_{DM}$ is

$$\frac{df}{dt} = \frac{\Delta f}{\Delta t} \sim Q_L Q_{DM} \left(\frac{\eta \chi^2 m_{A'} \rho_{A'} V_{\text{eff}} \beta}{\text{SNR} T_n (\beta + 1)} \right)^2. \quad (5)$$

The scan rate equation, Equation 5, happens to be the same whether $Q_L \gg Q_{DM}$ or $Q_L \ll Q_{DM}$ [25]. In both cases, the scan rate is directly proportional to Q_L [26].

As a comparison, ADMX uses copper cavities with $Q_L \sim 8 \times 10^4$ [27], whereas niobium SRF cavities can achieve $Q_L \sim 10^9 - 10^{11}$ depending on the temperature and cavity treatment [28]. This suggests that SRF cavities can increase the instantaneous scan rate of haloscope experiments by as much as a factor of 10^5 .

Dark Photon Dark Matter Search with an SRF Cavity.—The Superconducting Quantum Materials and Systems (SQMS) Center, hosted by Fermilab, performs a wide range of multidisciplinary experiments with SRF cavities. An experiment studying the material properties of an SRF cavity for temperatures below 1 K was underway when it was decided that a fixed-frequency dark photon dark matter search should be performed with the same cavity. This proof-of-principle search using a $Q_L \approx 8 \times 10^9$, a HEMT amplifier, and the standard haloscope analysis is enough to demonstrate superior sensitivity to wavelike dark photons compared to previous searches.

The haloscope consists of a TESLA-shaped single-cell niobium cavity [29] with TM_{010} resonant frequency $f_0 \approx 1.3$ GHz. The cavity is made of fine-grain bulk niobium with a high residual resistivity ratio of $\simeq 300$. The cavity volume is 3875 mL, and the effective volume calculated from Equation 4 is $V_{\text{eff}} = 669$ mL, assuming a randomly polarized DP field. Electromagnetic coupling to the cavities is performed using axial pin couplers at both ends of the beam tubes.

The cavity underwent heat treatments in a custom-designed oven to remove the niobium pentoxide (Nb_2O_5) and to mitigate the two-level system (TLS) dissipation [30, 31]. The central cell 1.3 GHz cavity is heat treated at $\sim 450^\circ\text{C}$ in vacuum for eight hours.

The cavity is cooled to ≈ 45 mK using a BlueFors XLD 1000 dilution refrigerator. A double-layer magnetic shielding around the entire cryostat is used, and magnetometers placed directly on the outside cavity surfaces indicate that the DC ambient magnetic field level is shielded to below 2 mG.

A diagram of the microwave electronics is shown in Fig. 1. A series of attenuators on the cavity input line attenuates the room-temperature noise. The power from the cavity is first amplified by a cryogenic HEMT amplifier (LNF-LNC0.3.14A [32]). At 1.3 GHz, the amplifier noise temperature is 4.9(5) K and the gain is about 36 dB. These values are obtained from the manufacturer’s calibration. The uncertainty in the amplifier noise temperature comes from private correspondence with Low Noise Factory, and additional references include [33, 34].

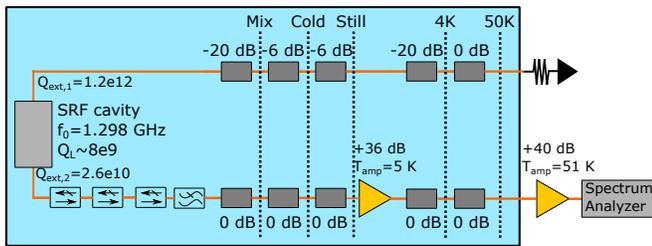

FIG. 1. The microwave electronics for the dark photon dark matter search. Power from the cavity is amplified by a cryogenic HEMT amplifier and a room temperature amplifier before reaching the spectrum analyzer. A series of isolators prevent the cavity from being excited by the amplifier’s noise.

Between the HEMT and SRF cavity, there is a series of three microwave isolators (QuinStar QCY-G0110151AS circulators with the third port terminated) and a low pass filter (Mini-Circuits VLFX-1350+). The isolators prevent the HEMT amplifiers from injecting noise into the cavity. According to the manufacturer datasheets, the combined insertion loss is at maximum 2.5 dB.

The signal is further amplified at room temperature using a Fairview FMAM1028 amplifier. The signal is then injected into the appropriate measurement device (spectrum analyzer, network analyzer, or phase noise analyzer).

The cavity’s resonant frequency is identified using a self-excited loop [35, 36]. The thermal noise from the output of the cavity is amplified, phase-shifted, and fed back into the input of the cavity. The phase shifting is performed with an ATM P2506. A power splitter feeds the cavity’s output power to the spectrum analyzer to monitor the response to the self-excited loop. The peak of the power spectrum corresponds to the cavity resonance.

The cavity’s loaded quality factor Q_L is measured using a decay measurement [37]. This decay measurement is implemented with a Keysight ENA Network Analyzer E5080B. At the resonant frequency, the network analyzer injects a 15 dBm signal with a bandwidth of 1 kHz into the input transmission line. Port 2 of the VNA measures the absolute power from the cavity output line. The network analyzer source is then turned off, and the output power is observed to decay over several seconds until it reaches an equilibrium. The measured power is fitted using $P_t = A \exp(-t/\tau_L)$, and $Q_L = 2\pi f_0 \tau_L$. Three decay measurements were taken. Of the three trials, smallest loaded quality factor measured is $Q_L = 8.7 \times 10^9$.

The antenna external quality factors are measured beforehand in a separate test stand following the procedure outlined in Reference [38]. From the measured external quality factors Q_e and the measured Q_L , the cavity coupling coefficient of the cavity output port can be determined using $\beta = (Q_L/Q_e)/(1 - Q_L/Q_e)$. From the measured Q_L and Q_e , $\beta = 0.68 \pm 0.11$.

For this proof-of-principle measurement, there is no tuning mechanism. A single power spectrum is measured. In the absence of a discovery, an exclusion on the ki-

netic mixing strength χ is determined from the measured power spectrum, the system noise temperature, and cavity properties. The relevant properties for determining the dark photon signal power and system noise temperature are shown in Table I.

η	β	V_{eff}	$m_{A'}$	Δt	Q_L	T_n	b
0.56	0.68(11)	669 mL	$5.3 \mu\text{eV}$	1000 s	8.7×10^9	5.0(5) K	0.1 Hz

TABLE I. Operating parameters for the dark photon dark matter search with the SQMS SRF cavity.

The signal attenuation factor η is determined from cascaded insertion loss of the three isolators and low-pass filter in between the cavity and cryogenic amplifier (Fig. 1). From the manufacturer datasheets, the maximum combined loss is 2.5 dB. This leads to a signal attenuation factor of $\eta = 0.56$. Since this is derived from cascading the maximum loss of four devices, this value is treated as a conservative lower bound.

For modeling the system noise temperature, the cryogenic electronics in Fig. 1 can be approximated as a cavity connected to the first-stage amplifier by a transmission line. The system noise temperature is then

$$T_n = T_{\text{cav}} + T_{\text{amp}} \quad (6)$$

where T_{cav} is the physical temperature of the cavity and T_{amp} is the noise temperature of the cryogenic amplifier. Boson statistics need not be considered in the Raleigh Jeans limit ($k_b T_{\text{cav}} \gg hf$). The three isolators and the low-pass filter are not included in the thermal model because they are at the same temperature as the cavity. The electronics beyond the cryogenic amplifier are also not included in the thermal model because their contribution is suppressed by the Friis cascade equation [39, 40]. The amplifier noise temperature $T_{\text{amp}} = 4.9(5)$ K dominates the system noise temperature. The cavity temperature, measured to be $T_{\text{cav}} = 45(5)$ mK, is much less than the uncertainty in T_{amp} .

The detector sensitivity is estimated from the operating parameters shown in Table I. The equation for sensitivity in χ is

$$\chi = \sqrt{\frac{\beta + 1}{\beta} \frac{\text{SNR} \times T_n}{\eta m_{A'} \rho_{A'} V_{\text{eff}} Q_{\text{DM}}} \left(\frac{\Delta f_c}{\Delta t} \right)^{1/4}} \quad (7)$$

Equation 7 is derived from rearranging the SNR equation. For this estimate, the bandwidth b is set to the cavity bandwidth, $\rho_{A'} = 0.45 \text{ GeV/cm}^3$, and $Q_{\text{DM}} = 10^6$. The SNR is also chosen to be two as this approximates a 90% exclusion limit. The parameters in Table I are converted to natural units, and the sensitivity is estimated to be $\chi = 2.1 \times 10^{-16}$.

For the dark photon search, power from the cavity is measured using the Rohde & Schwarz FSW-26 Signal and Spectrum Analyzer. The cavity $Q_L = 8.7 \times 10^9$, so the frequency resolution needs to be $b \sim 100 \text{ mHz}$.

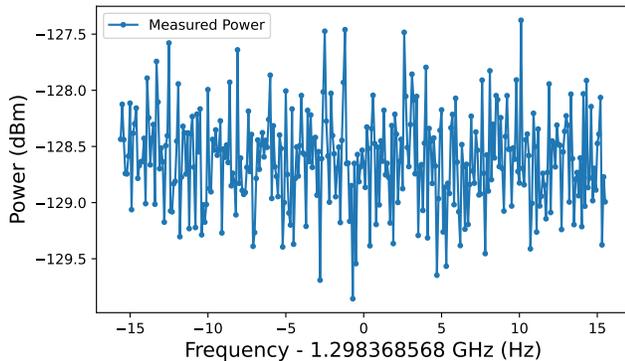

FIG. 2. Raw spectrum as measured by the spectrum analyzer. Assuming the spectrum is just noise, the raw spectrum is the noise power of the system.

This sub-Hertz resolution is achieved using the spectrum analyzer’s I/Q-analyzer mode. For these measurements, a 312 Hz sample rate is used, and the sweep time of 10 s is used. The spectrum’s center frequency is set to the cavity’s resonant frequency. The frequency bin size is 100 mHz. After the data is recorded, the spectrum is truncated even further so that the span is about 31 Hz centered around the cavity resonance. On this frequency scale, the power fluctuations are Gaussian without the need for the application of a low pass filter (the Savitzky-Golay filter is typical of haloscope analysis [41, 42]). The resulting power spectrum is shown in Fig. 2.

The manufacturer’s calibrated T_{amp} is corroborated with the measured power P_m in Fig 2. Because T_n is dominated by T_{amp} , $T_{amp} \approx P_m / (k_b b G_{sys})$, where G_{sys} is the system gain and $b = 0.1$ Hz. $T_{amp} \sim 5$ K is obtained if $G_{sys} = 73$ dB. This G_{sys} is consistent with the cascaded amplifier gain of 76 dB (Fig. 1) and a reasonable insertion loss of 3 dB from the cables, connectors, and a 1300 MHz bandpass filter (Lorch 6BC-1300/75-S) installed immediately before the spectrum analyzer (not shown).

Once the power spectrum is measured, the standard haloscope analysis is applied to either find a spectrally narrow power excess consistent with a dark photon signal or to exclude parameter space. The procedure for deriving the exclusion limits follows the procedure developed by ADMX and HAYSTAC [41–43], and is adapted for dark photon searches [9, 10, 19].

There are a few important deviations from the standard haloscope analysis for this search. First, only one spectrum was measured, so combining many spectra at different RF frequencies is not necessary. Second, the frequency range of interest is narrow enough such that the measured power is unaffected by the frequency-dependent gain variation of the electronics. So, the Savitzky-Golay filter is not needed to remove this gain variation. This is advantageous because the Savitzky-Golay filter is known to attenuate the dark matter signal by as much as 10%-20% [41, 42].

Third, most of the data points in Fig. 2 used to verify the noise’s Gaussianity and determine the statistical parameters are well outside the cavity bandwidth. Fortunately, in the absence of a dark matter signal, the statistical distribution of the power fluctuations is the same inside and outside of the cavity bandwidth.

Fourth, past haloscope experiments with $Q_L \ll Q_{DM}$ typically convolved the spectra with the dark matter halo lineshape to account for the signal being spread across multiple bins. For this search, $Q_L \gg Q_{DM}$, so the signal will be Lorentzian from the cavity response. So the spectrum is convolved with the cavity lineshape $L(f, f_0, Q_L) = 1 / (1 + 4\Delta^2)$.

Fifth, a single measurement is sensitive to a range of dark photon masses. Thus the excluded power on resonance is convolved with the dark matter halo lineshape. This convolution was also performed in other dark photon searches with $Q_L > Q_{DM}$ [44]. When performing this convolution, it should be noted that the photon frequency (which corresponds to the cavity frequency) is fixed, and it is the dark photon mass that varies.

No spectrally narrow power excess with an $SNR > 4$ is found in the measured power spectrum. The excluded parameter space using a 90% confidence limit is shown in Fig. 3. The derived limit assumes dark photon dark matter is randomly polarized and that the dark photon energy distribution follows the standard halo model. The excluded kinetic mixing strength is $\chi_{90\%} = 1.8 \times 10^{-16}$ for a dark photon mass of $m_{A'} = 5.370 \mu\text{eV}$. This is consistent with the expected sensitivity estimated from Equation 7. This is also the deepest exclusion to wavelike dark photon dark matter by almost an order of magnitude.

Outlook and the Potential of SRF Cavities for Axion Dark Matter Searches—The exclusion in Fig. 3 is an impressive demonstration of how SRF cavities can benefit dark matter searches. But an honest dark matter search with a finite probability of making a discovery requires that the haloscope tune through a broader range of frequencies. SQMS is currently developing experiments using tunable SRF cavities that will search through a broader range of parameter space.

In addition to dark photons, there is a growing interest in dark matter axions. Axions are particularly well motivated because they solve the strong CP problem [46]. Axion haloscope searches require multi-Tesla magnetic fields to be sensitive enough to the QCD axion. The scan rate for axion haloscope searches is still directly proportional to Q_L . Unfortunately, the performance of superconductors degrades under an external magnetic field. Achieving high quality factors is thus a very active area of research [47–50], and it seems likely that axion haloscopes with $Q_L > 10^7$ are achievable in the near future.

This experiment also demonstrates that axion haloscopes with $Q_L \sim 10^{10}$ are worth striving for. Applying a hypothetical 8 T magnetic field to the dark photon data in Fig. 2 would have led to an exclusion on the axion-photon coupling constant at $g_{a\gamma\gamma} \sim 4 \times 10^{-16}$, well be-

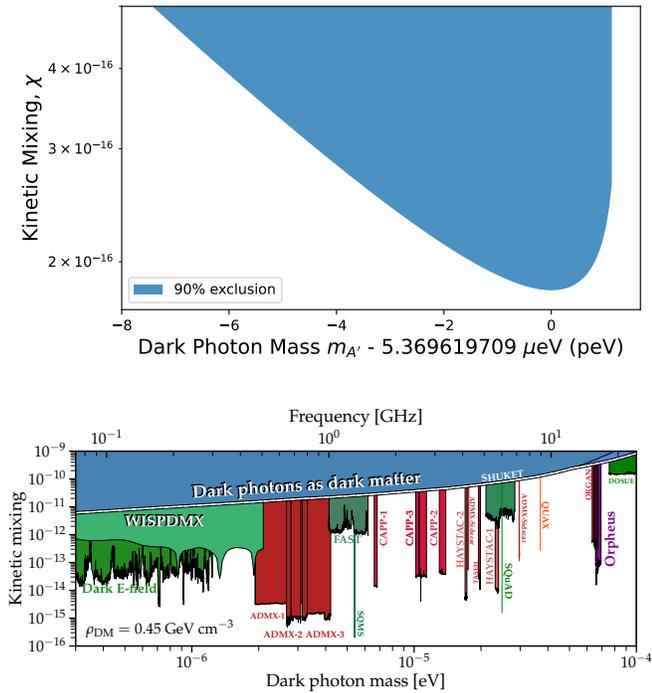

FIG. 3. Top: A 90% exclusion on the kinetic mixing strength parameter space. Bottom: SQMS limits in the context of other microwave cavity haloscopes. Figure adapted from [45].

low DFSZ coupling ($g_{a\gamma\gamma} = 8 \times 10^{-16}$).

Despite decades of searching for the axion, only a small fraction of the QCD axion parameter space has been explored. Perhaps a combination of ultrahigh Q cavities, subSQL metrology [44, 51], multiwavelength detector designs [25, 52–58], and innovations in multi-Tesla continuous magnets will enable experiments to probe most of the post-inflation QCD axion parameter space within the next few decades.

- [26] Ref. [20] also addresses the scan rate for ultrahigh Q haloscopes, but our treatment differs in a few major ways. For reasons explained in the text, we set the tuning step to $\Delta f \sim f_0/Q_{DM}$ instead of $\Delta f \sim f_0/Q_L$ and $b \sim f_0/Q_L$ instead of $b \sim f_0/Q_{DM}$. Finally, the derived T_n in Ref. [20] does not appear to apply systems ubiquitous to microwave haloscope experiments that implement circulators between the cavity and first-stage amplifier. For such a system, T_n is independent of β [24]. This independence is recognized in Fig. 5 but is not reflected in their equations.
