## Abstract

Heterostructures composed of the intrinsic magnetic topological insulator  $\text{MnBi}_2\text{Te}_4$  and its non-magnetic counterpart  $\text{Bi}_2\text{Te}_3$  host distinct surface band structures depending on the stacking order and exposed termination, allowing fine control of their magnetic, electronic and optical properties. Here, we probe the ultrafast dynamical response of  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$  following near-infrared optical excitation using time- and angle-resolved photoemission spectroscopy. We gain access to the out-of-equilibrium surface electronic structure of both  $\text{MnBi}_2\text{Te}_4$  and  $\text{Bi}_2\text{Te}_3$  surface terminations of  $\text{MnBi}_4\text{Te}_7$ , revealing an instantaneous occupation of states that are resonant with the optical excitation in the  $\text{Bi}_2\text{Te}_3$  layer followed by carrier extraction into the adjacent  $\text{MnBi}_2\text{Te}_4$  layers with a laser fluence-tunable delay of up to 350 fs. The ensuing thermal relaxation processes are driven by in-plane phonon scattering with significantly slower relaxation times in the magnetic  $\text{MnBi}_2\text{Te}_4$  septuple layers. The competition of interlayer charge transfer and intralayer phonon scattering establishes  $\text{MnBi}_2\text{Te}_4$ -based compounds as a platform for controlling ultrafast charge transfer processes in combination with magnetism and topology in van der Waals heterostructures.

**KEYWORDS:** Magnetic topological insulators,  $\text{MnBi}_2\text{Te}_4$ , van der Waals heterostructures, ultrafast carrier dynamics, time- and angle-resolved photoemission spectroscopy.

Heterojunctions composed of two-dimensional (2D) semiconducting materials are highly promising for developing novel optoelectronic devices due to tunable band gaps and charge carrier dynamics.<sup>1</sup> The interplay of charge and phonon interactions has been intensively examined in transition metal dichalcogenide heterostructures, unveiling sub 50-fs interlayer carrier extraction that is ideal for light harvesting and photovoltaics.<sup>2,3</sup> Van der Waals compounds based on the antiferromagnetic topological insulator  $\text{MnBi}_2\text{Te}_4$  present another attractive candidate for advanced opto- and spintronics applications due to the realization of exotic phases such as the quantum anomalous Hall effect<sup>4</sup> and axion electrodynamics.<sup>5</sup> Yet, optically-induced ultrafast carrier dynamics and charge transfer processes in these materi-

als remain largely unexplored. Moreover, the properties of these materials can be elegantly engineered via van der Waals stacking. For example, combining a quintuple layer (QL) of the non-magnetic topological insulator  $\text{Bi}_2\text{Te}_3$  with a septuple layer (SL) of  $\text{MnBi}_2\text{Te}_4$  reduces the antiferromagnetic exchange interaction between neighbouring planes of Mn atoms, while strengthening the affinity of the system to undergo a spin-flop transition to ferromagnetic order.<sup>6</sup> As a result, van der Waals heterostructures of the form  $\text{MnBi}_2\text{Te}_4(\text{Bi}_2\text{Te}_3)_m$  ( $m = 1, 2, 3, \dots$ ) offer a platform for tuning the magnetic properties<sup>7,8</sup> as well as accessing topological magnetotransport<sup>9</sup> and the quantum anomalous/spin Hall effects.<sup>10,11</sup>

In order to gain access to the energy- and momentum-resolved ultrafast carrier dynamics of  $\text{MnBi}_2\text{Te}_4(\text{Bi}_2\text{Te}_3)_m$  heterostructures, we employ time- and angle-resolved photoemission spectroscopy (TR-ARPES). This approach utilizes a near-infrared optical excitation to induce direct optical transitions from the occupied to the unoccupied states. The out-of-equilibrium electronic band structure of the excited state is then measured by a time-delayed ultraviolet probe pulse, giving direct insights into charge transfer processes and phonon relaxation between bulk and surface states on a given heterostructure termination.<sup>12</sup> This approach has revealed thermal dynamics with a duration of 4 ps in  $\text{MnBi}_2\text{Te}_4$  across the magnetic ordering temperature,<sup>13</sup> as well as photoinduced filling of the surface state hybridization gap of the QL termination in a heterostructure with stoichiometry  $m = 3$ .<sup>14</sup> Here, we determine how carrier extraction and relaxation is controlled by the balance of inter- and intralayer interactions by comparing the time-dependent evolution of excited electronic states between the  $m = 0$  and  $m = 1$  heterostructures, i.e.  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$ . We find that carriers are instantaneously excited in the QL of  $\text{MnBi}_4\text{Te}_7$  and are then gradually extracted into the SL with a fluence-dependent delay of up to 350 fs. Thermal relaxation then proceeds at a slower rate within the magnetic SL layer, implying that the layer-dependent electronic and magnetic properties can be optically controlled on an ultrafast timescale.

The  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$  crystals were grown by the flux method. High purity Mn, Bi, and Te powders were sealed in quartz tubes with a ratio of  $\text{Mn}:\text{Bi}:\text{Te} = 1:10:16$ . The tubes

were heated to 900°C and then cooled to 595/590°C, respectively. The flux was removed by centrifuging after cooling. Our TR-ARPES measurements were performed at the T-ReX facility (Trieste, Italy). Pump and probe pulses were generated by a 250 kHz Ti:sapphire Coherent Reg A laser system, whose output was centered at an energy of 1.55 eV. The fourth harmonic (6.2 eV) of the fundamental beam was used as an *s*-polarised probe pulse. The remainder of the beam was used as a *p*-polarised pump with a tunable fluence in the range of 40-280  $\mu\text{J}/\text{cm}^2$ , arriving at the sample at a variable time delay,  $\Delta t$ , with respect to the probe. The experimental time, energy and angular resolution were better than 200 fs, 50 meV and 0.2°, respectively. The samples were cleaved *in situ* at a base pressure of  $2 \cdot 10^{-10}$  mbar at room temperature, and kept at a temperature of 100-110 K during the measurement.

Figures 1(a)-(f) provide an overview of the heterostructure terminations and their respective electronic dispersions around the  $\Gamma$ -point of the Brillouin zone, measured at equilibrium conditions before optical excitation ( $\Delta t < 0$ ) and during the initial moments of the excitation ( $\Delta t = 40$  fs). Fig. 1(a) presents the SL  $\text{MnBi}_2\text{Te}_4$  structure which can be thought of as a QL with an intercalated Mn-Te bilayer, introducing a plane of unpaired spins. Non-trivial topology in this system derives from its Te  $5p$  valence band (VB) and Bi  $6p$  conduction band (CB) which undergo band inversion due to spin-orbit coupling (SOC).<sup>20</sup> The dispersion before excitation at  $\Delta t < 0$  in Fig. 1(d) shows intense bands within 200 meV below the Fermi level,  $E_F$ , revealing that the crystals are strongly electron-doped.<sup>21</sup> We identify the ARPES intensity as being composed of bulk conduction bands (BCBs) in addition to a set of bands that are known to exhibit quasi-2D behavior.<sup>16,17</sup> During excitation we observe that the bands crossing  $E_F$  become occupied up to 200 meV above  $E_F$  with high intensity in the quasi-2D bands that consist of two crossing parabolas. These features have previously been attributed to a Rashba-like spin splitting,<sup>17</sup> suggesting a significant non-equilibrium occupation of spin-polarized carriers in this system. The topological surface state (TSS) in the bulk band gap indicated in Fig. 1(d) is characterized by a linear dispersion and is anticipated to exhibit an exchange gap below the Néel temperature.<sup>6,15</sup> We do not resolve

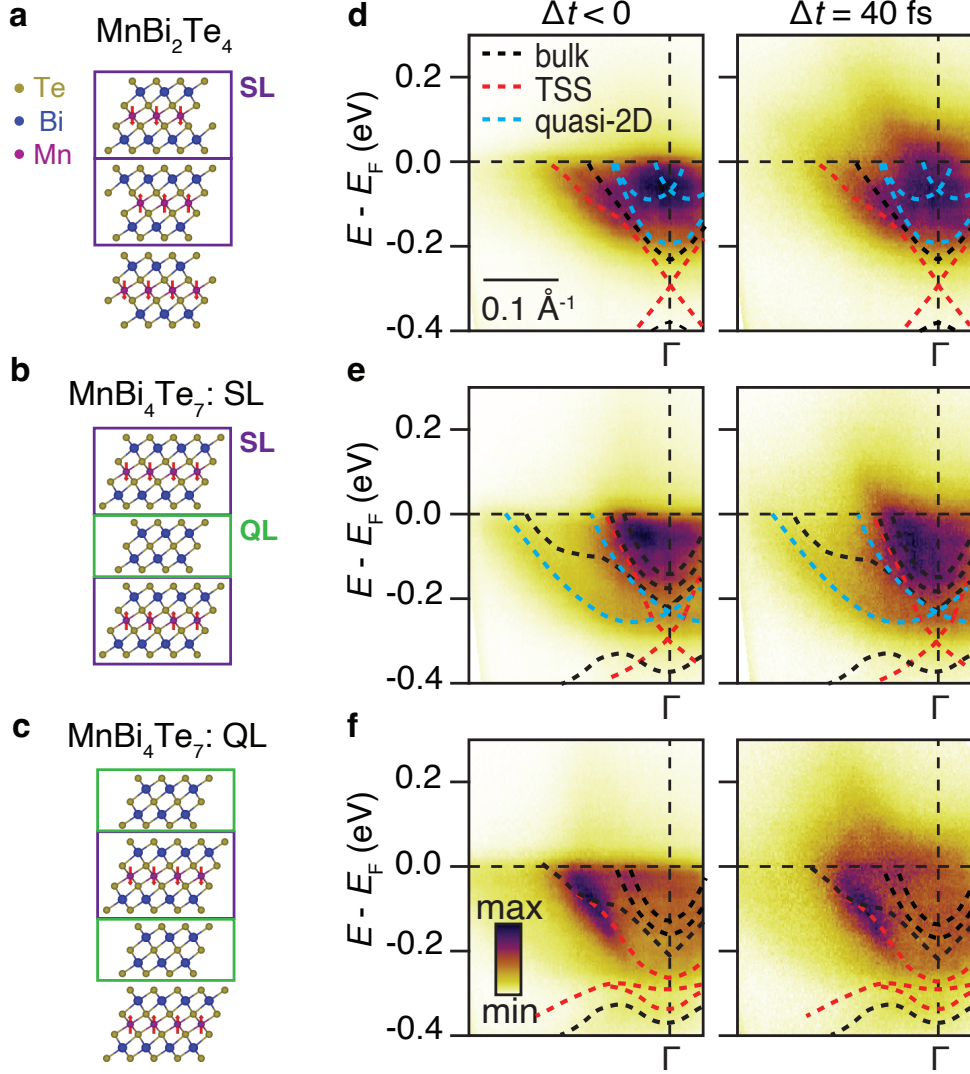

Figure 1: Overview of crystal structure and dispersion of magnetic van der Waals materials  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$ . (a)-(c) Layered crystal structures of (a)  $\text{MnBi}_2\text{Te}_4$  and (b)-(c)  $\text{MnBi}_4\text{Te}_7$  with a septuple (SL) or quintuple (QL) layer exposed at the surface. The red arrows indicate spins on the Mn atoms. (d)-(f) Photoemission intensity of the structures sketched in the same row in (a)-(c) before the arrival of the pump pulse ( $\Delta t < 0$ ) and in the initial stage of excitation ( $\Delta t = 40$  fs) with a laser fluence of  $280 \mu\text{J}/\text{cm}^2$ . The spectra were collected around the  $\Gamma$ -point of the Brillouin zone. The overlaid dashed black, red and blue dispersion lines and the noted character of the bands are based on previous high-resolution ARPES studies of the same surfaces<sup>7,8,15–20</sup>

intensity from the TSS here due to the low cross section compared with the CB states at our probe polarization and photon energy.<sup>16</sup>

In  $\text{MnBi}_4\text{Te}_7$ , SL and QL units are alternating as sketched in Figs. 1(b)-(c). Cleaving the

bulk crystal can expose either of these terminations, which exhibit distinct surface electronic structures, as shown in Figs. 1(e)-(f). Both terminations exhibit a similar level of electron-doping as  $\text{MnBi}_2\text{Te}_4$ , leading to dominant photoemission intensity from BCB states around  $E_F$ . The SL termination supports quasi-2D Rashba-like spin states that are illustrated by dashed blue parabolic bands in Fig. 1(e).<sup>18,19</sup> Photoexcitation leads to dominant intensity along the BCB states and only a faint signal above  $E_F$  around these quasi-2D bands. We note that the TSS in the SL termination is a single ungapped Dirac cone,<sup>8,18</sup> whereas the nature of TSS in the QL termination remains debated, with calculations showing a gapped state due to the hybridization with the underlying SL,<sup>18</sup> but some ARPES measurements indicating a vanishing gap.<sup>7,8</sup> For all surfaces the optical excitation primarily leads to a redistribution of carriers between occupied and unoccupied conduction band states. No changes in the TSS or the bulk band gaps are revealed within the resolution of our measurements.

We proceed to evaluate the detailed energy-, momentum- and time-dependent evolution of the photoexcited carriers across the three surfaces as presented in Figure 2. Panel (a) shows the photoemission intensity difference between the excited state spectrum taken 40 fs after the arrival of the pump pulse and an average of the equilibrium spectrum measured at  $\Delta t < 0$ . The red (blue) regions correspond to the gain (loss) of the photoemission signal, and can be interpreted as excited electron (hole) populations. From the difference spectrum of  $\text{MnBi}_2\text{Te}_4$  we are able to see a distinct excitation of electrons above the quasi-2D bands with a Rashba-like splitting, while the excited holes are distributed across the continuum of BCB states. In contrast, both SL and QL terminations of  $\text{MnBi}_4\text{Te}_7$  exhibit strong excitation signals from electrons mainly in regions above the BCB states.

The time-dependence of the electron (hole) dynamics in the BCB and quasi-2D states is examined by integrating the intensity within an energy- and  $k$ -window of 40 meV and  $0.03 \text{ \AA}^{-1}$ , respectively, centered  $\pm 40$  meV above (below)  $E_F$ . These integration regions are placed at different  $k$ -values for electrons and holes in order to track the intensity difference in distinct BCB and quasi-2D bands. Fig. 2(b) presents the resulting time-dependent intensity

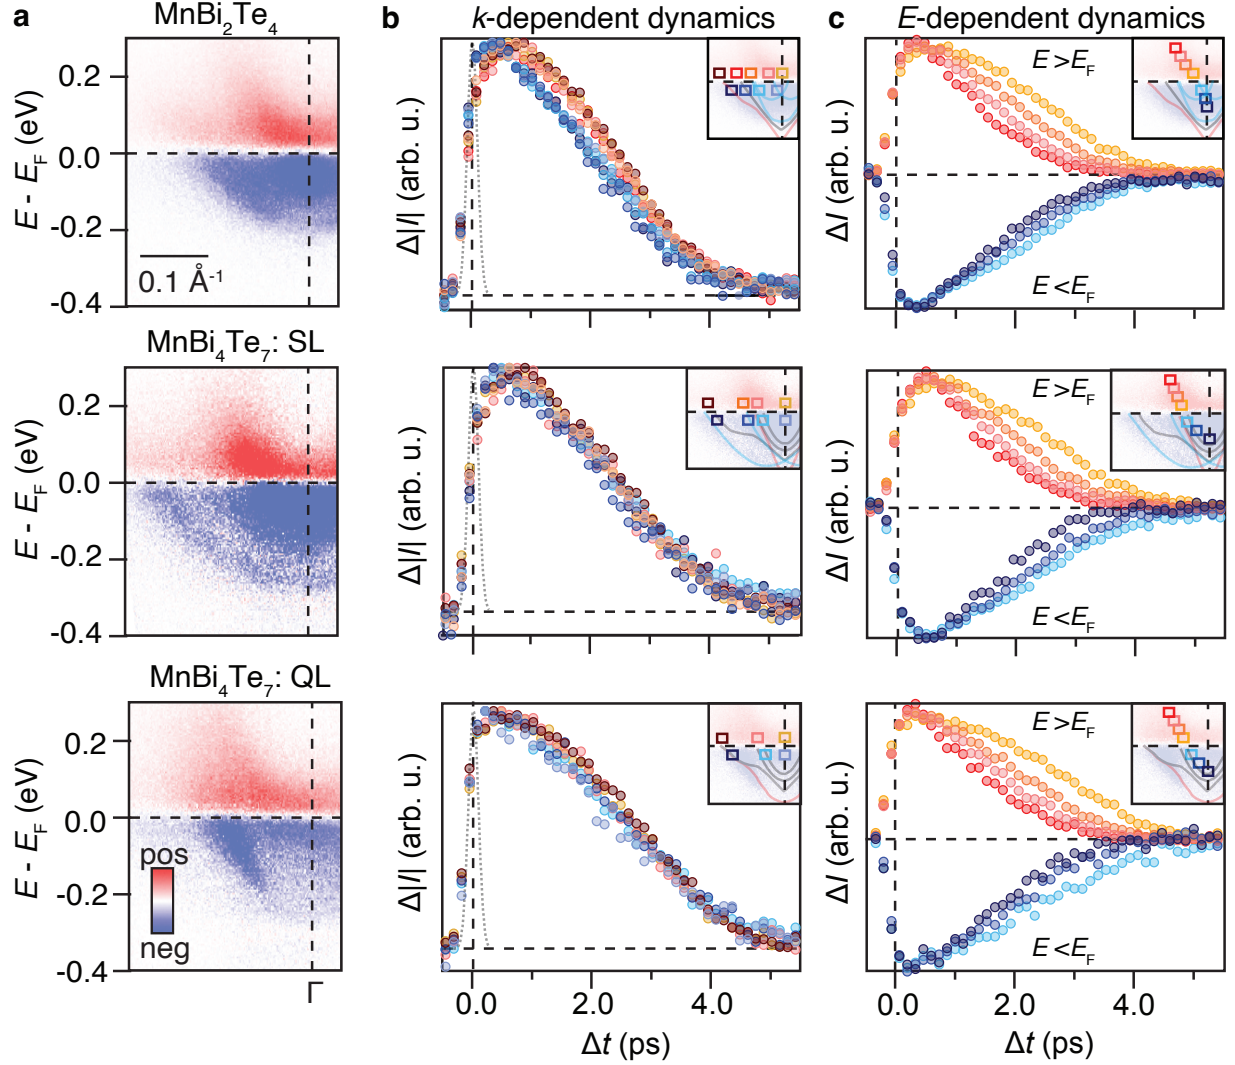

Figure 2: Energy-, momentum- and time-dependent dynamics of  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$ . (a) Intensity difference spectra of  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$  with SL and QL terminations obtained by subtracting an average of the equilibrium spectrum measured at  $\Delta t < 0$  from the excited state signal at  $\Delta t = 40$  fs. (b) Absolute values of the normalised intensity difference integrated within the  $(E, k)$ -regions demarcated by correspondingly coloured boxes in the insets, measured for different time delays. The integration regions are placed symmetrically  $\pm 40$  meV with respect to  $E_F$  in order to determine the dynamics of excited holes and electrons. (c) Normalised time-dependent intensity difference integrated within  $(E, k)$ -regions demarcated by the coloured boxes centered at varying energies in the insets, placed along the most intense band. The measurements were performed with a laser fluence of  $280 \mu\text{J}/\text{cm}^2$ .

around  $E_F$  for electrons, represented by red, orange and brown circles, as well as holes, represented by light and dark blue circles that are color-coded according to the integration regions in the insets. For all surfaces, the intensity due to excited carriers initially matches

the pump-probe cross-correlation integral (see dashed peak in Fig. 2(b)). The increase in the signal then slows down before reaching a short plateau which is followed by a decay back to equilibrium that is achieved around 5 ps after the excitation.

In  $\text{MnBi}_2\text{Te}_4$ , the intensity difference corresponding to holes at -40 meV reaches its maximum at  $\Delta t \approx 0.2$  ps. For the electrons at 40 meV, the maximum excitation density is achieved significantly later, at  $\Delta t \approx 0.8$  ps. This electron-hole asymmetry in the dynamics diminishes in the SL termination of  $\text{MnBi}_4\text{Te}_7$  and is absent in the QL termination where both excited electron and hole populations reach a maximum at  $\Delta t \approx 0.2$  ps. The pronounced delay between the peak of electron and hole populations in  $\text{MnBi}_2\text{Te}_4$  is attributed to the main excitation signal above  $E_F$  stemming primarily from occupation of quasi-2D bands whereas the signal below  $E_F$  is juxtaposed with the BCB continuum. Holes in the occupied part of the BCB are generated via direct optical transitions into unoccupied CB states that are resonant with the 1.55 eV pulse energy and then redistribute via efficient intra- and interband Auger processes, faster than our time resolution. The quasi-2D states above  $E_F$  are primarily filled via interband charge transfer from the initially occupied bulk states, causing a delay in the peak of the corresponding excited state population. Similar quasi-2D dynamics contributes to the intensity above  $E_F$  in the SL termination of  $\text{MnBi}_4\text{Te}_7$ , however the prevalent BCB states diminish the effect. In the QL termination the excited state signal above  $E_F$  derives entirely from BCB states, leading to fully symmetric electron-hole dynamics deriving from identical inter- and intralayer charge redistribution processes.

The  $E$ -dependent decay dynamics is determined by inspecting the intensity difference integrated in  $(E, k)$ -regions following the band with strongest excitation signal as shown in Fig. 2(c), as demarcated by color-coded boxes in the inset. The behavior is qualitatively similar across the three systems, as in all cases the signal furthest from  $E_F$  rapidly increases during excitation and then decays exponentially while the transient population of the states closer to  $E_F$  builds up more slowly. This behavior is consistent with a cascading of intra-band scattering processes from higher-lying states.<sup>22,23</sup> The slower decay dynamics of excited

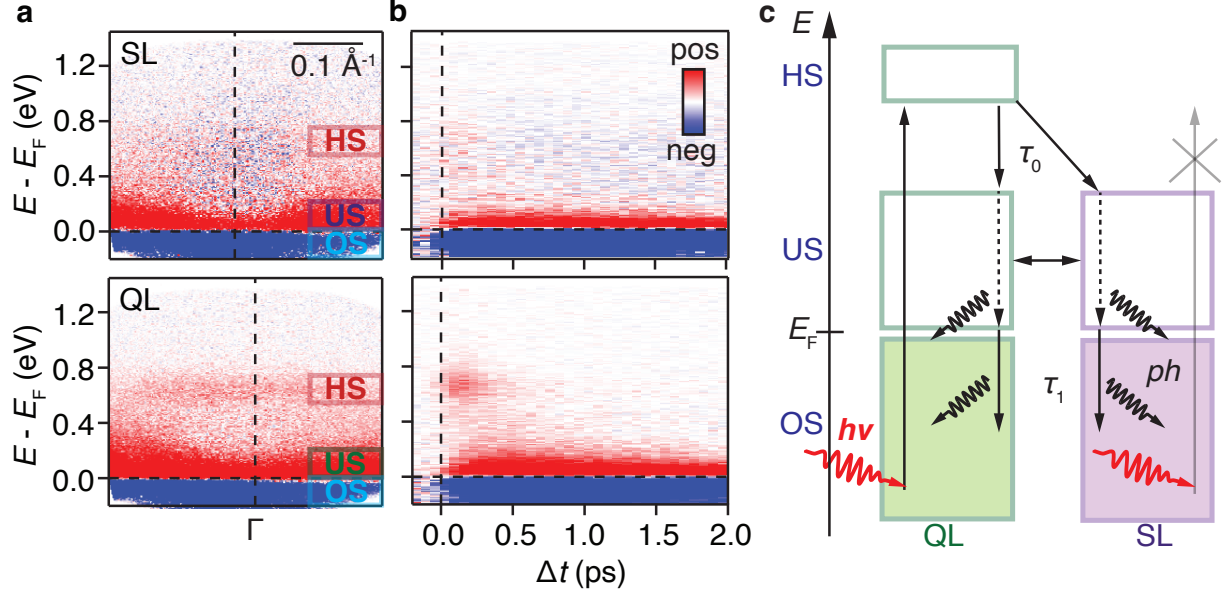

Figure 3: Intra- and interband dynamics in the van der Waals heterostructure  $\text{MnBi}_4\text{Te}_7$ . (a) Intensity difference spectra of SL and QL terminations of  $\text{MnBi}_4\text{Te}_7$  obtained by subtracting an average of the equilibrium spectrum measured at  $\Delta t < 0$  from the excited state signal at  $\Delta t = 40$  fs. (b) Energy-distribution curves (EDCs) extracted at  $\Gamma$  as a function of time delay for SL (top) and QL (bottom) terminations. (c) Model of interband (solid straight arrows) and intraband (dashed straight arrows) charge transfer and phonon relaxation (wiggled arrows labeled as  $ph$ ) processes in the QL and SL layers of the van der Waals heterostructure initiated by the optical excitation. The high-lying states, the unoccupied states and the occupied states of the CB around  $E_F$  are labeled as HS, US and OS, respectively, as indicated by boxes in (a).

electrons and holes close to  $E_F$  is driven by the evolution of the electronic temperature and associated Fermi-Dirac distribution after excitation when a quasi-thermal equilibrium is attained.<sup>24</sup>

Having established the time-dependent dynamics in states at different  $E$ - and  $k$ -regions of the excited state signal across  $\text{MnBi}_2\text{Te}_4$  and both  $\text{MnBi}_4\text{Te}_7$  surface terminations, we are now in a position to disentangle the layer-dependent contributions to the dynamics of the van der Waals stacked  $\text{MnBi}_2\text{Te}_4$  and  $\text{Bi}_2\text{Te}_3$  layers of  $\text{MnBi}_4\text{Te}_7$ . In Figure 3(a) we inspect the transient occupation of both terminations in a wider energy window in order to determine where the initially excited electrons are generated. The QL spectrum is characterized by a strong excitation signal 0.7 eV above  $E_F$  while no states are present in this region in the

SL termination. These signals are consistent with spatially-resolved pump-probe ARPES spectra obtained on the two terminations using a micro-focused beam.<sup>12</sup> In analogy with  $\text{Bi}_2\text{Te}_3$ , the shallow excited band may be a surface resonance in the projected bulk band gap.<sup>25</sup>

Time-dependent energy distribution curves (EDCs) at  $\Gamma$ , displayed in Fig. 3(b), reveal that the band at 0.7 eV in the QL is rapidly depleted while the electron and hole signals grow in the states closer to  $E_F$  in both the QL and SL. Note that the optical pump affects the electron dynamics within many layers but surface-sensitive ARPES probes primarily the first layer. We therefore propose that the initial optical excitation generates electrons in the high-lying states (HS) of the QLs in the van der Waals stack via direct transitions from the initially occupied states (OS).<sup>22,23</sup> Carriers are then extracted to the unoccupied states (US) above  $E_F$  in both the QL and SL via interband charge transfer with a timescale given by  $\tau_0$ . The cascade of intraband scattering discussed above in connection with Fig. 2(c) then results in excited carriers trickling down these states and finally recombining with holes via electron-phonon coupling on a timescale labeled as  $\tau_1$ . Our model is summarised schematically in Fig. 3(c).

The optical tunability of inter- and intralayer charge transfer and phonon relaxation between QL and SL layers of  $\text{MnBi}_4\text{Te}_7$  is demonstrated in Figure 4. We analyze the  $(E, k)$ -integrated intensity difference in the initially unoccupied states within 70 meV of  $E_F$  as a function of laser fluence and consider separately the rise part of the signal in Fig. 4(a) and the decay part on a logarithmic intensity scale in Fig. 4(b). The initial increase of the signal in Fig. 4(a) is highly fluence-dependent in the SL, exhibiting a significantly slower timescale with decreasing fluence, whereas the QL rise signal is faster and less sensitive to the fluence. In all cases, the rising part of the signal is well-described by a fit to a sigmoid function given by  $(1 + \exp(2.35\Delta t/\tau_0))^{-1}$ , providing an estimate of the charge transfer time  $\tau_0$ . After the initial increase in intensity, the excited state population enters a plateau region. This occurs due to the competition between the charge being transferred from the

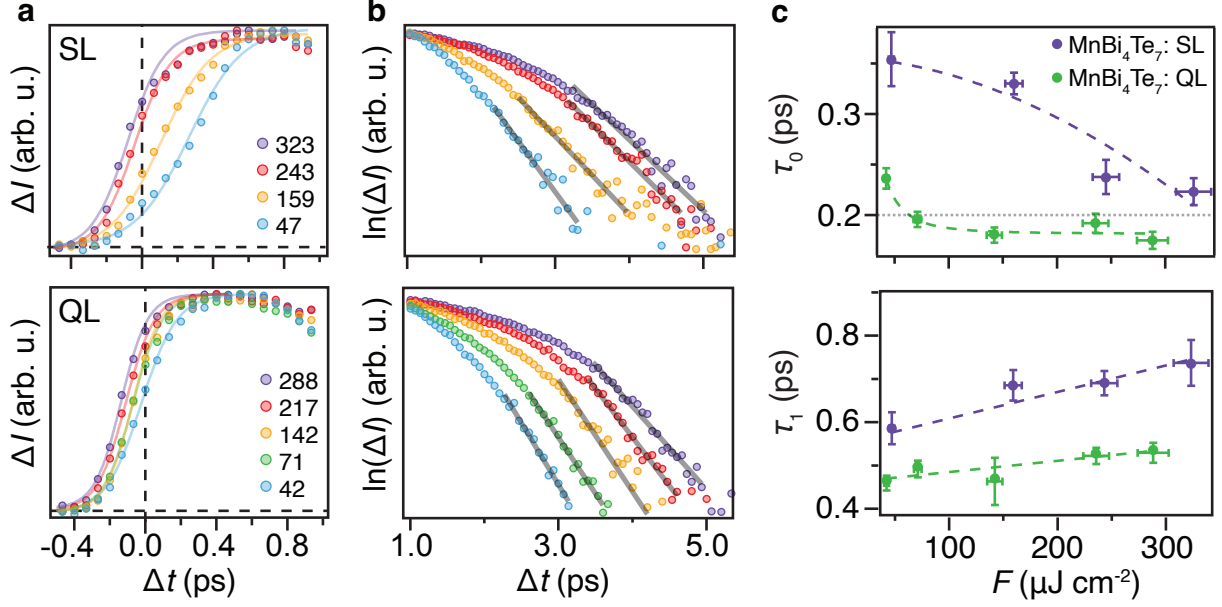

Figure 4: Charge transfer and phonon relaxation in  $\text{MnBi}_4\text{Te}_7$ . (a)-(b)  $(E, k)$ -integrated intensity difference from 0 to 70 meV above  $E_F$  and from  $-0.2$  to  $0.2 \text{ \AA}^{-1}$  for SL and QL terminations of  $\text{MnBi}_4\text{Te}_7$ . Each data set was acquired with the fluence stated in (a) in units of  $\mu\text{J}/\text{cm}^2$ . In (a) we examine the rising edge of the signal (circles), representing the filling of unoccupied states above  $E_F$ , and fit a sigmoid function (curves) to extract the timescale  $\tau_0$  of the filling. In (b) we analyze the decay part of the signal on a logarithmic intensity scale and perform exponential fits (lines) to extract the phonon relaxation timescale  $\tau_1$ . (c) Extracted timescales from (a)-(b) as a function of laser fluence. Dashed curves provide a guide to the eye. Dotted gray line indicates the time resolution in this experiment.

high-lying state in the QL into unoccupied states around  $E_F$  in both the SL and QL and their subsequent recombination with holes. Finally, when the rate of refilling becomes slower than the electron-hole recombination processes, the transient occupation diminishes exponentially as shown in Fig. 4(b). We quantify the timescale  $\tau_1$  of this process via the slope of a linear fit to the logarithm of the trace in Fig. 4(b).

The extracted fluence dependence of  $\tau_0$  and  $\tau_1$  is shown in Fig. 4(c). The growth rate of the population in the SL reaches a maximum of  $\tau_0 = 0.35 \text{ ps}$  at a low fluence of  $47 \mu\text{J}/\text{cm}^2$ , such that the population reaches its peak around  $\Delta t = 0.80 \text{ ps}$ . This is substantially delayed compared to the peak being reached around  $\Delta t = 0.40 \text{ ps}$  for  $\tau_0 = 0.22 \text{ ps}$  at a high fluence of  $323 \mu\text{J}/\text{cm}^2$ . As we are considering the population in an energy range immediately above  $E_F$ , the rise time is strongly affected by interlayer charge transfer from the excited carriers

in the high lying state in the QL. For low fluence, the intralayer filling of states from the high lying state to near the Fermi level is more favourable than the interlayer charge transfer to the SL CB. Therefore the filling rate of the SL CB is slower for low excitation densities. For high excitation density, on the other hand, a large initial population is generated in the QL, thereby removing this bottleneck effect. For the QL termination,  $\tau_0$  exhibits a less dramatic fluence-dependence and merely reflects the efficiency of intralayer interband scattering.

Finally, the decay time  $\tau_1$  provides information on electron-hole recombination mediated by energy transfer to phonons.<sup>23</sup> The relaxation dynamics extracted in Fig. 4(c) are notably faster for QL than SL, suggesting that intralayer phonons play a dominant role in the scattering processes, in line with a substantially weakened out-of-plane interlayer vibrational interaction in the heterostructure<sup>26</sup> in comparison to its non-magnetic counterpart  $\text{Bi}_2\text{Te}_3$ .<sup>27</sup> In all cases, the decay constant increases with applied fluence, indicating that the electron-phonon coupling becomes less efficient with a larger population of excited carriers. This trend can be explained by increased screening of the electron-phonon interaction by the photoinduced charge carriers.<sup>28</sup>

In conclusion, we have determined the ultrafast charge carrier dynamics of intrinsic magnetic topological insulator van der Waals heterostructures  $\text{MnBi}_2\text{Te}_4$  and  $\text{MnBi}_4\text{Te}_7$ . The out-of-equilibrium distribution of excited carriers exhibit distinct dynamics in quasi-2D bands that host spin-polarized carriers in  $\text{MnBi}_2\text{Te}_4$ , suggesting that optical pulses can be used as a tuning knob to control the magnetic properties of the system on ultrafast timescales. In  $\text{MnBi}_4\text{Te}_7$  the dynamics is strongly affected by interlayer interactions between the  $\text{Bi}_2\text{Te}_3$  quintuple layers and the  $\text{MnBi}_2\text{Te}_4$  septuple layers. Direct optical excitation with a 1.55 eV laser pulse leads to a transient population of carriers in the  $\text{Bi}_2\text{Te}_3$  layers. These excited carriers are then extracted via interband and interlayer scattering into conduction band states around the Fermi energy within the  $\text{Bi}_2\text{Te}_3$  and in the adjacent  $\text{MnBi}_2\text{Te}_4$  layers, respectively. In the regime of low laser fluence, the charge transfer processes into the  $\text{MnBi}_2\text{Te}_4$  layers exhibit a bottleneck, opening the possibility to optically control the population of spin-

polarized carriers in the magnetic layers of the van der Waals stack. Furthermore, as the subsequent electron-phonon mediated relaxation is less efficient in the magnetic  $\text{MnBi}_2\text{Te}_4$  compared to the non-magnetic  $\text{Bi}_2\text{Te}_3$  layers it might be feasible to optically modify the magnetic properties of the heterostructure when designing spintronic and optoelectronic devices with layers of  $\text{MnBi}_2\text{Te}_4$ .
