#### Abstract

Müntz's theorem asserts, for example, that the even powers $\mathbf{1}, \boldsymbol{x}^{\mathbf{2}}, \boldsymbol{x}^{\mathbf{4}}, \ldots$ are dense in $\boldsymbol{C}([\mathbf{0}, \mathbf{1}])$. We show that the associated expansions are so inefficient as to have no conceivable relevance to any actual computation. For example, approximating $\boldsymbol{f}(\boldsymbol{x})=\boldsymbol{x}$ to accuracy $\varepsilon=\mathbf{1 0}^{\mathbf{- 6}}$ in this basis requires powers larger than $\boldsymbol{x}^{\mathbf{2 8 0}, \mathbf{0 0 0}}$ and coefficients larger than $\mathbf{1 0}^{\mathbf{1 0 7 , 0 0 0}}$. We present a theorem establishing exponential growth of coefficients with respect to $1 / \varepsilon$.

Keywords: Müntz approximation theorem, expansion coefficients
MSC Classification: 41A10, 42C30

## 1 Introduction

The Müntz approximation theorem, conjectured by Bernstein in 1912 [4] and proved by Müntz in 1914 [12], is a beautiful result. Suppose we are interested in continuous functions on $[0,1]$, i.e., $f \in C([0,1])$, and we want to approximate them as linear combinations of the monomials

$$
x^{a_{1}}, x^{a_{2}}, \ldots,
$$

where $\left\{a_{k}\right\}$ is a set of exponents (not necessarily integers) satisfying

$$
0=a_{0}<a_{1}<a_{2}<\cdots .
$$

Certainly this is possible if $a_{k}=k$ for each $k$, by the Weierstrass approximation theorem [14], but what if the set of powers is sparser? For example, are the even powers

$$
\begin{equation*}
1, x^{2}, x^{4}, \ldots \tag{1}
\end{equation*}
$$

dense in $C([0,1])$ ? The theorem characterizes all suitable sets of exponents:

Theorem 1 (Müntz approximation theorem) The family $\left\{x^{a_{k}}\right\}$ is dense in $C([0,1])$ if and only if

$$
\begin{equation*}
\sum_{k=1}^{\infty} \frac{1}{a_{k}}=\infty \tag{2}
\end{equation*}
$$

Thus the set (1) easily qualifies, as do many other collections of exponents, such as the primes:

$$
\begin{equation*}
1, x^{2}, x^{3}, \ldots, x^{89}, x^{97}, \ldots \tag{3}
\end{equation*}
$$

For discussions of the theorem with proofs, see [2], [6], and [11]. After 1914, Müntz's theorem was generalized by Szász and others.

As a numerical analyst, I work with algorithms based on expanding functions in nonorthogonal bases, a powerful technique in certain contexts [1, 10]. This led me to consider Müntz's theorem from a computational angle, and what emerged is startling. To make the point, it is enough to consider a particular case of what might be regarded as the most basic nontrivial Müntz approximation. The name " E " alludes to the use of even powers.

Problem E. Given $\varepsilon>0$, find an integer $n \geq 0$ and coefficients $c_{0}, \ldots, c_{n}$ such that

$$
\begin{equation*}
\left|x-\sum_{k=0}^{n} c_{k} x^{2 k}\right| \leq \varepsilon, \quad x \in[0,1] \tag{4}
\end{equation*}
$$

We shall prove:

Theorem 2 If $\varepsilon<1 / 2$, then any solution of Problem E has

$$
\begin{equation*}
n>\frac{1}{20 \varepsilon} \tag{5}
\end{equation*}
$$

and

$$
\begin{equation*}
\max _{k}\left|c_{k}\right|>0.75 \varepsilon 2^{1 /(40 \varepsilon)} \tag{6}
\end{equation*}
$$

Actually, I believe the following sharper bounds hold:

$$
\begin{align*}
n & >\frac{1}{8 \varepsilon}  \tag{7}\\
\max _{k}\left|c_{k}\right| & >\frac{(1+\sqrt{2})^{2 n}}{16 n^{1.5}} \tag{8}
\end{align*}
$$

For accuracy $\varepsilon=10^{-6}$, my estimate is that one needs $n>140,000$ and $\max _{k}\left|c_{k}\right|>10^{107,000}$. In such an expansion, the enormous coefficients have oscillating signs, so that they cancel almost exactly (namely to one part in $\left.10^{107,000}\right)$. On a computer in floating-point arithmetic, all information will be lost unless one works in a precision of more than 107,000 digits. (The usual precision is 16 digits.)

## 2 Proof

Problem E is equivalent to the more familiar problem of approximation of $|x|$ on $[-1,1]$ :

$$
\begin{equation*}
\left||x|-\sum_{k=0}^{2 n} c_{k} x^{2 k}\right| \leq \varepsilon, \quad x \in[-1,1] \tag{9}
\end{equation*}
$$

Since Lebesgue first used approximations of $|x|$ for a proof of the Weierstrass approximation theorem at age 23 in 1898, a great deal has been learned about this problem, as recounted in chapter 25 of [14]. In particular, Bernstein's 1914 paper [5] was a landmark contribution. Among many other things, Bernstein proved that $\varepsilon$ satisfies

$$
\begin{equation*}
\varepsilon>\frac{1}{4(1+\sqrt{2})(2 n-1)} \tag{10}
\end{equation*}
$$

for any $n \geq 1$, which implies, since $4(1+\sqrt{2}) \approx 9.66$,

$$
\begin{equation*}
n>\frac{1}{20 \varepsilon} \tag{11}
\end{equation*}
$$

Since $\varepsilon<1 / 2$ in (9) implies $n \geq 1$, this establishes condition (5) of Theorem 2.
To establish condition (6), we make use of (11). Given $\varepsilon$, let $n$ and $\left\{c_{k}\right\}$ define a solution (4) of Problem E. If we split the series into roughly the first quarter and the last three-quarters,

$$
\begin{equation*}
\sum_{k=0}^{\lfloor 1 /(80 \varepsilon)\rfloor} c_{k} x^{2 k}+\sum_{k=1+\lfloor 1 /(80 \varepsilon)\rfloor}^{n} c_{k} x^{2 k} \tag{12}
\end{equation*}
$$

then by (11), the first part can approximate $|x|$ no more closely than $4 \varepsilon$. More to our purpose, by a linear scaling, it can approximate $|x|$ over the subinterval $[-1 / 2,1 / 2]$ no more closely than $2 \varepsilon$. Therefore, since the sum of the two series in (12) has accuracy better than $\varepsilon$, the second series must have maximal size at least $\varepsilon$ over $[-1 / 2,1 / 2]$. Since $\left|x^{2 k}\right| \leq 2^{-2 k}$ for $x \in[-1 / 2,1 / 2]$, this implies that there must be some huge coefficients. Specifically, summing a power series involving powers of 4 shows that the second series of (12) is bounded by

$$
\begin{equation*}
\sum_{k=1+\lfloor 1 /(80 \varepsilon)\rfloor}^{n}\left|c_{k} x^{2 k}\right| \leq \frac{4}{3} \max _{k}\left|c_{k}\right| 2^{-2(\lfloor 1 /(80 \varepsilon)\rfloor+1)} . \tag{13}
\end{equation*}
$$

Therefore we must have

$$
\begin{equation*}
\frac{4}{3} \max _{k}\left|c_{k}\right| 2^{-2(\lfloor 1 /(80 \varepsilon)\rfloor+1)}>\varepsilon \tag{14}
\end{equation*}
$$

that is,

$$
\begin{equation*}
\max _{k}\left|c_{k}\right|>0.75 \varepsilon 2^{2(\lfloor 1 /(80 \varepsilon)\rfloor+1)} \tag{15}
\end{equation*}
$$

This implies (6), completing the proof of Theorem 2.

## 3 Numerical estimates

The theorem and proof just given were all about lower bounds, but now let us look at more accurate (though unrigorous) estimates. Bernstein [5] also proved that the best degree $2 n$ maximum-norm approximation errors $\varepsilon$ satisfy

$$
\begin{equation*}
\varepsilon \sim \frac{\beta}{2 n}, \quad n \rightarrow \infty \tag{16}
\end{equation*}
$$

for some $\beta$, and in 1985 Varga and Carpenter [16] gave the numerical estimate

$$
\begin{equation*}
\beta \approx 0.28016949902386913303643649 \ldots \tag{17}
\end{equation*}
$$

To achieve $\varepsilon \leq 10^{-1}, 10^{-2}, 10^{-3}$, and $10^{-4}$, respectively, this suggests (rounding up to the next even numbers) that we will need degrees $2 n$ of approximately $4,28,282$, and 2802. It turns out that the actual minimal degrees (as computed with the Chebfun minimax command $[7,8]$ ) are exactly these four numbers. For accuracy $10^{-6}$, for example, though this is beyond Chebfun, it seems clear that the required degree will be close to $n=280,170$.

Thus we see again that an approximation (4) requires degrees of order $O(1 / \varepsilon)$, but why are the coefficients so large? The explanation is that the monomials $1, x^{2}, x^{4}, \ldots, x^{2 n}$ are an exponentially ill-behaved basis for the space of even degree $2 n$ polynomials on $[-1,1]$. Numerical analysts quantify this observation by noting that the condition number of this set of functions is of the approximate order

$$
\begin{equation*}
\kappa_{2 n} \approx(1+\sqrt{2})^{2 n} \approx 10^{0.766 n} \tag{18}
\end{equation*}
$$

[3, 9]. With $2 n=280,170$ for accuracy $10^{-6}$, this suggests the expansion coefficients will need to be of order about $10^{107,000}$. Our best empirical approximation based on calculations for $n$ up to 300 is

$$
\begin{equation*}
\max _{k}\left|c_{k}\right| \approx 0.066 \times \frac{(1+\sqrt{2})^{2 n}}{n^{1.5}} \tag{19}
\end{equation*}
$$

Table 1 summarizes our computations and estimates for accuracies $\varepsilon=$ $10^{-1}, \ldots, 10^{-8}$.

Figure 1 illustrates graphically where the big coefficients come from. For $2 n=28,56, \ldots, 140$, it plots the coefficients $\left|c_{k}\right|$ for $k=0,1, \ldots, n$ in a monomial expansion of the best approximations.

Table 1 Numerical data for approximation of $x$ by even powers on $[0,1]$, or equivalently, approximation of $|x|$ on $[-1,1]$. The numbers up to 2802 are based on numerical computations, and the remaining ones are estimates.

| accuracy $\varepsilon$ | minimal degree $2 n$ | maximal coefficient $\left\|c_{k}\right\|$ |
| :---: | :---: | :---: |
| $10^{-1}$ | 4 | 1.93 |
| $10^{-2}$ | 28 | $7.4 \times 10^{7}$ |
| $10^{-3}$ | 282 | $3.5 \times 10^{103}$ |
| $10^{-4}$ | 2802 | $10^{1068}$ |
| $10^{-5}$ | 28018 | $10^{10,700}$ |
| $10^{-6}$ | 280170 | $10^{107,000}$ |
| $10^{-7}$ | 2801696 | $10^{1,070,000}$ |
| $10^{-8}$ | 28016950 | $10^{10,700,000}$ |

Fig. 1 Monomial coefficients $\left|c_{k}\right|$ of best approximations of $x$ by even powers on $[0,1]$, or equivalently, of $|x|$ on $[-1,1]$, for $2 n=28,56, \ldots, 140$. These values correspond to approximation errors approximately $0.01,0.01 / 2, \ldots, 0.01 / 5$. The end of the curve is of order $2^{2 n}$, and the peak in the middle is of order $(1+\sqrt{2})^{2 n}$.

## 4 A remark about mathematics

Theorem 2 is startling and interesting. From the usual mathematical point of view, however, it is not much more than that. After all, Müntz's theorem remains valid and beautiful. From the usual mathematical perspective, Müntz's theorem expresses a fundamental truth, and Theorem 2, however interesting, is an engineering footnote.

As I have discussed in the context of other problems [13, 15], I believe this usual perspective is too comfortable. Theorem 2 implies that typical sets of powers deemed useful by Müntz's theorem would in fact be useless in any actual application. If it was not the business of mathematicians to notice and analyze this effect in the past 110 years, then whose business was it?

Acknowledgments. I am grateful for helpful suggestions to Michael Ganzburg, Daan Huybrechs, Christian Lubich, Doron Lubinsky, Yuji Nakatsukasa, Allan Pinkus, and Endre Süli.

Conflict of Interest. The author has no relevant financial or non-financial interests to disclose.
