We revisit LHC searches for heavy invisible particles by exploiting QCD initial state radiation. We recast a dijet signal region in a general multijet plus MET search by ATLAS. We find that non-trivial mass limit can be obtained for various models of the electroweakino sector with the present data in hadronic channels. The winos are bound to be heavier than $m_{\tilde{W}} \gtrsim 160$ GeV and higgsinos $m_{\tilde{h}} \gtrsim 100$ GeV, depending on the chargino-neutralino mass splitting.

I. INTRODUCTION

A variety of independent astrophysical and cosmological observations [1] have grounded the inclusion in cosmological models of an electromagnetically neutral, non-barionic matter species generically referred to as dark matter (DM). Despite a rich experimental effort to unveil the nature of dark matter via direct detection, collider searches, and indirect detection signals, it remains elusive.

In the case where DM has a substantial interaction with the Standard Model (SM), it can be produced at colliders. However, being electrically and color neutral, it will escape the detector without leaving any signal. Thus, an appropriate strategy to look for its production at collider experiments would be to measure an imbalance in a sum of transverse momentum of the visible particles traveling through a detector, when DM is produced in association with visible particles.

The signal where DM production is accompanied by at least one jet from initial state radiation (ISR) has been considered conventionally as the most promising channel to detect DM at colliders. A number of dedicated searches have been performed, for recent ones see [2, 3], which typically require 1–4 jets, with a very energetic leading jet, and large missing transverse energy (MET). Early searches required exactly one [4] or up to two jets [5] but it turned out that vetoing additional jets reduced acceptance [6]. Nevertheless this strategy is usually called “monojet”.

Supersymmetry (SUSY) and in particular the Minimal Supersymmetric Standard Model (MSSM) [7] has been a benchmark model for direct New Physics searches at the Large Hadron Collider (LHC). The lightest supersymmetric particle (LSP) is a DM candidate, though providing the right relic abundance is tricky [8–10]. Here we focus on several specific scenarios where the LSP is the lightest neutralino, and is accompanied by charginos

and heavier neutralinos, the supersymmetric partners of gauge and Higgs bosons [7].

The monojet strategy does not have enough sensitivity to constrain electroweakinos [11] even around the LEP limit of 95–100 GeV [12–16].* Therefore in this work we test sensitivity of another search strategy which was originally applied for squark and gluino pair production. As it turns out the main difference will be in the requirement of two energetic leading jets rather than one as for monojet.

II. SCENARIOS

The realization of DM as a new species of weakly-interacting massive particle (WIMP) has been hypothesized, justified by the feature of being able to reproduce the correct relic density for non-relativistic matter in the early universe. A popular family of complete models including WIMPs is supersymmetry. Binos, higgsinos and winos represent fermionic SU(2) singlets, doublets and triplets respectively, and the stability of the LSP is a consequence of the symmetries required to stabilize the proton.

DM candidates charged under SU(2) can be directly produced at hadron colliders through W and Z mediated processes:

$$u + \bar{d} \rightarrow \tilde{\chi}^+ + \tilde{\chi}^0 + X \quad (\text{II.1})$$

$$q + \bar{q} \rightarrow \tilde{\chi}^+ + \tilde{\chi}^- + X \quad (\text{II.2})$$

$$q + \bar{q} \rightarrow \tilde{\chi}^0 + \tilde{\chi}^0 + X \quad (\text{II.3})$$

where $X = 0j, 1j, 2j, \dots$ denotes any number of additional jets, generically depicted in Fig. 1. In that case, the signal of a pair of DM particles with an additional hard ISR jet can be strong enough to produce a distinguishable signal in jets+MET searches.

In the following, we are going to analyze the detection possibilities of WIMPs at the LHC, using the MSSM as a benchmark model with all of the spectrum decoupled,

* Results of Ref. [17] suggest it might be sensitive when 300 fb⁻¹ of data is collected.

FIG. 1. Jets+MET signal from DM pair production at a hadron collider.

except for higgsinos, winos or binos. In this simplified model, the collider phenomenology can be characterized by a small number of parameters (higgsino and gaugino masses and $\tan\beta$). We are selecting three cases for study:

- higgsino LSP, heavy winos and bino:
 $\{\tilde{\chi}_1^0, \tilde{\chi}_1^\pm, \tilde{\chi}_2^0\} \equiv \{\tilde{H}_1^0, \tilde{H}^\pm, \tilde{H}_2^0\}$;
- bino LSP, light wino and heavy higgsino:
 $\{\tilde{\chi}_1^0, \tilde{\chi}_1^\pm, \tilde{\chi}_2^0\} \equiv \{\tilde{B}, \tilde{W}^\pm, \tilde{W}^0\}$;
- wino LSP, heavy higgsinos and bino:
 $\{\tilde{\chi}_1^0, \tilde{\chi}_1^\pm\} \equiv \{\tilde{W}^0, \tilde{W}^\pm\}$.

We refer to these scenarios by higgsino, bino-wino and wino models, respectively. A characteristic feature of these models are small mass gaps between particles, which are the consequence of the mixing structure in the gaugino and higgsino sectors, see e.g. [18] for details. The full calculation within the MSSM must necessarily include higher order corrections [19, 20]. In our simplified model setup, however, we will assume the mass gap to be a free parameter. In the following we only consider mass gaps of the order 1 GeV but larger than 300 MeV. Generally the small mass differences will result in signatures specific to long-lived particles which are beyond the scope of this study. Figure 2 shows schematically the particle spectra of the scenarios.

In the higgsino LSP model there are three states: $\tilde{\chi}_1^0$, $\tilde{\chi}_1^\pm$, $\tilde{\chi}_2^0$ with the following production modes:

$$pp \rightarrow \tilde{\chi}_1^0 \tilde{\chi}_2^0, \tilde{\chi}_1^0 \tilde{\chi}_1^\pm, \tilde{\chi}_2^0 \tilde{\chi}_1^\pm, \tilde{\chi}_1^+ \tilde{\chi}_1^- \quad (\text{II.4})$$

The total production cross section of mass degenerate higgsinos at $m_{\tilde{H}} = 100$ GeV is 18 pb at the NLO-NLL accuracy [21, 22]. For the mass gap of up to several GeV the LEP limits are between 92–102 GeV [14–16]. At the LHC the ATLAS experiment has constrained higgsinos above the LEP limit for the mass gap between neutralinos larger than 2 GeV [23]. Similarly CMS constraints the scenario with mass difference between neutralinos larger than 3 GeV [24].[†] The constraints rely on the soft leptons

[†] The values lower than 3 GeV are not presented in the exclusion plot.

arising in the decays of charginos and neutralinos via off-shell EW gauge bosons:

$$\tilde{\chi}_1^\pm \rightarrow W^* \tilde{\chi}_1^0, \quad (\text{II.5})$$

$$\tilde{\chi}_2^0 \rightarrow Z^* \tilde{\chi}_1^0. \quad (\text{II.6})$$

An ISR jet provides a necessary boost to the chargino-neutralino system, so that the soft leptons can be detected above the SM background.[‡] For the purpose of comparison with the experiments we assume the chargino mass to be halfway between neutralinos, i.e. $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{\chi}_1^0} + m_{\tilde{\chi}_2^0})/2$ though in realistic full-model calculations the chargino mass tends to be closer to the heavier neutralino [27, 28]. In any case, this results in a kinematic suppression of a decay mode $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^\pm + X$.

In the bino-wino model there are three states ordered with a growing mass: $\tilde{\chi}_1^0$, $\tilde{\chi}_1^\pm$, $\tilde{\chi}_2^0$. The winos are mass degenerate, while the mass gap between the bino and the winos, Δm , is of the order of several GeV.[§] Owing to the coannihilation mechanism, such a setup can in principle provide a correct relic DM abundance [31–34]. The following production modes are available:

$$pp \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^\pm, \tilde{\chi}_1^+ \tilde{\chi}_1^- \quad (\text{II.7})$$

The total production cross section of mass degenerate winos at $m_{\tilde{W}} = 100$ GeV is 34.3 pb at the NLO-NLL accuracy [21, 22]. The production modes involving bino vanish. The general limits from LEP at around 100 GeV apply here as well. At the LHC, this scenario is excluded for a mass difference of 1.8 GeV between bino and winos at the mass of 100 GeV [23]. For the mass difference of 10 GeV, the limit goes as far as 270 GeV [24].

Finally for the wino model there are two states, \tilde{W}^0 and \tilde{W}^\pm , with a mass difference $\Delta m = \mathcal{O}(\text{GeV})$. The production modes are the same as in the bino-wino model. The LEP constraints are in a range 92–102 GeV for $\Delta m < 10$ GeV. No LHC constraints existed to date.

III. METHODS

For each point of the parameter corresponding to the supersymmetric scenarios, with the spectrum calculated as explained in the previous section, we proceed as follows: We generate Monte Carlo events using `MadGraph5_aMC@NLO 3.1.0` [35–37] for the hard process corresponding to the inclusive production of a pair of higgsinos or winos plus the emission of up to two partons at matrix element level. A generator-level cut is imposed

[‡] It was proposed that the higgsino scenario could also be probed by a search for soft tracks [25] as well as in the mono- Z/W channel [26].

[§] The second lightest neutralino, $\tilde{\chi}_2^0$, tends to be long-lived in this scenario depending on the higgsino mass [29, 30]. We do not consider such a case.

FIG. 2. The schematic spectra of the models discussed in Sec. II with main decay modes proceeding via off-shell electroweak gauge bosons.

requiring at least one jet with 200 GeV of transverse momentum and the NNPDF23LO [38, 39] PDF set is used. The events are then interfaced to Pythia-8.244 [40] for modeling of the higgsino/wino decay, parton showering and hadronization. Jet matching and merging to parton-shower calculations is accomplished by the MLM algorithm [41]. The inclusive cross-section obtained is re-scaled using the K -factor corresponding to the exclusive hard process without ISR emission calculated using Resummino 2.0.1 [21, 22, 42–46] at NLO+NLL. The resulting events are fed to CheckMATE [47–52] to test against the present limits from ATLAS monojet [2] and multi-jet [53] searches. In addition, we implemented a shape fit over the multi-bin signal regions MB-SSd and MB-C defined in [53], using the package HistFitter 2.0 [54]. This method turns out to be superior to the usual limits calculated by CheckMATE with only the most sensitive signal region. The method was validated by reproducing the exclusion curves for squark pair production as detailed in Ref. [54].

Following this prescription, we test masses of the LSP in the range 60–160 GeV and values of the mass gap between the LSP and the NLSP in the range 0.4–20 GeV. Below 0.4 GeV the searches for long-lived massive particles become sensitive, especially long-lived charginos that travel a microscopic distance in the detector resulting in the “disappearing track” signature [55]. As expected the monojet search is weaker than the multijet search over the whole tested parameter space. In the multijet search the sensitivity comes from the shape fit in the SSd signal regions with 2 or 3 jets. The key feature of the SSd signal regions is the requirement that for the two leading jets $p_T(j) > 250$ GeV and $\text{MET} > 300$ GeV.

An uncertainty in the cross section calculation is estimated in MadGraph5 by varying factorization, renormalization and emission scales in the range [0.5–1.5] around the central values. The largest contribution comes from the emission scale variation: ${}^{+20\%}_{-25\%}$. PDF uncertainty of 2.4% was subdominant and the cross section was stable within a few % against the choice of different dynamic scales schemes as implemented in MadGraph5.

IV. RESULTS

Following the strategy discussed in the previous section, we obtained exclusions for both the gaugino and higgsino scenarios and these are shown in Fig. 3. The horizontal axis corresponds to the LSP mass, while the vertical axis to the characteristic mass splitting for each model. In the plots we also include the best limits obtained using the soft lepton search by the ATLAS experiment [23] (the red line). The LEP limits [12–16] are also shown as the grey shaded area and for the wino model we include the result of search for long-lived charginos [55] (orange shaded).

The weakest constraint is derived for the higgsino model, see the top left panel of Fig. 3. At the mass splitting $\Delta m = 0.5$ GeV we exclude higgsinos with the masses up to 100 GeV, which just slightly improves the LEP limit of 95 GeV. This model exhibits the lowest cross section which amounts to $\sigma \cdot K = 220 \text{ fb} \cdot 1.5 = 330 \text{ fb}$, where σ is the cross section calculated by MadGraph5 for the pair production of higgsinos with up to two additional partons and the $p_T > 200$ GeV for the leading parton, while K is the scaling factor calculated using Resummino at the NLO-NLL order.

For the bino-wino model, the top right panel of Fig. 3, we significantly extend previous limits. Wino with a mass up to 158 GeV and wino-bino mass difference 2 GeV are excluded. The total effective cross section for the winos of mass 100 GeV is much higher compared to the higgsino scenario: $\sigma \cdot K = 425 \text{ fb} \cdot 1.55 = 660 \text{ fb}$, obtained as explained above. For the mass difference $\Delta m > 6$ GeV the sensitivity is lost because of the selection requirement

$$\Delta\phi(j, \mathbf{p}_T^{\text{miss}}) > 0.8, \quad (\text{IV.1})$$

i.e. that the azimuthal distance between three leading signal jets and the missing transverse momentum is larger than 0.8 radians. This can be understood in the following way: the decay products of winos, albeit generally soft, will be highly boosted due to the presence of ISR. The direction of the boost will align with the boost of the LSPs system and hence with the direction of $\mathbf{p}_T^{\text{miss}}$. With the increasing mass splitting the jet formed by the decay products will be increasingly more likely to pass a

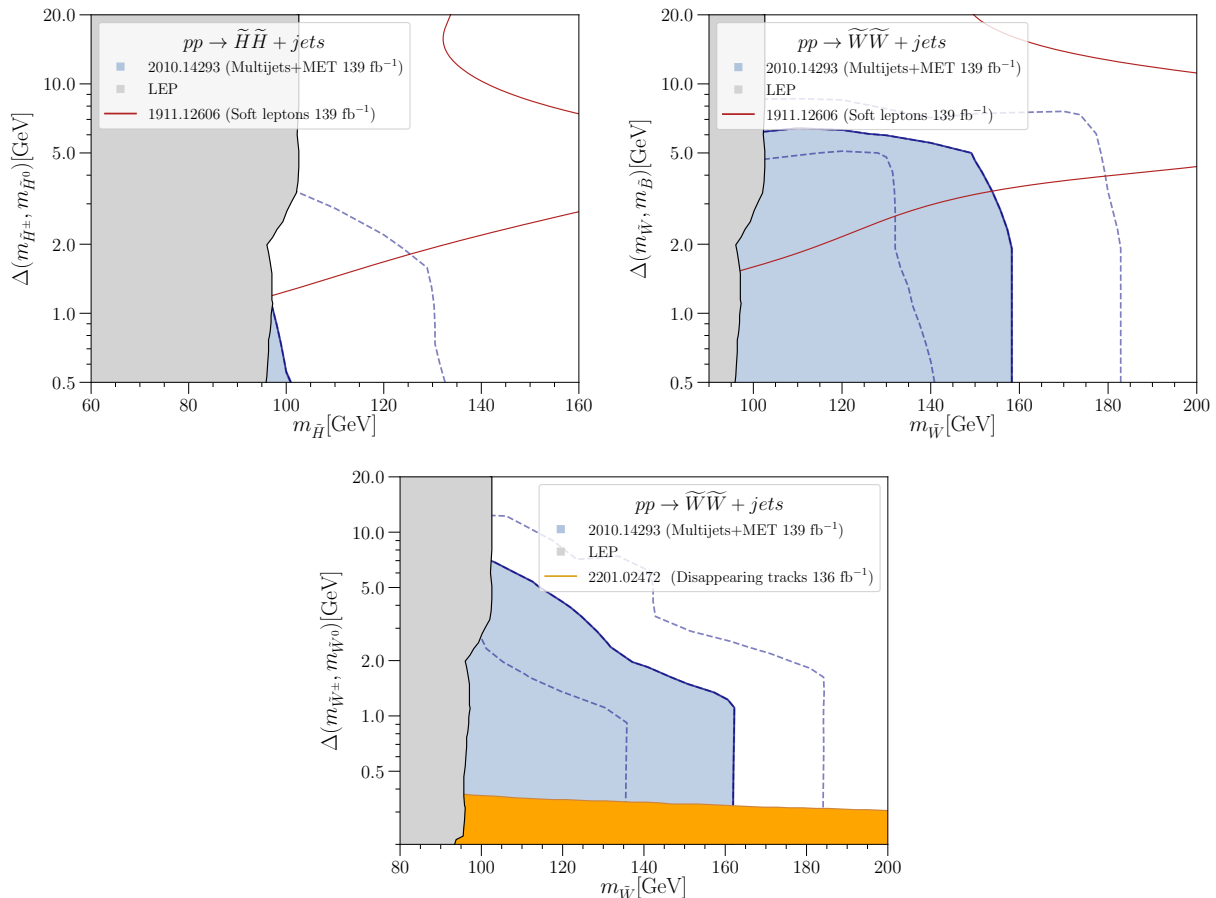

FIG. 3. The top left, top right and bottom plots represent the limits on the $(m_{\tilde{H}}, \Delta(m_{\tilde{H}\pm}, m_{\tilde{H}^0}))$ plane of the higgsino model, $(m_{\tilde{W}}, \Delta(m_{\tilde{W}\pm}, m_{\tilde{B}^0}))$ plane of the wino-bino model and $(m_{\tilde{W}}, \Delta(m_{\tilde{W}\pm}, m_{\tilde{W}^0}))$ plane of the wino model, respectively. Blue area is excluded by ATLAS multijet search [53] recasted in this work and the uncertainty from the cross section calculation is denoted by the blue-dashed lines. The gray area is excluded by the combination of LEP data [14–16]. The area inside of the red line is excluded by ATLAS soft lepton searches [23] and the orange area is excluded by the disappearing track search [55].

threshold of 50 GeV and become classified as one of the signal jets violating selection Eq. (IV.1).

Finally, in the lower panel of Fig. 3 we present a result for the wino scenario. Winos up to the mass of 160 GeV are excluded for the mass difference $\Delta m < 1$ GeV. At $m_{\tilde{W}} \sim 110$ GeV, on the other hand, the exclusions goes up to $\Delta m \sim 7$ GeV. The only competing exclusion, apart from the LEP results, comes from the long-lived chargino search exploiting the disappearing track signature [55]. The soft lepton searches are not sensitive to this scenario as they require a pair of same-flavour opposite-charge leptons with a low invariant mass originating from the neutralino decays. Here, a pair of leptons can only be produced in chargino pair production, cf. Eq. (II.7), and the following decay mediated via on off-shell W , Eq. (II.5). Hence the limit presented here is the only existing constraint at the LHC for promptly decaying winos. Similarly to the bino-wino case, the sensitivity of the multijet search decreases for a larger mass difference within the wino system.

V. CONCLUSIONS

We have proposed that the existing searches at the LHC in the multijet+MET final state can be applied to the challenging case of compressed MSSM electroweakino spectra near the electroweak scale. We recasted the ATLAS analysis and obtained new exclusion limits when the mass difference between the LSP and NLSP is below 5 GeV. For the higgsino LSP the limit improves only slightly over the existing LEP limit, while for the bino LSP accompanied by winos we exclude the respective wino up to a mass of 160 GeV for the mass differences up to 2 GeV. In the pure wino model, the winos are excluded up to 160 GeV for the mass difference of 1 GeV. This fills an important gap in the coverage of electroweakino spectra.
