ABSTRACT

Until now, our knowledge of the extragalactic Universe at mid-IR wavelengths $> 5 \mu\text{m}$ was limited to rare active galactic nuclei (AGN) and bright normal galaxies up to $z \sim 2$. The advent of the *JWST* with its Mid-Infrared Instrument (MIRI) is expected to revolutionise the ability of the mid-IR regime as a competitive wavelength domain to probe the high- z Universe. In this work we present a first study of the nature of *JWST* MIRI 7.7 μm sources selected with $> 3\sigma$ significance from the lensing cluster field SMACS J0723.3 07327. We model their spectral energy distribution fitting with 13 *JWST* and *HST* broad bands, in order to obtain photometric redshifts and derived physical parameters for all these sources. We find that this 7.7 μm galaxy sample is almost exclusively composed of normal galaxies up to $z_{\text{phot}} \approx 6.8$ and has an AGN at $z_{\text{phot}} = 7.2$. The vast majority of our galaxies have $[3.6]-[7.7] < 0$ colours and very few of them need high dust extinction values ($A_V = 3 - 4$) for their SED fitting. The resulting lensing-corrected stellar masses span the range $10^7 - 10^{11} M_\odot$. Overall, our results clearly show that the first MIRI 7.7 μm observations of deep fields are already useful to probe the high-redshift Universe and suggest that the deeper 7.7 μm observations to be available very soon will open up, for the first time, the epoch of reionisation at mid-IR wavelengths.

Keywords: infrared astronomy — high- z galaxies — galaxy surveys

1. INTRODUCTION

Our knowledge of the extragalactic background sky has significantly improved over the past decades with observations from space and ground-based observatories operating at different wavelengths. In the mid-infrared (mid-IR) regime (3 – 30 μm), in particular, a major leap forward has been achieved with the *Spitzer Space Telescope* (Werner et al. 2004), which has shown the important contribution of mid-IR wavelengths to the general extragalactic background light (Dole et al. 2006).

Moreover, *Spitzer* observations allowed us for the first time to reveal the high-redshift Universe at mid-IR wavelengths (see e.g. Bradač (2020) and references therein). Using the Infrared Array Camera (IRAC, Fazio et al. 2004) 3.6 and 4.5 μm , numerous works have detected and studied thousands of high- z galaxies up to $z \sim 6$ (e.g., Caputi et al. 2015, 2017; Davidzon et al. 2017) and even hundreds of galaxies at higher redshifts (e.g., Stefanon et al. 2021).

At wavelengths $\lambda > 5 \mu\text{m}$, the decreasing instrumental performance coupled with the increasing background noise implies that reaching high sensitivities is much

more difficult. Indeed, IRAC could reach at most 21–22 mag (5σ) in its extragalactic surveys at 5.8 and 8.0 μm (e.g., Sanders et al. 2007; Ashby et al. 2009). This resulted in a very limited utility of these photometric bands for the study of galaxies at $z > 2$, except for rare, mid-IR bright active galactic nuclei (e.g., Stern et al. 2005).

The advent of the *JWST* with its Mid-Infrared Instrument (MIRI; Rieke et al. 2015; Wright et al. 2015) is expected to radically change the ability of mid-IR astronomy to study of the high- z Universe. The goal of this work is to showcase the major leap forward produced by MIRI from its first observations of extragalactic fields.

In this Paper, we adopt a flat Λ -CDM cosmology with $\Omega_\Lambda = 0.7$, $\Omega_m = 0.3$, and $H_0 = 70 \text{ km/s/Mpc}$. All magnitudes are in the AB photometric system (Oke 1974).

2. TARGET AND DATA

Our target is SMACS J0723.37327 (hereafter SMACS 0723), a galaxy lensing cluster located in the southern celestial hemisphere (R.A. ($J2000.0$) = $07^h23^m19.5^s$, Dec. ($J2000.0$) = $-73^\circ27'15.6''$) at $z = 0.39$. Here we describe the datasets used in our study, which comprise

observations from *JWST* (MIRI, NIRC*am*) and the *Hubble Space Telescope* (*HST*). We also briefly describe the lensing model we adopted to retrieve the physical parameters of our background sources.

2.1. *JWST* imaging

The *JWST* observations of SMACS 0723 (ID proposal: 2736¹, PI: K. M. Pontoppidan) were publicly released as part of the *JWST* Early Release Observations (EROs) program on the 13th of July 2022. The observations were carried out with the *JWST* Near Infrared Camera (NIRC*am*, Rieke et al. 2005), the Mid-Infrared Instrument (MIRI, Rieke et al. 2015; Wright et al. 2015), the Near Infrared Imager and Slitless Spectrograph (NIRISS, Willott et al. 2022) and the Near Infrared Spectrograph (NIRSpec, Jakobsen et al. 2022). In the following, we briefly describe the MIRI and NIRC*am* observations we exploited in our work.

2.1.1. MIRI

The MIRI instrument on-board of *JWST* observed the central region of SMACS 0723 with the wide-band filters F770W, F1000W, F1500W and F1800W. The observations were carried out on the 14th of June 2022, and covered an area of $112.6'' \times 73.5''$, i.e. the MIRI field-of-view (FoV). In this work, we only make use of the F770W image.

We downloaded the fully-reduced MIRI images available at the Mikulski Archive for Space Telescopes (MAST)². From a visual inspection we found strong background patterns such as vertical stripes and gradients. The intensity of these features varies significantly among filters, thus suggesting that the calibration files available for the MIRI data reduction are not performing well. To improve the background cleaning and homogenisation, we decided to re-run the *JWST* pipeline (version 1.6.1) implementing an ad-hoc algorithm able to remove systematics from the fully calibrated exposures generated by the pipeline at the end of Stage 2 and before the final mosaicing performed in Stage 3. The introduction of this extra-step during the data reduction does not only impact on the images cosmetic. In fact, by running and comparing **SExtractor** catalogues obtained with the same configuration file and based on both the final image obtained with and without the extra-step, we found a substantial reduction of spurious detections (especially along the vertical stripes). Contextually, the extra-step helped in maximising the num-

ber of real sources detected. Ultimately, to ensure that the extra-cleaning of the background did not impact on our magnitude estimates, we compared the magnitudes of bright (< 24 mag) sources. We found no systematic offset between the two estimates.

A comparison between the MIRI and *HST* images highlighted an astrometric offset between the two dataset. We decided to register the MIRI observations to the *HST* astronomical coordinate system. To do so, we generated catalogues of sources for all MIRI images and a stacked image of the *HST* observations via the Source Extractor software (**SExtractor**, Bertin & Arnouts 1996). We then matched the catalogues, minimising the offsets between the detected sources.

Finally, we resampled the MIRI images to *HST* via the Python library **reproject**³, an affiliated package of **Astropy** (Astropy Collaboration et al. 2013, 2018).

2.1.2. NIRC*am*

The NIRC*am* instrument on-board of *JWST* observed SMACS 0723 both in the short-wavelength and long-wavelength regime with the wide-band filters F090W, F150W, F200W, F277W, F356W and F444W. The observations were carried out on the 6th of June 2022. NIRC*am* is constituted by two modules (A and B) pointing to adjacent fields of view and covering an area of $2.2' \times 2.2'$ (each). For the observations of SMACS 0723, only module B targeted the centre of the cluster, while module A provided observations for a parallel field.

We downloaded the fully-reduced NIRC*am* images available at MAST. Differently from MIRI, a visual inspection of the dataset revealed a good quality of the automatic reduction of NIRC*am* images by the *JWST* pipeline.

Also for the NIRC*am* observations, we used **SExtractor** to correct the astrometry of the images and register them to the *HST* dataset. We finally resampled the NIRC*am* images to the *HST* spatial sampling.

2.2. *HST* imaging

SMACS 0723 was observed with *HST* as part of The Reionization Lensing Cluster Survey (RELICS, Coe et al. 2019) that targeted 41 massive galaxy clusters at redshift $z \sim 0.2-1.0$, including 21 of the 34 most massive known according to *Planck* (Planck Collaboration et al. 2011). The observations of SMACS 0723 were carried out with the ACS/WFC F435W, F606W and F814W filters, and with the WFC3/IR F105W, F125W, F140W and F160W filters.

² <https://mast.stsci.edu/portal/Mashup/Clients/Mast/Portal.html>

³ <https://reproject.readthedocs.io/en/stable/>

We downloaded the fully-reduced *HST* images from the RELICS repository⁴.

2.3. Lensing model

To derive the physical properties of our targets, we adopted the recent lensing model of SMACS 0723 by Caminha et al. (2022). The lensing model was obtained using the software `lenstool` (Kneib et al. 1996; Jullo et al. 2007; Jullo & Kneib 2009) to model the mass distribution of the galaxy cluster. In particular, the fiducial mass model was constructed by means of an elliptical cluster-scale dark matter halo, a truncated spherical isothermal mass profile for each cluster galaxy member, and an external shear. The positions of multiple images detected in the *JWST*/NIRCam images and (when available) spectroscopic redshifts from the the Multi-Unit Spectroscopic Explorer (MUSE, Bacon et al. 2010) were adopted to constrain the model. We refer the reader to Caminha et al. (2022) for a more detailed description of the SMACS 0723 lensing model.

3. PHOTOMETRIC CATALOGUE AND SAMPLE SELECTION

After registering and resampling all the images to a same system of coordinates, we constructed our sample. To do so, we extracted photometric catalogues by making use of the software `SExtractor` (Bertin & Arnouts 1996). We ran `SExtractor` in dual-mode, using for detection the MIRI 7.7 μ m image and measuring the photometry in each of the 14 filters considered here (Table 1). To identify the 7.7 μ m sources, we adopted a *hot-mode* configuration (Galamez et al. 2013) and used the weights extension of the MIRI images to improve the rejection of spurious sources.

We measured each source photometry adopting circular apertures of 1 arcsec diameter via the `MAG_APER` task. We corrected these flux estimates for aperture effects f_{aper} , see Table 1. For NIRCam and MIRI, we estimated the aperture correction factor from the `Python` software `WebbPSF` (Perrin et al. 2014).

Whenever dealing with bright and extended sources, circular aperture photometry fails in estimating the galaxy total magnitude. Similarly, it is not suitable for retrieving the photometry of sources significantly stretched by the cluster lensing effect. For these reasons, for all the detected sources in our catalogue, we also measured Kron aperture photometry (Kron 1980) via the `SExtractor` task `MAG_AUTO`. In our final catalogue we adopt the aperture-corrected `MAG_APER` in all cases with > 23 mag, while at < 23 mag we kept the

brightest measurement between the aperture-corrected `MAG_APER` and `MAG_AUTO`.

Finally, we corrected our photometry for Galactic extinction. This was done by means of the `Python` packages `extinction` and `dustmaps` (Green 2018), and assuming the Galactic extinction curve by Cardelli et al. (1989) with $R_V = 3.1$. We derived values for the colour excess $E(B-V)$ in perfect agreement with⁵ those by Schlafly & Finkbeiner (2011).

Since `SExtractor` has been found to generally underestimate photometric errors (e.g. Sonnett et al. 2013), we manually set a minimum error of 0.05 mag in all the available filters. This is the value commonly considered as minimum systematic error for *HST* imaging data and we adopted it for the *JWST* observations too.

Finally, we computed flux upper-limits in all cases of a `SExtractor` non-detection. To do so, we masked all sources based on the `SExtractor` segmentation map and estimated the local background flux by randomly placing 1 arcsec diameter apertures in the background and at a maximum distance of 10 arcsec of the non-detected source. After applying a 3σ clipping (until convergence) on the distribution of fluxes retrieved, we obtained the standard deviation (1σ) of the local background. In our final catalogue, we consider the 3σ background level as upper-limit on the source flux.

To assess the quality of our photometry, we compared it with the RELICS catalogue⁶. The agreement with the RELICS magnitudes allowed us to validate our own photometric measurements. In addition, we compared our photometry with that provided in the SMACS 0723 photometric catalogue obtained by Kokorev et al. (2022). As this catalogue includes IRAC photometry at 3.6 and 4.5 μ m, we could directly assess the quality of the NIRCam absolute flux calibration at its longest wavelengths. The absence of *Spitzer*/IRAC observations in channel 4 (8.0 μ m) prevented us from verifying the quality of the absolute flux calibration for the MIRI F770W filter.

To construct a reliable sample of sources, we limit our analysis to objects having at least a 3σ detection both at 7.7 μ m (MIRI F770W filter) and 3.6 μ m (NIRCam F356W filter). We have excluded 11 Galactic stars identified from the Gaia DR3 catalogue (Gaia Collaboration et al. 2022) and other 4 close sources whose reliability and/or photometry are compromised by the bright stellar light.

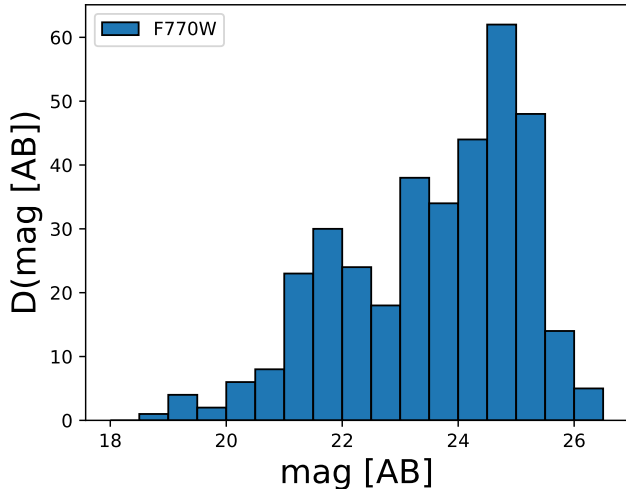

Figure 1. Distribution of *JWST* F770W magnitudes for our sample of $7.7\ \mu\text{m}$ -selected galaxies with $S/N(\text{F770W}) > 3$ and $S/N(\text{F356W}) > 3$ in SMACS 0723. There are 362 sources in total.

As a result, we end up with a final sample constituted by 362 sources. We present the F770W magnitude distribution of our sample in Figure 1 and show their spatial distribution in the SMACS 0723 F770W image in Figure 2. The F770W magnitude distribution shows that the number counts increase up to ~ 25 mag and then we quickly lose completeness at higher magnitudes. This is about 2.5 magnitudes deeper than any IRAC $8\ \mu\text{m}$ image available for extragalactic fields.

Figure 3 shows the (F356W-F770W) colour of our sources as a function of their F770W magnitudes. It is clear that most of the F770W sources are blue, with $[3.6] - [7.7] \sim -1$. A minority of sources ($\sim 9\%$) are red instead ($[3.6] - [7.7] > 0$), and these red sources appear mostly at $[7.7] > 24$ mag.

4. SED FITTING AND GALAXY DERIVED PARAMETERS

We performed the SED fitting of our sources by means of the software *LePhare*⁷ (Arnouts et al. 1999; Ilbert et al. 2006). For the SED fitting we considered only the photometry up to the NIRCcam F444W filter, for a total of 13 *HST* and NIRCcam broad bands (see 1). We explicitly excluded the MIRI $7.7\ \mu\text{m}$ filter for the modelling because, a priori, we do not know the redshifts of our sources and, thus, we do not know whether the MIRI bands mainly trace stellar or dust emission.

NOTE—For every *HST* (ACS, WFC3) and *JWST* (NIRCcam, MIRI) filter at our disposal (columns 1 and 2), in this table we report its photometric zero-point ZPT_{AB} (column 3), the Galactic extinction correction factor f_{ext} (column 4), the aperture correction factor f_{aper} for a circular aperture of $1''$ diameter (column 5), and, finally, the total exposure time t_{exp} (column 6).

We ran *LePhare* making use of the stellar population synthesis models from Bruzual & Charlot (2003) (hereafter BC03) based on Chabrier initial mass function (IMF, Chabrier 2003), and considering two-sets of stellar metallicities: solar ($Z_{\odot} = 0.02$) and sub-solar ($Z = 0.2Z_{\odot}$). We considered a range of star formation histories (SFHs): an instantaneous burst, i.e., a single stellar population (SSP) model, and a number of exponentially declining SFH (τ -model), i.e. $\text{SFR}(t) \propto e^{-t/\tau}$. For the τ -models, we adopted values of τ (the so-called e -folding time) equal to 0.01, 0.1, 0.3, 1, 3, 5, 10, 15 Gyr. We also complemented the BC03 stellar templates with the empirical QSO templates available in *LePhare* from Polletta et al. (2006). To take into account the effects of internal dust extinction, we convolved each synthetic spectrum with the attenuation law by Calzetti et al. (2000) and with the extrapolation proposed by Leitherer et al. (2002) at short wavelengths, leaving the colour excess $E(B-V)$ as a free parameter with values ranging between 0.0 – 1.0 in steps of 0.1. We ran *LePhare* in the redshift range $z = 0 - 8$ in a mode that takes into account the possible presence of nebular emission lines.

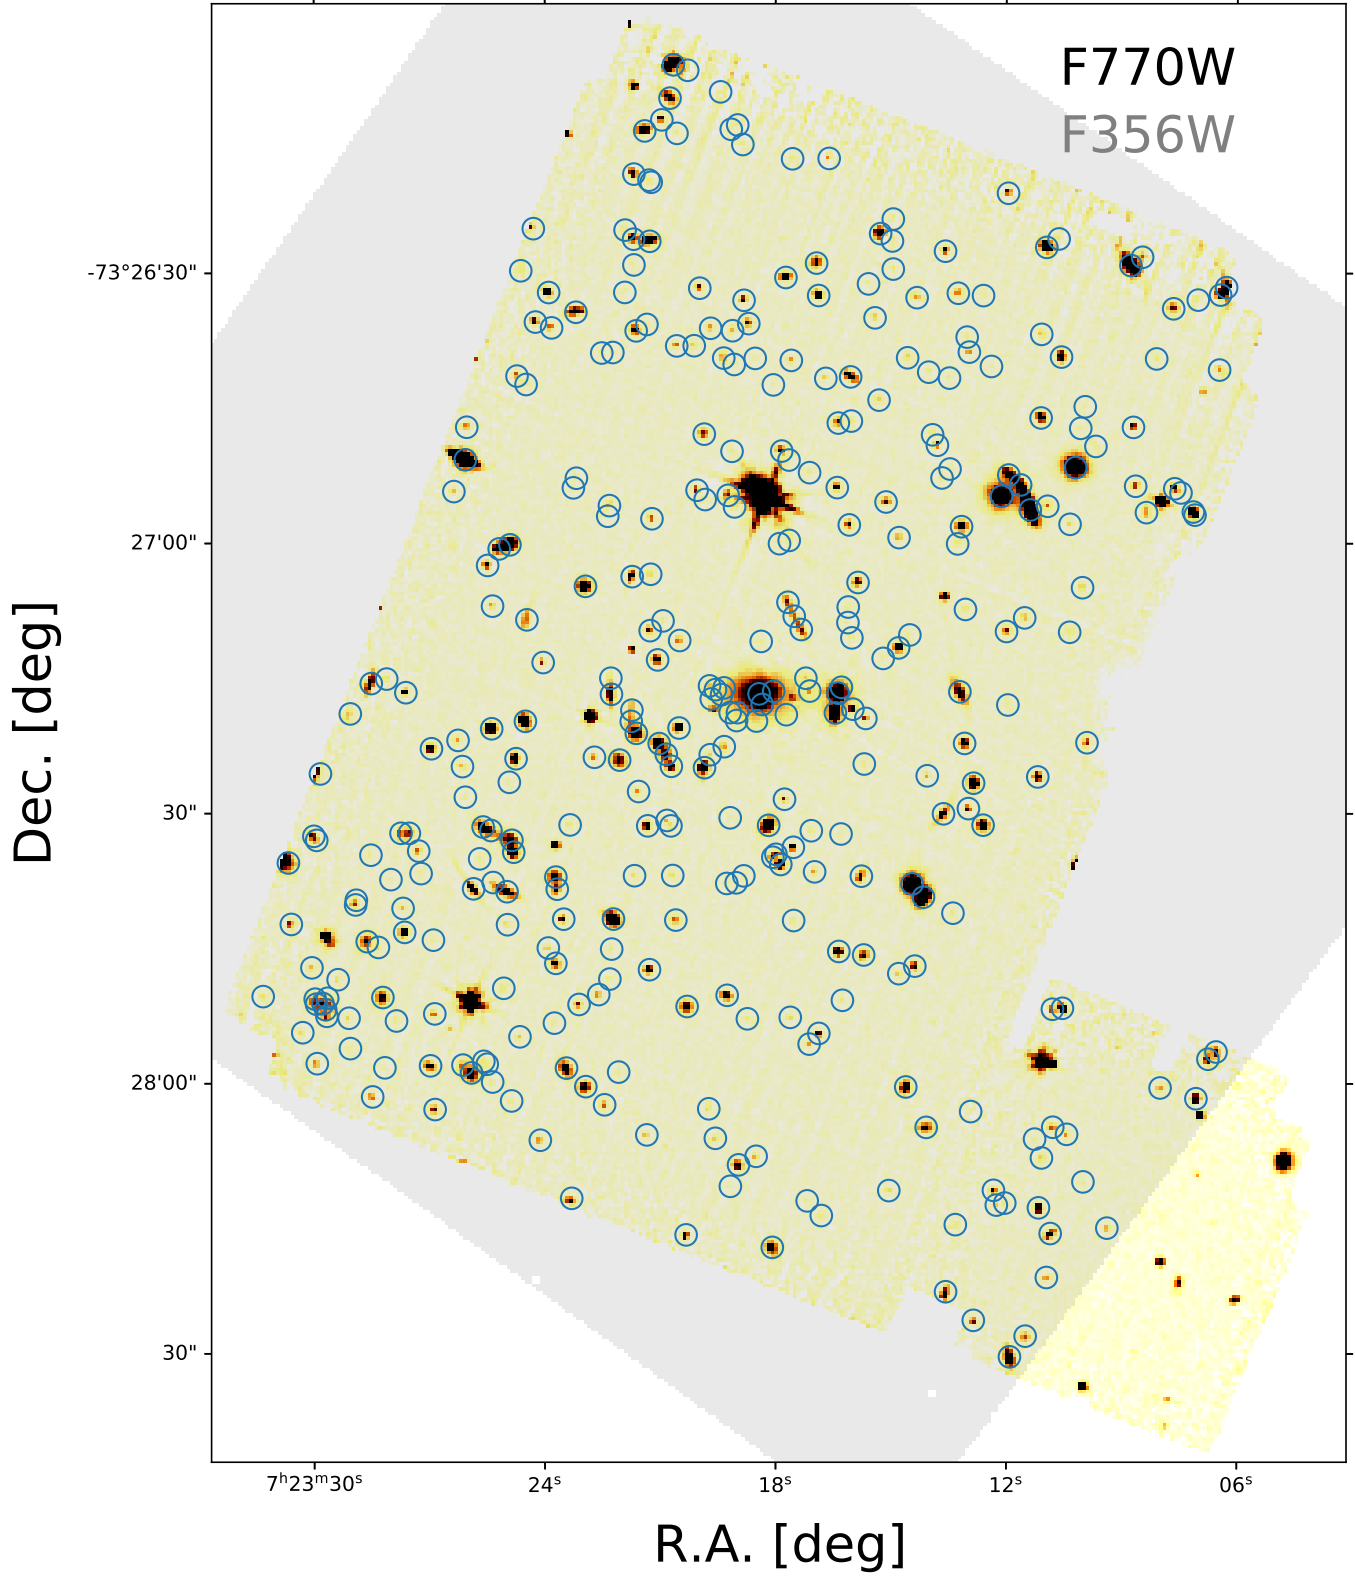

Figure 2. Layout of the *JWST*/MIRI 7.7 μ m (F770W) image for SMACS 0723. The blue open circles indicate the spatial position of our final sample of 362 sources having a 3σ detection in both F770W and the *JWST*/NIRCam F356W filter. The grey-shaded area shows the region of SMACS 0723 covered by the *JWST*/NIRCam B module.

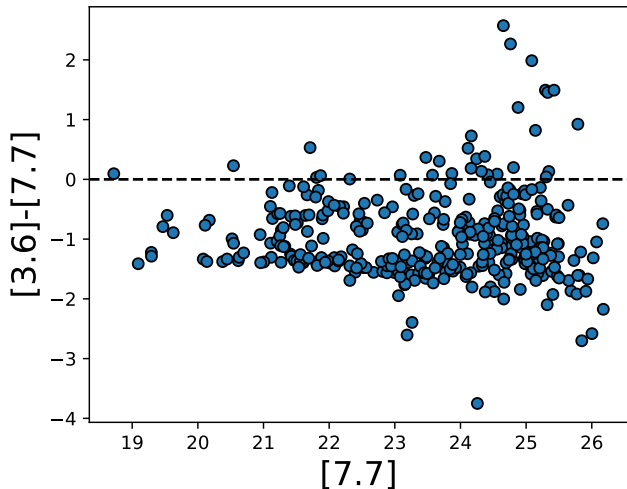

Figure 3. Colour magnitude diagram of our sample of 362 $7.7 \mu\text{m}$ -selected sources in SMACS 0723.

4.1. Photometric Redshifts

From *LePhare*'s output we obtained photometric redshift estimates, as well as derived physical parameters, for all our galaxies. *LePhare* yielded a good SED fit for all our sources, except one, for which the reduced χ^2 is very high. We removed this single source from all our subsequent analysis. The resulting redshift distribution of the remaining 361 sources is shown in Fig. 4.

We compared our photometric redshifts estimates with the secure spectroscopic redshifts⁸ obtained by *Caminha et al. (2022)*, which were derived from observations with MUSE at the Very Large Telescope (VLT). Although the galaxies in our $7.7 \mu\text{m}$ which are detected in MUSE are only ~ 45 , we compared the photometric redshifts and spectroscopic values for the common sources and confirmed the reliability of our photometric estimates.

Fig. 4 shows that the $7.7 \mu\text{m}$ galaxy populations spans a very wide redshift range from $z = 0$ through $z \sim 7.28$, with 60% of the sources lying at $z < 1$ and the remaining $\sim 40\%$ at higher redshifts. The highest redshift source in our sample (at $z \sim 7.28$) is actually the only one best-fit by *LePhare* with a QSO template. All the others are well fit with normal galaxy templates. We will only consider these normal galaxies in all our following discussion of galaxy physical parameters (dust extinction A_V , stellar masses).

The observed $7.7 \mu\text{m}$ corresponds to rest-frame wavelengths which, at different redshifts, trace very different

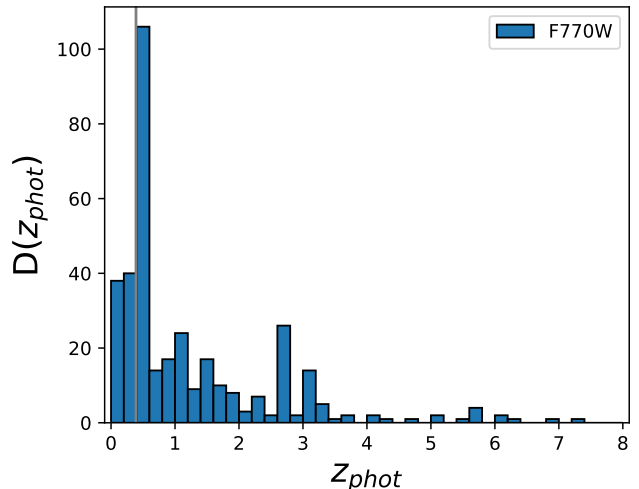

Figure 4. Photometric redshift distribution for our $7.7 \mu\text{m}$ -selected source sample in SMACS 0723.

physical processes. At $z < 1$, the observed $7.7 \mu\text{m}$ emission is dominated by the galaxy hot dust emission. At higher redshifts, the $7.7 \mu\text{m}$ wavelength domain becomes increasingly dominated by stellar emission. Therefore, the breadth of the redshift distribution indicates the varied nature of the $7.7 \mu\text{m}$ selected sources.

4.2. NIRCam/MIRI colours and galaxy internal extinctions

The varied nature of the $7.7 \mu\text{m}$ source population is also illustrated in Fig. 5. Even at similar redshifts, galaxies span a range of $[3.6]-[7.7]$ colours.

The best-fit SEDs of the $7.7 \mu\text{m}$ sources are characterised by a wide range of A_V values (Fig. 6). Only a minority ($< 15\%$) require high dust extinctions ($A_V > 2$ mag) for the SED fitting and are virtually all sources at $z < 4$ in our sample. Interestingly, the sources with red colour $[3.6]-[7.7] > 0$ do not preferentially correspond to cases with high A_V values.

Stern et al. (2005) proposed to isolate potential AGN using IRAC $[3.6]-[4.5]$ versus $[5.8]-[8.0]$ colours. Unfortunately we do not have MIRI $5.6 \mu\text{m}$ photometry for SMACS 0723, but we can analyse $[3.6]-[4.4]$ colours instead. We find that we only have a few sources with $[3.6]-[4.4] > 0$ at $z > 2$, so AGN with an IR power-law do not seem to be a significant fraction of our high- z sample (the surface density of these sources is likely too low to see them in significant numbers in the small area covered by SMACS 0723).

4.3. Stellar masses of $z > 1$ galaxies

For completeness, we also analyse the derived stellar masses for our galaxies. As SMACS 0723 is a lensing cluster, the stellar masses of background sources need

⁸ https://wwwmpa.mpa-garching.mpg.de/~caminha/SMACS0723_Caminha/model_JWST_v01/

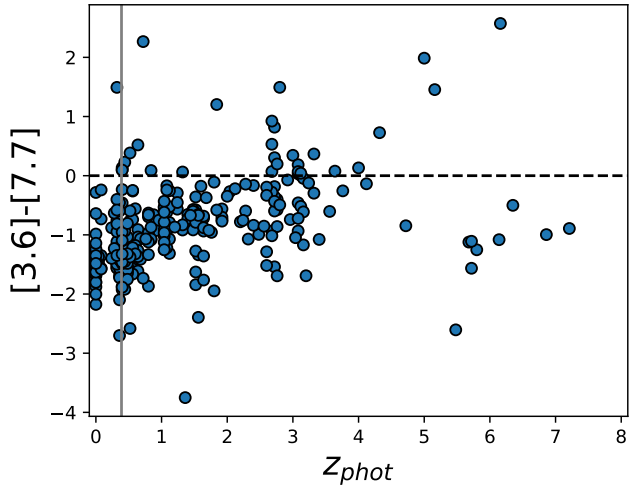

Figure 5. $[3.6] - [7.7]$ versus photometric redshift z_{phot} for our $7.7\ \mu\text{m}$ -selected galaxy sample. The vertical grey solid line indicates the redshift of the SMACS 0723 galaxy cluster ($z \simeq 0.39$).

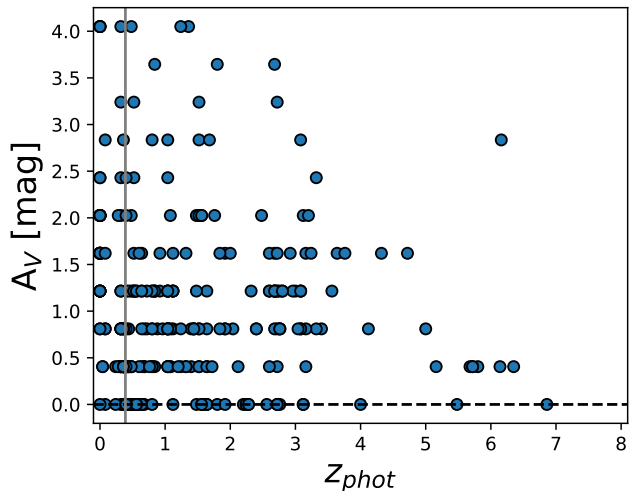

Figure 6. Dust extinction A_V as a function of photometric redshift z_{phot} . The vertical grey solid line indicates the redshift of the SMACS 0723 galaxy cluster ($z \simeq 0.39$).

to be corrected by lensing magnification. We used the lensing model by [Caminha et al. \(2022\)](#) to correct these stellar masses for magnification. The lensing-corrected stellar masses versus z_{phot} for all our galaxies at $z > 1$ are shown in Fig. 7.

The $7.7\ \mu\text{m}$ source sample contains galaxies with a wide range of stellar masses 10^7 - $10^{11}\ M_\odot$ at $z > 1$, indicating that a selection in this waveband does not necessarily correspond to a selection in stellar mass even at $z > 1$. Nevertheless, it should be noted that the sparse population of the stellar-mass plot at $z > 4$ is to some extent due to the fact that these galaxies are increasingly

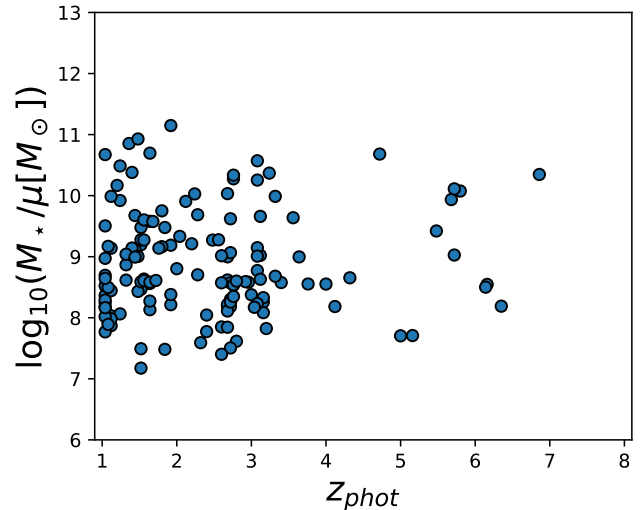

Figure 7. Diagram of the stellar mass (corrected for lensing magnification) of our sample of sources as a function of the photometric redshift z_{phot} .

rarer towards higher redshifts and the area sampled by SMACS 0723 is small. So not all stellar-mass galaxies at high z might be represented in this field due to sample variance, but not because of a consequence of the $7.7\ \mu\text{m}$ selection.

This is also true for our highest redshift sources at $z > 6$ in our sample. A few of them have stellar masses $10^8 - 10^9\ M_\odot$, while one has $\sim 2 \times 10^{10}\ M_\odot$, i.e., it is quite massive for such high redshifts (see §4.4).

4.4. Examples of $7.7\ \mu\text{m}$ sources at $z > 6$

Fig. 8 shows two examples of $7.7\ \mu\text{m}$ normal galaxies at $z > 6$. The postage stamps show their clear detection at both 7.7 and $3.6\ \mu\text{m}$. In both cases, the resulting SED fitting is of very good quality. Even the $7.7\ \mu\text{m}$ photometric point, which was not used for the SED fitting, is in excellent agreement with the extrapolation of the best-fit template at observed wavelengths $> 5\ \mu\text{m}$.

Source ID 382 at $z_{phot} = 6.14$ has a best-fit dust extinction $A_V = 0.4$ and delensed stellar mass of $3 \times 10^8\ M_\odot$. The other source, ID 399 at $z_{phot} = 6.86$, instead, has a best-fit dust extinction $A_V = 0$ and a delensed stellar mass of $2 \times 10^{10}\ M_\odot$.

5. SUMMARY AND CONCLUSIONS

In this paper we have presented the first physical-parameter characterisation of the $7.7\ \mu\text{m}$ -selected galaxy population based on *JWST* MIRI and NIRCcam data. We studied the lensing cluster SMACS 0723, which was one of the first extragalactic fields observed with this *JWST*. We complemented the *JWST* data with ancillary *HST* images, allowing us to perform the galaxy SED

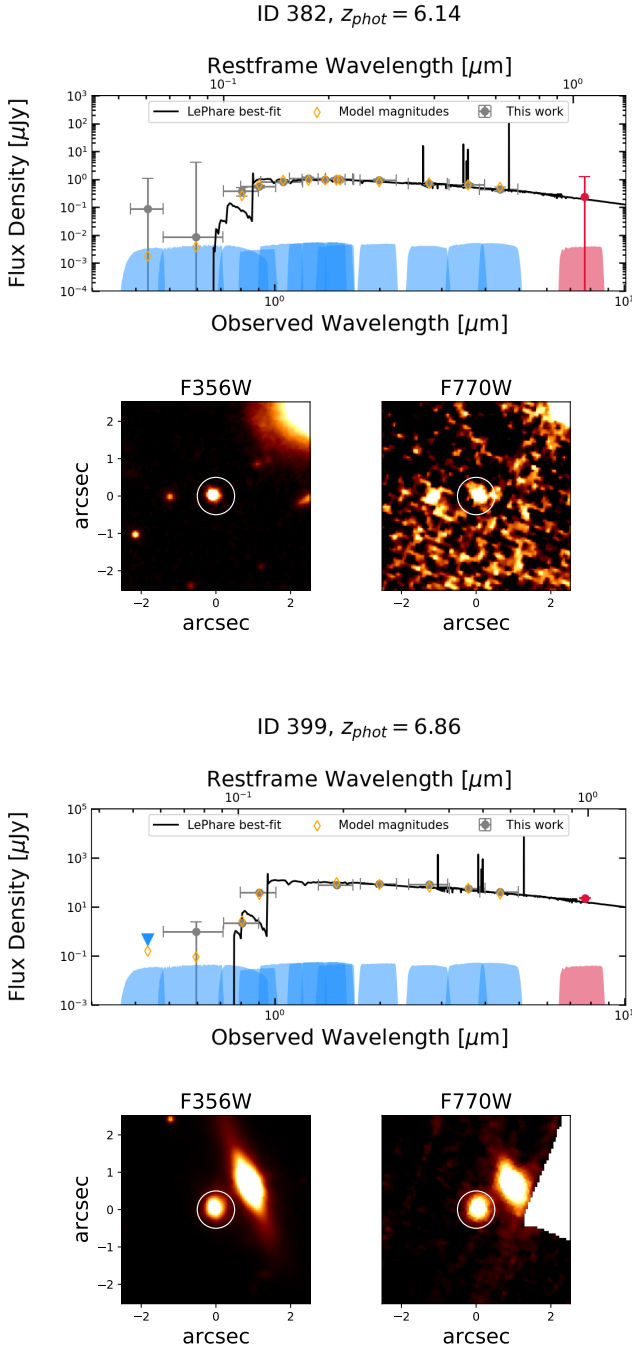

Figure 8. LePhare best-fit SED of galaxies ID382 (top) and ID399 (bottom), both at $z_{phot} > 6$. The MIRI $7.7 \mu\text{m}$ point has not been used for the SED fitting, but added a posteriori. For the two galaxies we show cutout images ($5'' \times 5''$) in the NIRCcam F356W and MIRI F770W bands.

fitting on a total of 13 broad bands for our total population of 362 $7.7 \mu\text{m}$ -selected galaxies with $S/N > 3$ in both F770W and F356W.

We obtained photometric redshifts and other derived physical parameters for all our sources. We showed that at the depth of the current MIRI survey, the $7.7 \mu\text{m}$ selection results in a heterogeneous galaxy population: 60% of the selected galaxies are at $z < 1$ for which the $7.7 \mu\text{m}$ light should be mostly produced by hot dust emission. The other 40% corresponds to galaxies at $z > 1$, a redshift regime where the $7.7 \mu\text{m}$ light is increasingly dominated by stellar emission. Our high- z sample has a tail that reaches $z = 7.28$, indicating that already at these depths the MIRI $7.7 \mu\text{m}$ images already contain galaxies towards the epoch of reionisation.

The highest redshift source in our sample at $z = 7.28$ is actually best-fit by a QSO template. All the others are best fit with normal galaxy templates. In addition, one of our galaxies at $z_{phot} = 2.76$ is an ALMA millimetre source observed in the ALCS program (P.I. K. Kohno; see Sun et al. 2022).

The vast majority of the $7.7 \mu\text{m}$ galaxies have blue $[3.6]-[7.7]$ colours, independently of redshift. Less than 10% of them have red colours $[3.6] - [7.7] > 0$ and this red colour is not necessarily associated with high A_V values. Although the $7.7 \mu\text{m}$ galaxies span a wide range of best-fit A_V values, only a few of them seem to need the maximum $A_V \approx 4$ permitted in our SED-fitting runs.

The $z > 1$ galaxies in our sample span stellar masses between 10^7 and $10^{11} M_\odot$. The access to low stellar masses is facilitated thanks to the gravitational lensing effect, as it has been shown by previous works (e.g., Rinaldi et al. 2022). We do not find any very massive $> 10^{11} M_\odot$ galaxy, but this is not surprising, given the small volume sampled by the SMACS 0723 field.

Overall, this work demonstrates the enormous potential of MIRI to open up the study of the high-redshift Universe at mid-IR wavelengths, particularly at $7.7 \mu\text{m}$ where MIRI still has relatively high sensitivity. Very soon, deeper MIRI $7.7 \mu\text{m}$ observations will be available with *JWST*, allowing us to investigate many more high- z galaxies, and even many at the epoch of reionisation, at mid-IR wavelengths for the first time.

EI and KIC acknowledge funding from the Netherlands Research School for Astronomy (NOVA). KIC acknowledges funding from the Dutch Research Council through the award of the Vici Grant VI.C.212.036. Cosmic Dawn Center is funded by the Danish National Research Foundation under grant No. 140. We thank Kotaro Kohno for discussion on the ALMA ALCS sources in SMACS 0723.
