Abstract

Nanofibrous networks are the foundation and natural building strategy for all life forms on our planet. Apart from providing structural integrity to cells and tissues, they also provide a porous scaffold allowing transport of substances, where the resulting properties rely on the nanoscale network structure. Recently, there has been a great deal of interest in extracting and reassembling biobased nanofibers to create sustainable, advanced materials with applications ranging from high-performance textiles to artificial tissues. However, achieving structural control of the extracted nanofibers

is challenging as it is strongly dependent on the extraction methods and source materials. Furthermore, the small nanofiber cross-sections and fast Brownian dynamics make them notoriously difficult to characterize in dispersions. In this work, we study the diffusive motion of spherical gold nanoparticles in semi-dilute networks of cellulose nanofibers (CNFs) using X-ray Photon Correlation Spectroscopy (XPCS). We find that the motion becomes increasingly *subdiffusive* with higher CNF concentration, where the dynamics can be decomposed into several *superdiffusive* relaxation modes in reciprocal space. Using simulations of confined Brownian dynamics in combination with simulated XPCS-experiments, we observe that the dynamic modes can be connected to pore sizes and inter-pore transport properties in the network. The demonstrated analytical strategy by combining experiments using tracer particles with a *digital twin* may be the key to understand nanoscale properties of nanofibrous networks.

Introduction

Networks of semi-flexible nanofibers make up many key architectural elements in nature, such as actin filaments and microtubules in the cytoskeleton of eukaryote cells, collagen nanofibrils in connective tissues and bones, chitin nanofibrils in exoskeletons of arthropods, fibroin nanofibrils in silk from spiders or silkworms, and cellulose nanofibers (CNFs) in plant cell walls.^{1–4} The primary function of the nanofibrous networks is to provide structural integrity and resist deformation from stretching, compressing, bending, and shearing forces. Additionally, these networks provide a natural porous scaffold for transport of essential substances and other nanoscale objects. Through intricate and complex hierarchical assemblies

that have evolved over millions of years, the nanoscale properties of these fibrous network can be transferred to macroscale, thus enhancing the chances of survival of the species they belong to.⁵

Nanofibrous networks also play an important role in another modern scenario. By extracting CNFs from the plant cell wall and reassembling them in a controlled manner, there have been numerous examples of advanced biobased nanomaterials made directly from biomass. These materials possess excellent mechanical properties and functionalizability.^{6,7} Some examples include strong filaments for new textile materials,⁸⁻¹¹ membranes for water purification,^{12,13} aerogels for therapeutic delivery,¹⁴ or artificial tissues and wound dressings in the biomedical field.^{15,16} By letting the CNFs provide a structural scaffold, other functional nanoparticles can be introduced to make new hybrid materials that are conductive, magnetic, fire retardant, or provide structural coloring and biosensing abilities.¹⁷⁻²³ The hydrophilic CNFs can further be dispersed in organic solvents, making them compatible as reinforcement agents in hydrophobic polymer materials.^{24,25}

Despite the wide range of applications for CNF materials, the nanoscale three-dimensional structures of the CNF networks, giving rise to the material properties, are notoriously difficult to characterize⁸ and therefore to control. The main techniques for characterizing CNFs include imaging techniques such as atomic force microscopy (AFM) or transmission electron microscopy (TEM), which can provide accurate descriptions of the individual CNF morphology, but fail to capture dynamics and structures in dispersions. Small-angle X-ray scattering (SAXS) can provide both statistical information about cross-section distributions²⁶ and segmental aggregation in dispersions.^{27,28} Additionally, rheological studies can address the mechanical response from the network subject to external deformation.²⁹ Still, there are no characterization techniques that have been able to provide a deeper insight into the nanoscale structures of the dynamic CNF networks, and especially the nanoscale transport properties within the network.

By *in situ* measurements of the diffusion of spherical gold nanoparticles (GNPs) us-

ing X-ray photon correlation spectroscopy (XPCS), we have probed the characteristics and nanoparticle transport properties of dilute nanofibrous (CNF) networks in liquid. In the first step of the developed methodology, we characterized the morphology of CNFs using AFM and SAXS to find average nanofiber lengths, cross-sections, degree of fibrillation and segmental aggregation. Thereafter, we characterized the diffusive motion and dimensions of GNPs in pure liquid and at different CNF concentrations using XPCS and SAXS. The data was analyzed to provide the mean diffusive time scales, showing that with increasing CNF concentration and GNP size, the dynamics become: (1) slower, (2) more non-uniform, and (3) increasingly subdiffusive.

The experimental data was parametrized as dynamic modes for the case of the largest GNP, which were fitted to simulated results from a digital twin of the experiments. This made it possible to extract the physical properties, such as pore sizes and pore connectivity. Apart from providing new insights into the CNF system used in this study, the presented methodology can be readily used to quantify general nanoparticle transport properties of nanofibrous networks in liquids for various applications, *e.g.* materials science or biomedicine.

Results

Morphological characterization of CNF samples

Dispersions of CNFs are extracted from paper pulp typically through mechanical high-pressure homogenization.⁶ Prior to homogenization, the material is usually oxidized (*e.g.* through carboxymethylation or TEMPO-mediated oxidation) to introduce charged groups, thus lowering the energy requirement for the CNF extraction due to electrostatic repulsion and allowing the CNFs to be stably dispersed in water. The individual morphologies of CNFs are strongly dependent on extraction methods, and specifically to the degree of oxidation applied to the material prior to homogenization.^{26,29} In this study, two aqueous TEMPO-

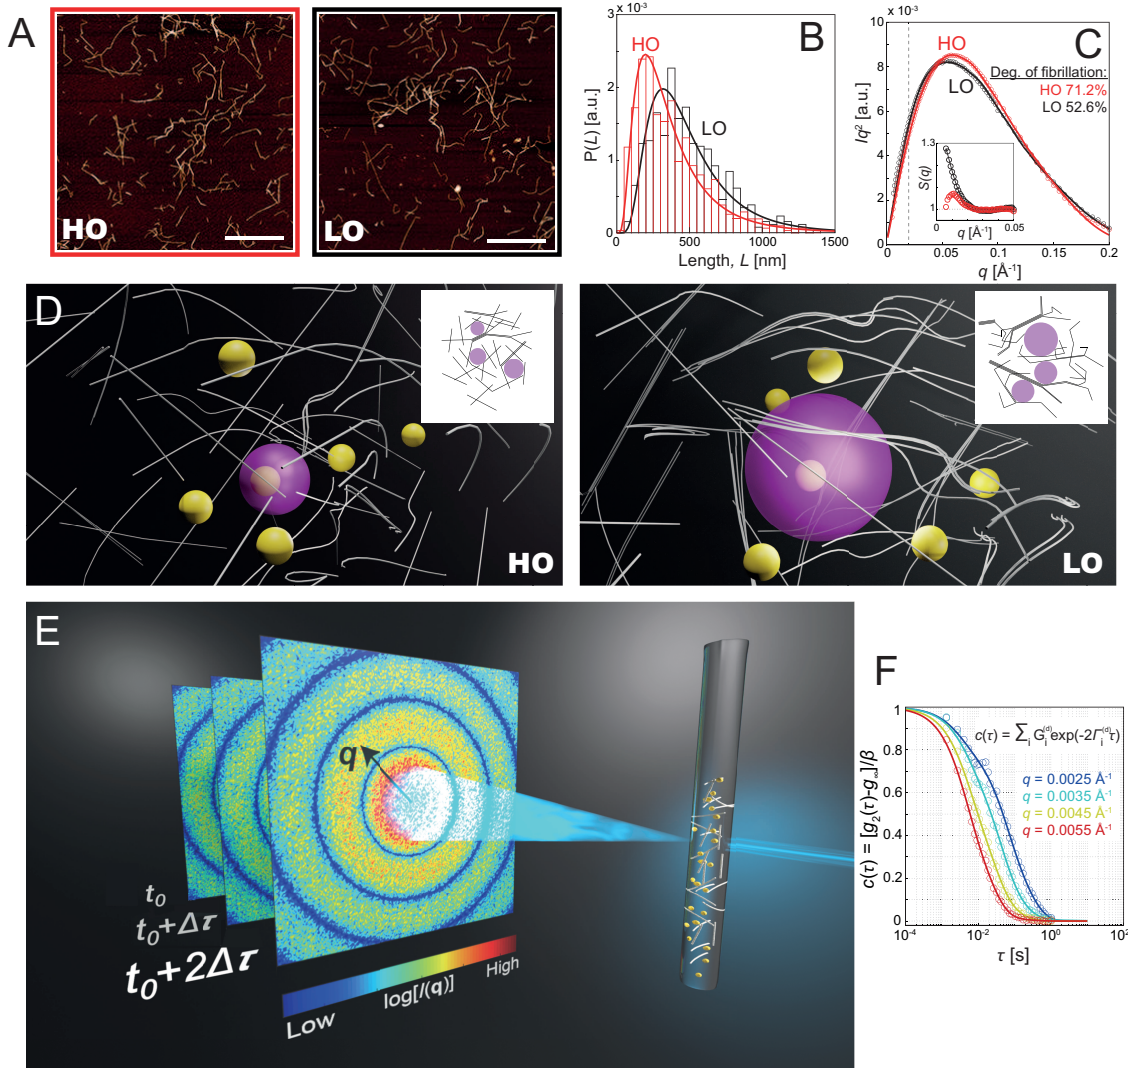

Figure 1: Illustration and characterization of the samples used in this study; two different dispersions of CNFs are used with high oxidation (HO) and low oxidation (LO); (A) AFM images of typical CNFs (scale bar $1 \mu\text{m}$); (B) length distribution of CNFs obtained from AFM images; (C) Lorentz-corrected SAXS data Iq^2 for CNFs at 0.3 wt%, where solid curves are fits of the cross-section form factor to determine the degree of fibrillation²⁶ and the dashed line shows the lower q -limit for this fit; the inset figure shows the structure factor $S(q)$ of the two dispersions at low q ; (D) three-dimensional renderings of the two CNF networks; the higher degree of fibrillation and less local entanglements (segmental aggregates) likely result in smaller pores in the HO network (typical pore size illustrated with purple semi-transparent sphere); (E) illustration of the XPCS experiment; an X-ray beam is focused on the sample containing a mixture of CNFs and gold nanoparticles (GNPs), where the scattering intensity $I(q, t)$ is recorded on a detector and will be dominated by GNPs; (F) representative correlation curves of $c(\tau) = g_1^2(\tau)/\beta$ at various q for a system with 200 nm GNPs in a HO CNF network at 0.24 wt%; the solid curves show the result from the CONTIN-algorithm.

oxidized CNF dispersions were prepared from wood pulp with two degrees of oxidation, which introduce different densities of charged COO^- groups on the CNF surfaces and the two dispersions are referred to as HO (high oxidation) and LO (low oxidation), respectively. Through a recently demonstrated solvent exchange process,²⁵ the CNFs are stably dispersed in propylene glycol (PG). Not only is this material interesting in terms of making novel bio-composites, but it has previously been shown that the solvent exchange does not affect the CNF morphology, but rather mainly causing a reduction of Brownian motion owing to the high viscosity of PG, which will be beneficial in order to capture the dynamics with XPCS.

Representative AFM images of the HO and LO CNFs are shown in Fig. 1A. Length distributions are determined in Fig. 1B, where it is found as expected that the higher oxidation treatment gives rise to shorter CNFs on average ($\bar{L} = 381$ nm for HO CNFs and $\bar{L} = 497$ nm for LO CNFs). Characterization of the dispersions at 0.3 wt% using SAXS (Fig. 1C) and fitting the Lorentz-corrected intensity curves Iq^2 with an assumption of quantized polydispersity²⁶ revealed that the HO CNFs also had a higher degree of fibrillation (71.2 % compared to 52.6 %). The inset figure in Fig. 1C shows the structure factor $S(q)$ in the two dispersions, where a value of $S(q) = 1$ would indicate no higher order structures, which is typical in dilute samples. The exponential shape of the LO CNF indicates strong segmental aggregation, *i.e.* locations where fibrils are locally entangled and thus in close proximity.^{27,28} The structure factor is fitted to determine the average diameter of the segmental aggregates²⁸ (solid curve in inset figure), which is found to be approximately 42 nm. The structure factor of the HO CNF instead shows a peak at $q \approx 0.01 \text{ \AA}^{-1}$ indicating that the stronger electrostatic repulsion causes nearby CNF segments to be separated at an average spacing of $d = 2\pi/q \approx 60$ nm, similar to values found in dispersions of cellulose nanocrystals.³⁰

The lower degree of fibrillation, longer fibrils and segmental aggregation suggest that the mass distribution inside the LO dispersion is more heterogeneous than the HO CNF, and that consequently pore sizes in the network will be larger for a given concentration (schematically

illustrated in Fig. 1D). Interestingly, despite these differences between the two dispersions, the rheology stays practically the same, which is shown in Fig. S1 in the supplementary information (SI). In this work, three different concentrations of CNFs are studied, which correspond to a transition from a dilute to a semi-dilute regime: 0.08, 0.16, and 0.24 wt%. More details of these initial characterizations of the CNF dispersions are provided in the Materials and Methods section.

The structure of the CNF network is probed indirectly through the motion of GNPs that are added to the dispersion. The GNPs themselves are sterically stabilized with a hydrophilic polymer coating to keep them stable in electrolytes regardless of pH (more details under Materials and Methods). This also ensures negligible electrostatic interactions with the CNFs, and that they can be passively transported through the network. The volume fraction of the GNPs is $\Phi \approx 0.0001$ and no aggregation is observed through the structure factor of the system, thus neglecting any influence of interactions between GNPs. Three different sizes of GNPs are used here: 50, 100, and 200 nm. Using the theory by Ogston^{31,32} for pore sizes in networks of randomly oriented rods (see Fig. S2 in SI), we find that the expected pore sizes at the present CNF concentrations are of the same order as the sizes of the GNPs. Thus, we expect to be able to study the effect on the GNP dynamics from an unconfined to a confined surrounding. Three-dimensional renderings of the approximate experimental conditions in the CNF/GNP dispersions are provided in a supplementary movie.

XPCS: experiments, analysis and validation

The CNF/GNP samples are mixed and injected in quartz capillaries, which are studied with XPCS at the CHX beamline (11-ID) at the National Synchrotron Light Source II (NSLS-II), Brookhaven National Laboratory, USA. The principle of XPCS is shown in Fig. 1E and described in detail in the Materials and Methods section. In brief, a coherent X-ray beam (with wavelength λ) is focused on the sample and the scattering intensity $I(q)$ is recorded on a detector at various $q = (4\pi/\lambda) \sin \theta$ (with scattering angle 2θ). Given the

much higher electron density of gold, the scattering intensity is completely dominated by the scattering from the GNPs. The interference maxima on the detector, the so called *speckles*, contain information about spatial correlations between particles in the sample at a length scale $2\pi/q$. By recording a sequence of speckle patterns with delay time τ , the average second-order autocorrelation of the speckle intensities over time $g_2(\tau)$ at a certain q can be extracted. Through the Siegert relation, the square first-order autocorrelation is obtained by $c(\tau) = g_1^2(\tau) = (g_2 - g_\infty)/\beta$, where g_∞ is the baseline and β is the speckle contrast.³³ As thermal fluctuations of particle positions give rise to decaying autocorrelations of speckle intensities, the decay of $c(\tau)$ thus captures the Brownian motion in the sample.

The square first-order autocorrelation $c(\tau)$ is assumed to consist of various exponential dynamic modes $c(\tau) = \sum_i G_i^{(d)} \exp(-2\Gamma_i^{(d)}\tau)$, where the discrete distribution $G_i^{(d)}$ of log-spaced relaxation rates $\Gamma_i^{(d)}$ is found through a regularized inverse Laplace transform using the CONTIN-algorithm^{34,35} (see Fig. 1F). The mean decay rate $\bar{\Gamma}$ is found through $\ln \bar{\Gamma} = \sum_i G_i^{(d)} \ln \Gamma_i^{(d)}$. Furthermore, a polydispersity index (*PDI*) is extracted from the relaxation rate distribution to describe the uniformity of dynamics using the method of cumulants³⁶ (see details in the Materials and Methods section). It was also noted that the data could be well fitted with a stretched exponential function, but there are no features in the data to suggest that the decay is truly non-exponential. More discussion and details of the various fitting techniques is found in Figs. S3 and S4 in SI.

The potential for radiation damage was carefully assessed and in the present systems it was found that radiation was starting to influence the dynamics at a dose equivalent to 5 s of exposure from the non-attenuated beam (see Fig. S5 in SI for details). In all the experiments in this work, we study 2 different attenuation levels for each sample: 0 % (full beam) and 81 % beam attenuation. As expected, no significant attenuation-dependent trends were found in the data since the total full-beam exposure never exceeded 1.4 s. Every measurement is repeated twice at a different spatial location in the sample, and we ensure that the sample is in thermal equilibrium with spatially homogeneous dynamics (see Materials and Methods

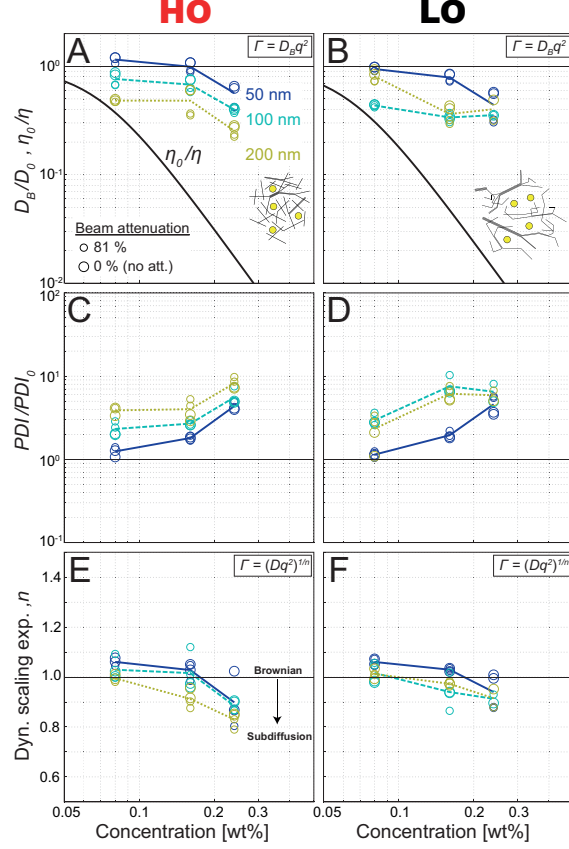

Figure 2: Mean results from the XPCS analysis for the three sizes of GNPs; (A) and (B) show the Brownian diffusion coefficient D_B of GNPs in HO and LO CNF, respectively, at various nanofiber concentrations compared to free diffusion in the solvent (propylene glycol) D_0 assuming $\Gamma = D_B q^2$; the solid black curve shows the zero-shear viscosity of the CNF suspension η compared to the viscosity η_0 of the solvent; (C) and (D) shows the polydispersity index PDI as function of concentration compared to PDI_0 of free diffusion; (E) and (F) shows the dynamic scaling exponent n assuming $\Gamma = (Dq^2)^{1/n}$, where a value of $n < 1$ indicates subdiffusive dynamics. The symbol sizes correspond to the two attenuation levels used in the study.

section for details). Furthermore, any direction-dependent dynamics arising from potential gravity-induced sedimentation were examined and determined to be negligible (see Fig S6 in SI).

When GNPs of uniform sizes are moving freely in the solvent without CNFs, $c(\tau)$ is expected to decay exponentially (low PDI) with $\bar{\Gamma} = D_0 q^2$ (D_0 is the Brownian diffusion constant in free solvent), which was analyzed in initial experiments for the three GNP sizes. The results in Figs. S7 and S8 in SI illustrate that there is some inherent non-uniformity

of dynamics in the GNP systems owing to a spread of actual geometric sizes (found with SAXS). Also interesting to note is that the polymer coating (with thickness $\lesssim 5$ nm) gives rise to discrepancies between geometric and dynamic radii. This effect is naturally larger for the smallest (50 nm) GNPs, where the mean geometric diameter is 39.9 nm and mean hydrodynamic diameter is 57.5 nm. This discrepancy does not play any major role to the study, where we investigate the *relative* effect of the dynamics compared to free diffusion in the solvent, *i.e.* the geometric diameter will stay the same but the hydrodynamic diameter will naturally change.

Mean dynamics of GNPs in CNF dispersions

Adding CNFs to the system and assuming a dispersion of straight rigid nanorods, previous theoretical works^{37–39} suggest that the GNP motion is not hindered if the characteristic pore size (*mesh size*) of the network is much larger than the GNPs, *i.e.* they will have mean diffusion constants being the same as in free diffusion $D_B = D_0$. At higher concentrations, when the mesh size is much smaller than the particle, the motion is determined by the momentum transfer within the network, which on the macroscopic scale is interpreted as an effective zero-shear viscosity η higher than the solvent viscosity η_0 . Consequently, the scaling of D_B/D_0 should approach the scaling of η_0/η . In Fig. 2A, we find that the expected behavior seems to be captured fairly well in the HO CNF dispersion. Most striking is the diffusion of 50 nm GNPs with dynamics similar to free diffusion ($D_B = D_0$) below a concentration of 0.2 wt% and then possibly approaching the scaling of η . Similar trends are seen also for the 100 and 200 nm GNPs, where of course the threshold concentration is lower with larger GNPs. Although the 50 nm GNPs show similar behavior in the LO CNF (see Fig. 2B), the larger GNPs are not as affected by CNF concentration between 0.16 and 0.24 wt%.

The mean diffusion constant however does not fully reflect the dynamic behavior in the systems. The increasing CNF concentration also results in less uniform GNP dynamics, reflected by higher values of PDI compared to the PDI_0 in free diffusion (see Fig. 2C-D).

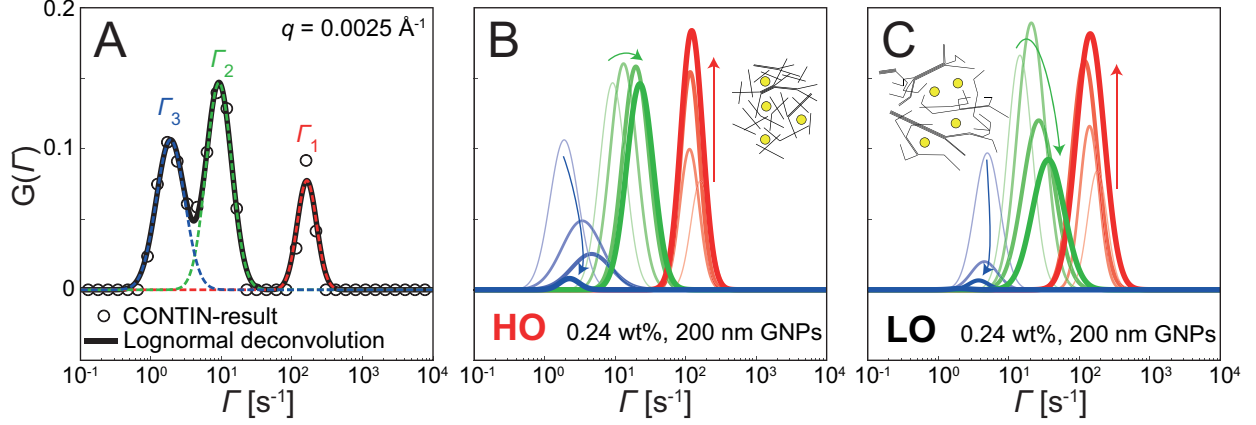

Figure 3: Illustration of the extraction of dynamic modes using a lognormal deconvolution; (A) the resulting discrete distribution $G_i^{(d)}$ of relaxation rates $\Gamma_i^{(d)}$ at $q = 0.0025 \text{ \AA}^{-1}$ as circles and the solid black line shows the continuous distribution $G(\Gamma)$ obtained by fitting three lognormal curves with mean values Γ_1 , Γ_2 and Γ_3 and magnitudes G_1 , G_2 and G_3 ; (B) and (C) shows the evolution of the three dynamic modes for 200 nm GNPs with increasing q (illustrated with arrows) for the HO and LO CNF networks, respectively, at 0.24 wt%.

The semi-dilute CNF network thus seems to slow down the GNP motion unevenly, with both faster and slower moving particles in the system.

An even stronger indication that the dynamics is more complicated is found when studying the q -dependence of the relaxation rate $\bar{\Gamma}$ in Fig. 2E-F. In a system with normal Brownian motion, the mean square displacement (MSD) of particles is known to be linear in time, with the diffusion constant being the proportionality constant ($MSD \propto D_B \tau$) with unit m²/s. However, in a confined system, the dynamics can become *subdiffusive* with $MSD \propto D\tau^n$, where $n < 1$ and the proportionality constant gets the unit m²/s ^{n} .⁴⁰ To ensure this dimension of D , the relaxation rate is assumed the form $\Gamma = (Dq^2)^{1/n}$ and it is found in Fig. 2E-F that the GNP dynamics are indeed subdiffusive in both CNF networks. Consequently, it can be argued that the comparison of D_B in Fig. 2A-B is not suitable, as these comparisons are based in an assumption of $n = 1$. Furthermore, the values of D are not comparable as their unit depends on the specific value of n . For this reason, we will now investigate the origin of this apparent subdiffusivity by studying more detailed features of the dynamic spectra and compare with a numerical simulation of the system.

Dynamic modes in the subdiffusive systems

Although various studies have been presented recently to analyze anomalous diffusion with XPCS,^{41–43} a different approach is employed here, similar to the method by Andrews *et al.*³⁵. Since Fig. 2 displays clear trends of slower, more polydisperse and subdiffusive dynamics with increasing CNF concentration and GNP size, we focus our attention to the system of large (200 nm) GNPs at high CNF concentration.

Fig. 3A shows the resulting distribution $G_i^{(d)}$ of relaxation rates $\Gamma_i^{(d)}$ from the dynamics of 200 nm GNPs in HO CNF at 0.24 wt%, where we can distinguish three individual peaks. Through a lognormal deconvolution, the discrete spectra is converted to a continuous function using three modes with mean relaxation rates Γ_{1-3} and magnitudes G_{1-3} as seen in Fig. 3B. The evolution of these dynamic modes can then be studied individually with respect to q as done in Fig. 3B-C for HO and LO CNF at 0.24 wt%, respectively. Interestingly, the individual relaxation rates Γ_{1-3} do not monotonically increase with q . Instead, for both CNF samples, there is a clear switching of which modes are relevant at a given q -range, where the slower mode (Γ_3) contributes more to dynamics at low q , while the faster mode (Γ_1) contributes more at high q . The main difference between the two samples is that the contributions of the slow and intermediate modes (Γ_3 and Γ_2) are much lower at higher q .

In Fig. 4, the switching of dynamic modes is illustrated in more detail. The figure shows the relaxation rates as function of q , where the line width of the three modes Γ_{1-3} is scaled with their individual magnitude G_{1-3} . The mean relaxation rate $\bar{\Gamma}(q)$ and the reference of freely diffusing GNPs $\Gamma_{\text{ref}}(q)$ are plotted with thick black dashed and solid lines, respectively. The thin dashed and dotted lines correspond to the expected scaling for Brownian dynamics ($n = 1$ and $\Gamma \propto q^2$) and ballistic dynamics ($n = 2$ and $\Gamma \propto q$), respectively. There are some interesting similarities and differences to highlight with respect to CNF concentration in the two systems. At some low threshold concentration, there is a transition from single-mode dynamics similar to the free diffusion ($\bar{\Gamma} \approx \Gamma_{\text{ref}}$) to dynamics governed by two modes: (1) one faster mode Γ_1 that is basically constant with q but only dominating at high q and (2)

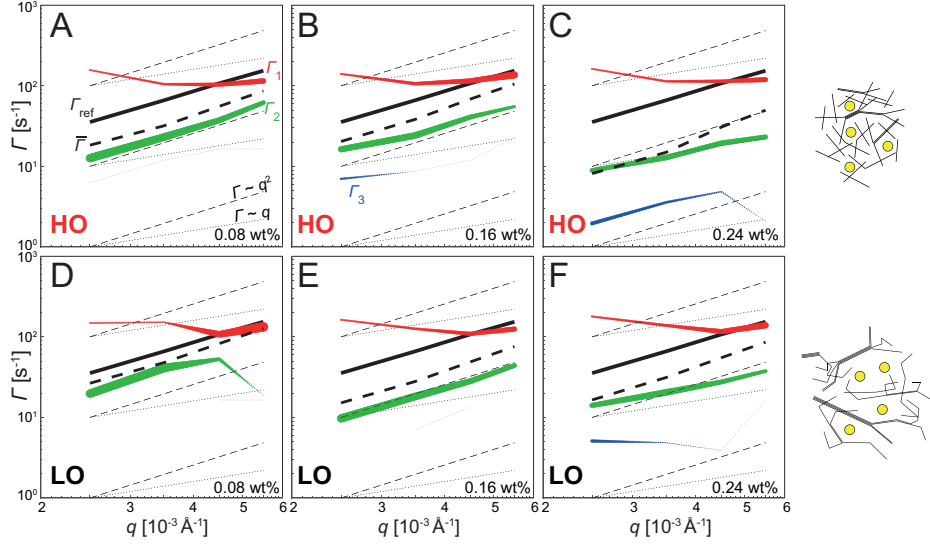

Figure 4: Evolution of the relaxation rates of the dynamic modes Γ_1 , Γ_2 and Γ_3 as function of q for the 200 nm GNPs; the line width is scaled with the magnitude of the mode G_1 , G_2 or G_3 , with linear interpolation between the q -values (note that $G_1 + G_2 + G_3 = 1$ at any given q); the thin dashed and dotted lines indicate expected scaling behavior for Brownian ($\Gamma \propto q^2$) and ballistic ($\Gamma \propto q$) dynamics, respectively; the thick black solid and dashed lines show the free diffusion of GNPs (Γ_{ref}) and mean relaxation rate ($\bar{\Gamma}$), respectively; (A)-(C) show the dynamic behavior in HO CNF with increasing concentration (0.08, 0.16 and 0.24 wt%), while (D)-(F) show the behavior in LO CNF at the same concentrations.

one slower mode Γ_2 that still remains Brownian ($n = 1$), but with slower rates than the reference and dominating at lower q . The main difference between the two CNFs is that the splitting of modes occurs at higher concentration in the LO CNF within the given q -range. In Fig. 4D, for LO CNF at a concentration of 0.08 wt%, the splitting of modes is clearly visible at around $q = 0.0045 \text{ \AA}^{-1}$, which corresponds to length scales of around 140 nm. In Fig. 4A on the other hand, for HO CNF at the same concentration, this mode-splitting seems to occur at higher q values, but it is likely that there exist a lower concentration where the mode-splitting is at a similar q -value as for the LO CNF.

At higher concentrations, the faster constant mode Γ_1 remains at the same level as for the lower concentrations, while the slower Brownian mode Γ_2 decreases. However, at some concentration between 0.16 and 0.24 wt%, it stagnates and turns towards a more ballistic behavior with $n \approx 2$ ($\Gamma \propto q$). At this stage, a new even slower Brownian mode appears at low q (Γ_3). Interestingly, even though none of the contributing modes is associated with subdiffusive dynamics ($n < 1$), the mean rate $\bar{\Gamma}$ is slightly subdiffusive, which is also the reason for the results presented earlier in Fig. 2. *The overall subdiffusive behavior is thus the result of superdiffusive modes contributing differently at different q .*

Additionally, since the trends with increasing concentration are similar for the two CNF networks, it is clear that the LO dispersion is going through the same stages as the HO dispersion, but generally at higher concentrations. This is of course in line with our assumption that the mass distribution of CNFs in the LO dispersion is more heterogenous and thus has a more open pore space.

Although the methodology provides detailed trends of the dynamic modes in reciprocal space, it is more complicated to relate these trends to actual physical properties of the CNF network. Instead of relying on theoretical models based on idealized systems to describe the trends, we use a concept of a *digital twin*, *i.e.* a numerical simulation of the system, where the same observable quantities are extracted and matched to the experiment. The same approach was recently used to study dynamics of flowing CNFs *in situ* using SAXS⁴⁴ and

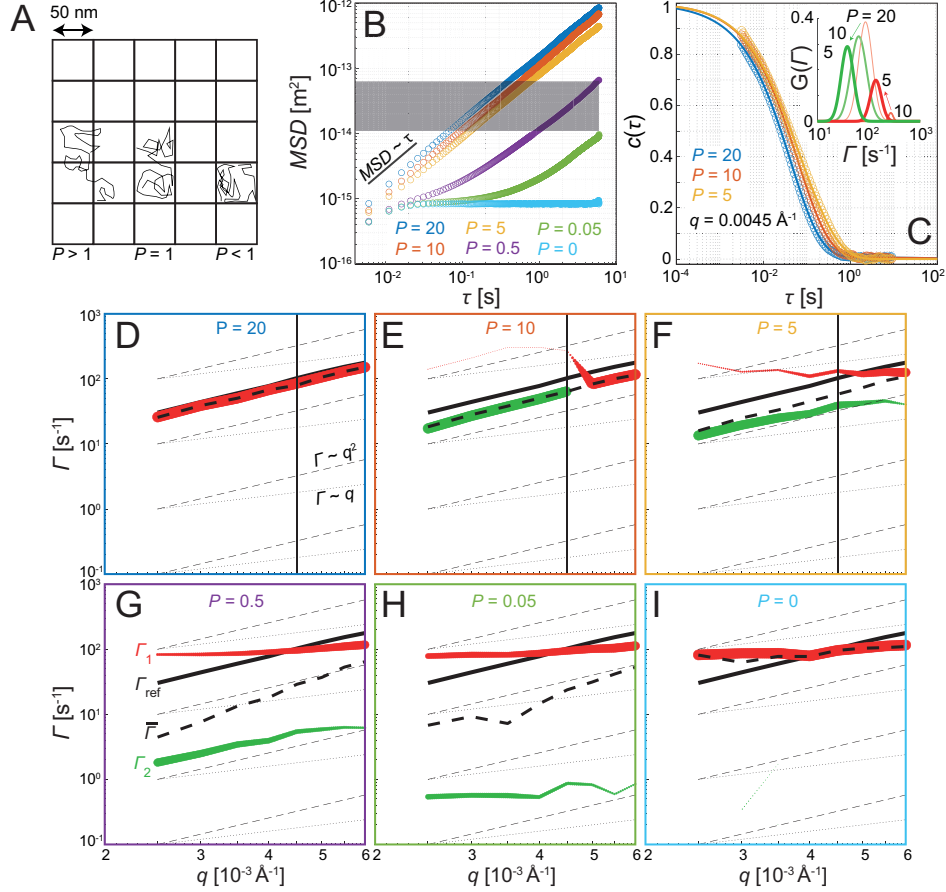

Figure 5: Results from the digital twin of confined Brownian motion of 200 nm spherical nanoparticles (NP) in propylene glycol (at room temperature); (A) the simulation domain is divided into cells of size 50 nm, within which the midpoint of the NP can move freely (effective pore size is thus 250 nm); the probability for an NP to cross to another cell is determined by the permeability P , where $P \rightarrow \infty$ leads to free diffusion while $P = 0$ leads to the NP being trapped inside the cell; (B) mean square displacement (MSD) as function of delay time τ and permeability P , where Brownian dynamics would lead to $MSD \propto \tau$; the shaded region shows the approximate length scales of the XPCS-experiment, *i.e.* between $(2\pi/q_{\text{max}})^2$ and $(2\pi/q_{\text{min}})^2$; (C) shows the square first order autocorrelation curves $c(\tau)$ at $q = 0.0045 \text{ \AA}^{-1}$ at three levels of P with solid curves being the fitting result; the inset figure shows the corresponding dynamic modes after the lognormal deconvolution; (D)-(I) show the evolution of the relaxation rates $\Gamma_1(q)$ and $\Gamma_2(q)$ with increasing permeability P illustrated in the same way as in Fig. 4; the black line in (D)-(F) shows the q -value used for the data in (C).

to study cross-sections of CNFs²⁶ with SAXS/WAXS.

Development of a digital twin

Subdiffusive motion of NPs in various semi-flexible networks has been demonstrated previously through numerical simulations, indicating that it is a natural consequence of the confined motion inside the network.^{40,45,46} However, it is not clear from these models what such behavior would look like in an XPCS experiment, where the dynamics are analyzed in reciprocal space rather than real space. Therefore, in order to investigate our experimental system, we set up numerical simulations of confined Brownian spherical nanoparticles (NPs) of 200 nm, where their individual positions are used to simulate speckle patterns through a Fourier transform, which in turn can be analyzed in the same way as in the experiment. The model is practically a 2D version of the simulation method presented by Ernst *et al.*⁴⁵, where NPs are moving within a square grid providing equally sized cells, which are here chosen to have side 50 nm (see Fig. 5A). Note that the cell size in the model is significantly smaller than the NP size, but since it is the midpoint that is restricted by the cell boundaries, the true pore size is actually 250 nm (the 200 nm NP can move undisturbed ± 25 nm from the middle of the cell). When a Brownian step causes the midpoint of the NP to cross the cell boundary, there is a probability of passing determined by a permeability P (unit $\text{s}^{-1/2}$, see Materials and Methods section for details). If the NP is not allowed to pass, it is simply bouncing off the boundary and remaining inside the cell. Thus, if $P \rightarrow \infty$, the NP is freely diffusing without any effect of the cell boundaries, but if $P \rightarrow 0$, the NP is contained within the cell where it started. Fig. 5B shows the MSD versus delay time τ of this system, where $P \geq 5$ demonstrates Brownian dynamics with $MSD \propto \tau$ ($n = 1$). As the NP motion gets more and more constrained by the cell boundaries around $P = 1$, the system still remains almost unaffected at small τ , but is clearly subdiffusive at intermediate τ when the particle has a "jumping" motion from one cell to another.^{45,46} When $P = 0$, the value of MSD is naturally limited by the size of the cell and remains constant for all larger τ .

In reciprocal space, at $q = 0.0045 \text{ \AA}^{-1}$, after performing the same dynamic mode analysis, we find very similar behavior as in the experiment (see Fig. 5C). The dynamic behavior at

$P = 20$ clearly is described by one single dynamic mode, with a faster mode appearing as the permeability decreases. The entire evolution of the splitting of modes with decreasing permeability is illustrated in Figs. 5D-I, which looks almost identical to the trends found in the experimental data. From being almost indistinguishable from free diffusion at $P = 20$, the dynamic behavior is described with two separate modes at lower P , where the faster mode remains stationary both with q and with decreasing P . The slower mode quickly slows down further with lower permeability, and with lower and lower contribution at higher q . Just like in the experiments, although both modes are superdiffusive with $n > 1$, the mean relaxation rate still shows a subdiffusive behavior (thick dashed line). Eventually, as the contribution of the slower mode diminishes, the dynamic behavior at $P = 0$, where NPs are completely contained inside the cell, is dominated by the fast stationary mode. The two modes can thus be explained by the two types of NP dynamics at different length scales using this simplified model: (fast) inter-cell dynamics and (slow) macroscopic "jumping" dynamics between cells.

Discussion

How can the above observation be connected to the network properties of the two CNF dispersions in the experiment and what do the simulated cell size and permeability correspond to for the real network structure? The GNPs undergo Brownian motion that is determined mainly by the interaction with solvent molecules. Individual CNFs are also highly Brownian with much faster dynamics than the GNPs, which can be interpreted on a nanometer scale as a solvent with seemingly higher apparent viscosity, thus slowing down the motion of the GNPs. At a higher CNF concentration, when the average pore becomes smaller than the GNP size, a loose cage of CNFs is also formed around the individual GNPs. The cage is naturally slightly larger than the GNP and provides some restriction to its motion. However, the GNP can escape its local cage as the surrounding dynamic CNF network will constantly undergo structural changes causing escape routes for the GNP. This probability of the GNP

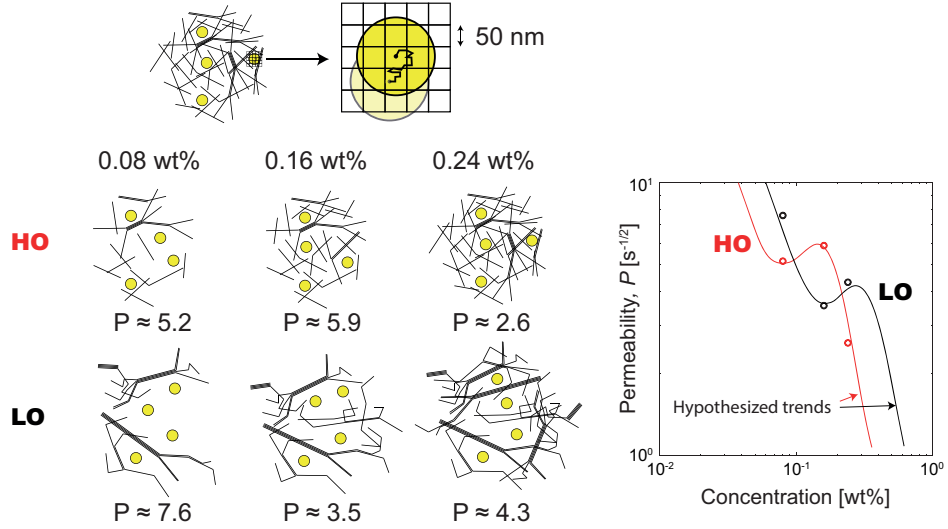

Figure 6: Schematic illustration of the dynamics of 200 nm GNPs in the two CNF dispersions during network formation with increasing concentration, quantified by permeability P by matching dynamic features to the digital twin; at dilute conditions, the GNPs are moving freely within the solvent and are unaffected by the fast Brownian CNFs; as concentration reaches a level where the average pore sizes are smaller than the GNPs, a local cage structure of nanofibers will restrict the GNP motion, but it has some probability of moving due to structural changes of the dynamic network; the local structure and dynamics would be the source of the apparent permeability P and unrestricted wiggle-room of ± 25 nm; the combination of less dynamic reconfiguration, and smaller pore sizes at higher concentrations gives rise to a plateau of the permeability.

escaping its local cage could thus be perceived as the source of the permeability in the model. With an increasing CNF concentration, the cage will become stronger and GNPs will remain essentially stationary, which corresponds to the case of zero permeability.

The main permeability-dependent feature of the dynamic modes in Fig. 5, is the decrease of the second mode Γ_2 with decreasing P , which also seems to correspond to the effect observed in the experimental system. By matching the mean rate of Γ_2 between the experiment and the digital twin, we can obtain quantitative values of P in the experimental system as illustrated in Fig. 6 (see details in Fig. S10 in SI). At low concentrations the permeability is higher in the LO CNF compared to HO CNF at a given concentration, which makes sense owing to the heterogeneous mass distribution and therefore less direct interactions for the GNPs with the CNFs. Interestingly, both for the HO CNF and LO CNF, we observe a slight increase of permeability values in a certain concentration range. We hypothesize that this is linked to the actual network formation, where the Brownian dynamics of CNFs slow down rapidly, thus decreasing the CNF-GNP interactions despite the smaller pore sizes. When the network is formed, the permeability P again decreases rapidly with concentration. Somewhat counter-intuitive, this plateau of P occurs at higher concentrations for LO CNF suggesting that the heterogeneity of the dispersion causes network formation at a higher volume fraction despite the larger CNF aspect ratios. At high concentrations, the LO CNF will again have higher permeability than the HO CNF owing to the larger physical pore sizes in the network.

It is natural to assume that the model cell size (or rather wiggle-room) should also be linked to CNF concentration. However, doing the same analysis for both larger (75 nm) and smaller (25 nm) model cell sizes reveals a different scenario for the splitting of modes (see Fig. S9 in SI for details), which indicates that both CNFs in our study indeed create a local surrounding of the 200 nm GNP with an unrestricted wiggle-room of ≈ 50 nm. We hypothesize that this apparent wiggle-room might rather be influenced by the flexibility of individual CNFs. The flexibility might also be influencing the magnitude of the stationary

mode (Γ_1). In a recent similar XPCS study by Reiser *et al.*⁴², the dynamics of spherical NPs in networks of wormlike micelles also revealed a stationary mode, which was argued to be related to the Kuhn length of the individual micelle. This could naturally not be investigated in this work as the cell boundaries are fixed.

Although revealing much of the relevant dynamics in the experiment, there are some features that the reduced model cannot capture. For example, the emergence of a third dynamic mode (Γ_3), which suggests the real system also includes dynamics on a higher hierarchical level. Obviously, the "network" in the reduced model is static, while the network of CNFs is dynamic, and it is therefore intuitive to assume that there should be an additional dynamic mode connected to the network dynamics, although this requires further investigation.

Conclusions

This work addressed the dynamics of sterically stabilized spherical gold nanoparticles (GNPs) in semi-dilute dispersions of cellulose nanofibers (CNFs) using X-ray photon correlation spectroscopy (XPCS). CNFs were prepared at two different degrees of oxidation, which provided differences in the CNF length distribution as well as the degree of fibrillation, which in turn had a clear effect on the pore spaces in the network at a given concentration. From the smallest GNPs (50 nm), it is found that their dynamics are unaffected by CNFs up until a concentration of ≈ 0.2 wt% in both systems, suggesting that the undisturbed pore sizes in the semi-dilute networks were of the similar order. However, the dynamics of the larger GNPs (200 nm) could be described by several dynamic modes, which through a comparison with a digital twin were found to be connected to the GNPs' ability to escape their local surrounding of CNFs. This in turn could be used to quantify the effective permeability of the GNPs in the dynamic semi-dilute CNF network and to characterize threshold concentrations for network formation.

The fact that the relatively simple model of confined Brownian motion was able to capture

the main dynamic modes from the demonstrated experiment in this study opens up vast possibilities for exploring nanofibrous networks by characterizing the dynamics of tracer NPs using XPCS. The obvious next step would be to study a wider q -range with the digital twin and carry out a proper parameter study of both pore size and permeability to pinpoint how these parameters can affect the measurable quantities. This in turn can aid in designing new improved experiments. As a future outlook, the digital twin can be improved using coarse-grained molecular dynamics simulations of a realistic nanofibrous network to directly connect the dynamic modes to CNF properties and interactions, possibly also capturing features that cannot be measured experimentally. This could potentially also be used as training data for machine learning, allowing physical properties to be directly obtained from the experimental data.

Finally, we would like to emphasize that the methodology is not limited to our experimental system but can be used more generally to other nanofibrous networks, *e.g.* from polymeric, ceramic or carbon fiber networks. Technically, the same methodology could also be applied to systems without a bounding solvent, *e.g.* transport in membranes or aerogels, although it might be more challenging/hazardous experimentally to study the unbounded NP transport through these networks.

Materials and Methods

Samples

The spherical gold nanoparticles (GNPs; diameters of 50 nm, 100 nm and 200 nm) dispersed in propylene glycol were purchased from NanopartzTM and were functionalized with a proprietary hydrophilic polymer with a MW 1500 Da (product name H11-PHIL-PRG). The dispersion was characterized by the vendor using both transmission electron microscopy (TEM) and dynamic light scattering (DLS) ensuring the quality and uniformity of the GNPs. Analysis in the present work using SAXS further confirmed high uniformity of the GNP sizes

(see Figs. S7 in SI for details).

Never dried sulfite softwood pulp (Domsjö dissolving pulp) was provided by RISE Research Institute of Sweden and was used for preparation of cellulose nanofibers (CNFs). Sodium hypochlorite (6-12 wt%, Alfa Aesar), TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy free radical, $\geq 98\%$, Alfa Aesar), sodium hydroxide ($\geq 99.2\%$, VWR Chemicals), sodium bromide (BioUltra, $\geq 99.5\%$, Sigma Aldrich), concentrated hydrochloric acid (VWR Chemicals, $\geq 35\%$) were used as received. The TEMPO-mediated oxidation was performed on never dried sulfite softwood pulp (41.6 wt%) following the protocol described elsewhere,⁴⁷ where two degrees of oxidation were achieved by adding 3 and 1.5 mmol of oxidant per gram of pulp for high oxidation (HO) and low oxidation (LO) CNFs, respectively. To extract CNFs, treated pulp was fibrillated by a high pressure (1600 bars) Microfluidizer (M-110EH, Microfluidics) with a 400/200 μm (1 pass) and a 200/100 μm (4 passes) wide chambers connected in series. The obtained 1 wt% CNF gel was further diluted to 0.3 wt% and homogenized by Ultra-Turrax dispersing tool (IKA, Sweden) for 10 min at 10000 rpm. Conductometric titration was performed to estimate the total CNF charge according to protocols described elsewhere⁴⁸ and average charge densities of carboxylic (COO^-) groups were estimated to be 448 ± 16 and 1023 ± 26 $\mu\text{mol/g}$ for the LO and HO CNF, respectively. The solvent exchange process to propylene glycol (PG) followed the same procedure as described elsewhere,²⁵ and the resulting PG-CNF dispersions were used to create dilutions of 0.1, 0.2 and 0.3 wt%. The final CNF concentrations 0.08, 0.16 and 0.24 wt% are reached after mixing with the GNP dispersions.

The mixing of GNPs into the CNF dispersions resulted in a final GNP concentration of 0.2 wt%, which is comparable to the weight fraction of CNFs. However, since the volume of a single GNP is much larger than a CNF, the number density in the network is still quite low (see examples of 3D rendered networks in the supplementary movie), and thus not affecting the overall structure of the network. The samples were mixed and dispersed through vortex-mixing (VWR Fixed-Speed Mini) and remain static for 24 hours before the experiment.

Before the actual XPCS measurements, the samples were re-dispersed by vortex-mixing (ORIGINAL Vortex-Genie 2) and then put into an ultrasonic bath for 5 minutes to prevent precipitation of nanoparticles. The samples were then injected to thin-walled quartz capillary tubes for the XPCS experiments with an approximate time of 1-2 h between injection and measurement.

Atomic Force Microscopy (AFM)

Topography of particles was visualized with the help of an Atomic Force Microscope (AFM, Multimode 8, Bruker, USA) in Tapping mode in air. The original dispersion of CNFs (0.3 wt% in DI water or PG) was diluted to 0.005 wt% and homogenized for 10 min at 10000 rpm using Ultra Turrax (IKA T25D, Sweden). Remaining aggregates were removed by centrifugation for 1 hour at 4000 rpm. Supernatant was collected and mixed on Vortex Genie 2 (Scientific Industries Inc., USA) for 5 min right prior casting. A 20 μ L drop of (3-aminopropyl)triethoxysilane (99%, Sigma Aldrich) was placed and kept on a freshly cleaved mica for 30 s, whereafter it was blown away intensively by nitrogen gas. A 20 μ L drop of CNF dispersion (0.005 wt%) was placed rapidly on functionalized mica and kept for 30 s until being blown away by nitrogen gas in a similar manner. Obtained substrates were left to dry overnight. Diameters and lengths of CNFs were estimated from height images using software Nanoscope Analysis and ImageJ, acquiring above 300 and 500 measurements, respectively. With the help of software Origin 2021 statistical analysis was performed on collected values and by fitting a Gaussian distribution function it was estimated that average diameters (d_{av}) for high and low charge CNF were 2.73 ± 0.63 and 2.56 ± 0.51 nm, respectively. Both CNF types demonstrated a broad distribution of lengths varying from 50 nm to 1.6 μ m. By fitting a lognormal distribution, the mean lengths \bar{L} were determined.

Small-angle X-ray scattering (SAXS)

The SAXS experiments were performed at the LIX beamline (16-ID) at the National Synchrotron Light Source II (NSLS-II), Brookhaven National Laboratory, USA. The CNF samples (without GNPs) are injected into liquid sample holders with mica windows, which are scanned at five different positions with 1 s exposure at each position, where a mean was used for analysis. The wavelength was $\lambda = 0.82 \text{ \AA}$ and the sample-detector distance was 3.7 m. The beam size was approximately $50 \times 50 \text{ }\mu\text{m}^2$. The scattered X-ray intensity $I(q)$ was recorded on a Pilatus 1 M detector with pixel size $172 \times 172 \text{ }\mu\text{m}^2$ at a range of $q = 0.006 - 0.2 \text{ \AA}^{-1}$, with scattering vector magnitude $q = (4\pi/\lambda) \sin \theta$ (the angle between incident and scattered light is 2θ). The background scattering intensity was subtracted using scans of DI water. The degree of fibrillation of the CNFs is determined with the fitting method by Rosén *et al.*²⁶ applied to the Lorentz-corrected SAXS data Iq^2 between 0.02 and 0.2 \AA^{-1} , resulting in the form factor of the system $P(q)$. The structure factor is found through $S(q) = I(q)/P(q)$, where the radius of segmental aggregates R can be found by fitting $S(q) = A \exp[-(0.396R)^2 q^2] + 1$ between 0.005 and 0.05 \AA^{-1} according to previous work.²⁸

Rheology

Steady shear viscosity measurements were performed on Rheometer DHR-2 (TA Instruments, USA) using plate-on-plate geometry (diameter 25 mm) with the gap set to 1 mm. Prior to the measurements, the CNF dispersions were degassed by vacuum to remove air bubbles and left to rest at normal conditions for at least overnight. The experiment consisted of two steps: sample conditioning at $25 \text{ }^\circ\text{C}$ for 5 min and flow sweep test with shear rate varying between 0.1 and 100 s^{-1} . Data was acquired in a logarithmic manner collecting 10 points per decade with equilibration time set to 5 s and averaging time reaching 30 s.

The approximate zero-shear viscosity η of the CNF dispersions was obtained by fitting the experimental curves. More details about the rheological characterization is provided in

Fig. S1 in SI.

X-ray photon correlation spectroscopy (XPCS)

The XPCS experiments were performed at the CHX beamline (11-ID) at NSLS-II, BNL. An X-ray beam with size $40 \times 40 \mu\text{m}^2$ and wavelength $\lambda = 1.28 \text{ \AA}$ was focused on the sample and the scattered X-rays were collected on a detector (Dectris 3-Eiger X, pixel size $75 \times 75 \mu\text{m}^2$) at a sample-detector distance of 16 m covering $q = 0.002 - 0.04 \text{ \AA}^{-1}$. Each sample was scanned with 1000 images at three different exposure times (1.3, 10 and 100 ms; also setting the frame rate) and four attenuation levels (0, 81, 96.4 and 99.3 %). Each scan was repeated twice, yielding a total of 24 measurements per sample, which all were taken at different positions in the capillary. It was however found that only the data with the lowest exposure time of 1.3 ms (frame rate 750 Hz) could be used for analysis and the scattering intensity using the highest attenuation levels (96.4 and 99.3 %) was too low to be used for standard XPCS analysis. An assessment of the influence of the beam on the sample dynamics revealed that the samples were affected with a total dose equivalent to 5 s of exposure to the non-attenuated beam (see Fig. S5 in SI for details), which is approximately four times higher than the maximum dose in any experiment used for analysis. The auto-correlation $g_2(q, \tau)$ at a certain delay time τ of the intensity at a certain pixel $I(q, t)$ is determined both through the one-time correlation function (1T) obtained through a multi-tau algorithm⁴⁹:

$$g_2^{(1T)}(q, \tau) = \frac{\langle I(q, t)I(q, t + \tau) \rangle}{\langle I(q, t) \rangle^2} \quad (1)$$

or through the mean over all $\tau = |t_2 - t_1|$ of the two-time correlation function (2T):⁵⁰

$$g_2^{(2T)}(q, \tau) = \left\langle \frac{\langle I(q, t_1)I(q, t_2) \rangle}{\langle I(q, t_1) \rangle \langle I(q, t_2) \rangle} \right\rangle_{\tau=|t_2-t_1|}. \quad (2)$$

The average correlations were determined in circular regions on the detector with centers $q = 0.0025, 0.0035, 0.0045$ and 0.0055 \AA^{-1} , where each region had a width of $\Delta q = 0.001 \text{ \AA}^{-1}$. Ideally, the two definitions above should provide the same results, but it was found that they differ for low scattering samples because of spurious parasitic scattering. Here, a data set was discarded due to low scattering intensity if the average relative difference (*ARD*) between $g_2^{(1T)}$ and $g_2^{(2T)}$ was larger than 1 %. Otherwise, a mean of the two was used as the true auto-correlation $g_2(q, \tau)$. To ensure spatial homogeneity of the samples, the repeated scans (at different positions) were used to determine the mean $g_2(q, \tau)$. However, if one repeated experiment showed significantly higher correlations than its counterpart ($ARD > 0.5 \%$), it was considered an outlier and removed from the analysis. The final square first order auto-correlation used for analysis $c(q, \tau) = g_1^2(q, \tau) = (g_2(q, \tau) - g_\infty)/\beta$ is found by subtracting the baseline $g_\infty = g_2(q, \tau > 5 \text{ s})$ and scaling with the speckle contrast β ($\beta = \beta^* + 1 - g_\infty$, where β^* is found through initial calibration with a test membrane). The time-dependence of the dynamics over the course of each experiment was also assessed with the two-time correlation function to exclude any heterogeneous dynamics or other time-dependent phenomena.

XPCS analysis

Each resulting correlation curve $c(\tau)$ at a certain q was assumed a form of:

$$c(\tau) = \sum_i G_i^{(d)} \exp(-2\Gamma_i^{(d)}\tau), \quad (3)$$

where the discrete distribution $G_i^{(d)}$ is found through a regularized inverse Laplace transform using the CONTIN-algorithm implemented in MATLAB 2020b and adapted from the code by Marino⁵¹. Here, we assumed 50 log-spaced modes in range $\Gamma_i^{(d)} \in [75, 750000] \text{ s}^{-1}$ with constraints $G_i^{(d)} \geq 0 \quad \forall i$, $G_i^{(d)} \rightarrow 0$ at the extreme values of $\Gamma_i^{(d)}$ and that $\sum_i G_i^{(d)} = 1$,

i.e. that $c(\tau \rightarrow 0) = 1$. The CONTIN-algorithm requires a regularization parameter for additional smoothing of the distribution,^{34,35} which was here chosen to 0.05. However, an assessment of the influence of the regularization parameter (provided in Figs. S3 and S4 in SI) showed that the exact value had little effect on the extracted dynamic modes for $RP \leq 0.1$.

The mean relaxation rate $\bar{\Gamma}$ of the decay is determined from the distribution through:

$$\ln \bar{\Gamma} = \sum_i G_i^{(d)} \ln \Gamma_i^{(d)}. \quad (4)$$

The q -dependence of $\bar{\Gamma}$ was then used to find the Brownian diffusion coefficient D_B through fitting $\bar{\Gamma}(q) = D_B q^2$ and the dynamic scaling exponent n through $\bar{\Gamma}(q) = (Dq)^{1/n}$.

Through a cumulant expansion,³⁶ the initial decay ($\tau \rightarrow 0$) of the auto-correlation can be approximated with $\ln c(\tau) \approx -2\bar{\Gamma}_0 \tau + k_2^2 \tau^2 + O(\tau^3)$, where $\bar{\Gamma}_0$ is the mean relaxation rate at $\tau = 0$ (note that $\bar{\Gamma}_0 \neq \bar{\Gamma}$). The polydispersity index (PDI) is determined through $PDI = k_2^2 / \bar{\Gamma}_0^2$. By doing a low τ expansion of $c(\tau)$ both from the CONTIN result and the cumulant expression and comparing terms, it can be found that:

$$\sum_i G_i^{(d)} = 1 \quad (5)$$

$$\sum_i G_i^{(d)} \Gamma_i^{(d)} = \bar{\Gamma}_0 \quad (6)$$

$$\sum_i G_i^{(d)} \left(\Gamma_i^{(d)} \right)^2 = \left(\bar{\Gamma}_0^2 + \frac{k_2^2}{2} \right) \quad (7)$$

and the polydispersity index can thus be found from the discrete relaxation rate distribution $G_i^{(d)}$:

$$PDI = \frac{2 \left(\sum_i G_i^{(d)} \left(\Gamma_i^{(d)} \right)^2 - \bar{\Gamma}_0^2 \right)}{\bar{\Gamma}_0^2}. \quad (8)$$

The polydispersity index was seen not to vary significantly with q and a mean value was taken over all q for comparisons in Fig. 2. The relative quantities D_B/D_0 and PDI/PDI_0 in Fig. 2 were obtained by using the values D_0 and PDI_0 from experiments of free diffusion of GNPs in the solvent (see Fig. S8 in SI for details).

Extraction of dynamic modes through lognormal deconvolution

The lognormal deconvolution is used to create a continuous distribution $G^{(c)}(\Gamma)$ of the resulting discrete distribution $G_i^{(d)}$ and was done by assuming the form with three dynamic modes in the continuous distribution (Γ_1 , Γ_2 , and Γ_3):

$$G^{(c)}(\Gamma) = \sum_{k=1}^3 G_k^{(c)} \exp(-a_k [\ln(\Gamma) - \ln(\Gamma_k)]^2), \quad (9)$$

where magnitude $G_k^{(c)}$, relaxation rate Γ_k and parameter a_k of each mode $k = 1, 2, 3$ are found through fitting. The fitted magnitude $G_k^{(c)}$ is then used to determine the contribution of each mode $G_{k,i}^{(d)}$ to the original discrete distribution $G_i^{(d)}$, where $G_i^{(d)} = \sum_{k=1}^3 G_{k,i}^{(d)}$. The magnitudes of each mode G_k is found by $G_k = \sum_i G_{k,i}^{(d)}$, which fulfills $\sum_{k=1}^3 G_k = 1$.

Numerical simulations of confined Brownian motion

The numerical simulation model is a 2D version of the model presented by Ernst *et al.*⁴⁵ to simulate subdiffusive Brownian motion in mucus. Here a square domain of $L = 5 \mu\text{m}$ was divided into $n = L/l$ quadratic subdomains ("cells") with cell size $l = 50 \text{ nm}$ (analysis of cell sizes $l = 25$ & 75 nm is provided in Fig. S9 in SI), where $N = 100$ particles are initially

randomly placed in the domain. The position of a particle, $\mathbf{r}(t)$ equals to integration of the stochastic differential equation (SDE) $\dot{\mathbf{r}}(t) = \sqrt{2D_0}\boldsymbol{\zeta}(t)$, where $\boldsymbol{\zeta}(t)$ is a stationary Markov process satisfying $\langle \boldsymbol{\zeta}(t) \rangle = \mathbf{0}$. The diffusion constant is set according to $D_0 = k_B T / (6\pi\eta R)$, where radius is $R = 100$ nm, temperature is $T = 293$ K, and viscosity is 0.042 Pa s (viscosity of PG at this temperature⁵²). If a particle crosses a boundary of a cell, it will be reflected with probability $r = 1 - P\sqrt{\Delta\tau}$, where $P > 0$ is the membrane permeability with unit $\text{s}^{-1/2}$ and $\Delta\tau = 1$ ms is the time step. The simulation is running for a total of 6000 iterations (*i.e.* 6 s). The mean-square-displacement is calculated as the ensemble average over all particles $MSD(\tau) = \langle [\mathbf{r}(t = \tau) - \mathbf{r}(t = 0)]^2 \rangle$. It can be noted that in the extreme case of $P = 0$, the particle is contained within its pore with $MSD(\tau \rightarrow \infty) = l^2/6$.⁴⁵

Simulated XPCS experiments

The simulated speckle patterns were created by a pre-defined detector with 200×200 pixels covering a range of $q_x, q_y \in [-0.0065, 0.0065] \text{ \AA}^{-1}$. The dynamic structure factor at a given time $S(q, t)$ was calculated using a discrete Fourier transform of the particle positions $\mathbf{r}(t)$:

$$S(q, t) = \left| \sum_{i=1}^N \exp[j\mathbf{q} \cdot \mathbf{r}_i(t)] \right|^2, \quad (10)$$

with $j = \sqrt{-1}$. The intensity $I(q, t) = P(q)S(q, t)$ is found by multiplication of the form factor for a sphere:⁵³

$$P(q) = \left(\frac{\sin(qR) - qR \cos(qR)}{(qR)^3} \right)^2 \quad (11)$$

using radius $R = 100$ nm. The q -regions for evaluating intensity autocorrelations in the simulated detector images were chosen with centers $q = 0.0025, 0.003 \dots 0.006 \text{ \AA}^{-1}$ and width of $\Delta q = 0.005 \text{ \AA}^{-1}$. The resulting autocorrelations are then analyzed through the same steps

as the experimental data by deriving the square first order correlation $c(\tau) = g_1^2(q, \tau) = (g_2(q, \tau) - g_\infty)/\beta$, where $g_2(q, \tau) = g_2^{(2T)}(q, \tau)$ and β is found through extrapolation to $\tau = 0$.

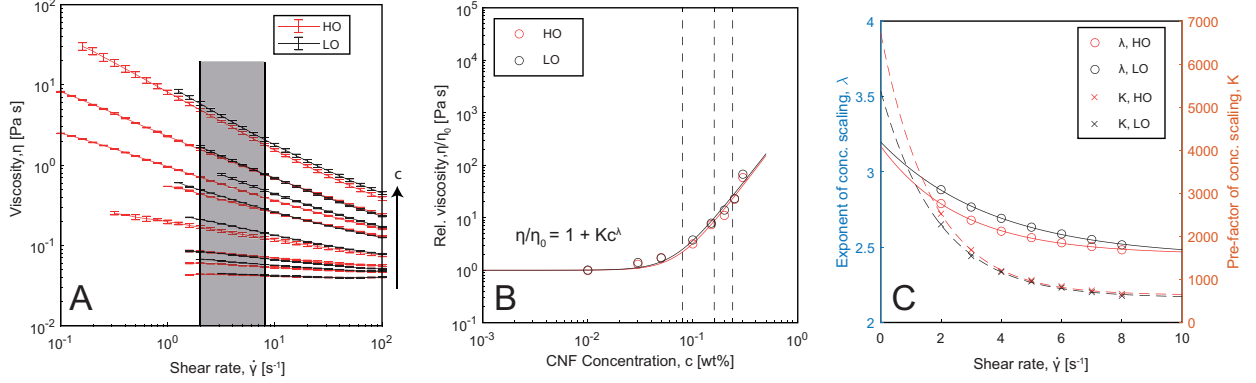

Figure S1: Steady shear viscosity measurements of CNF dispersions in the study; red and black curves/symbols indicate high and low degree of oxidation of dispersions (HO and LO), respectively; (A) dynamic viscosity η of dispersions with varying shear rates $\dot{\gamma}$ at concentrations $c = 0.01, 0.03, 0.05, 0.1, 0.15, 0.2, 0.25$ and 0.3 wt%; the shaded region shows the set of shear rates used to estimate zero-shear viscosity; (B) relative viscosity η/η_0 at $\dot{\gamma} = 5 \text{ s}^{-1}$; the dashed lines indicate the concentrations used in the XPCS-study; (C) the extracted parameters K and λ as function of shear rate $\dot{\gamma}$.

Rheology of CNF dispersions

Steady shear viscosity of the two CNF dispersions at high oxidation (HO) and low oxidation (LO) was measured according to the procedure described in the main manuscript. The results are shown in Fig- S1A-C. In Fig S1A, the viscosity η versus shear rate $\dot{\gamma}$ is shown of the two dispersions at 8 different concentrations ($c = 0.01, 0.03, 0.05, 0.1, 0.15, 0.2, 0.25$ and 0.3 wt%), where we can see increasing shear-thinning behavior at increasing concentration. The relative viscosity η/η_0 is determined using the viscosity of $\eta_0 = 0.042 \text{ Pa}\cdot\text{s}$ for propylene glycol (PG)^{S1} and the concentration dependent data at a fixed shear rate $\dot{\gamma}$ is fitted with a function of form $\eta/\eta_0 = 1 + K(\dot{\gamma})c^{\lambda(\dot{\gamma})}$, illustrated in Fig. S1B. The dashed lines in the figure show the three concentrations used in the XPCS-study ($c = 0.08, 0.16$ and 0.24 wt%). The shear rate dependence of parameters K and λ in region $\dot{\gamma} = 2$ to 8 s^{-1} is illustrated in Fig. S1C. The data is fitted to exponential functions:

$$\lambda(\dot{\gamma}) = C_1 \exp(-C_2 \dot{\gamma}) + C_3 \quad (1)$$

$$K(\dot{\gamma}) = C_4 \exp(-C_5 \dot{\gamma}) + C_6 \quad (2)$$

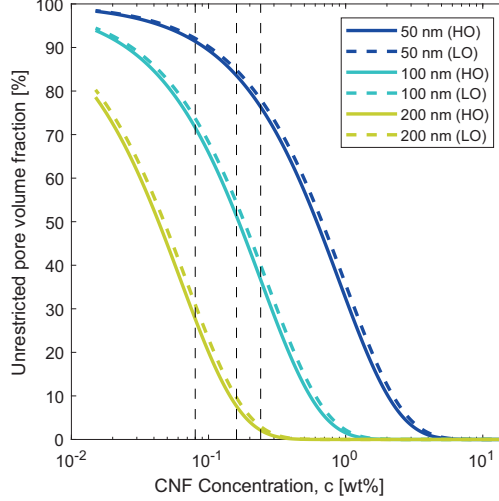

Figure S2: Unrestricted pore volume fraction UPV for spherical nanoparticles in typical random fiber networks of stiff cylindrical fibers with the same equivalent diameter as the CNFs in the experiments according to theory by Ogston.^{S2}

to estimate the zero-shear parameters $\lambda(0) = C_1 + C_3$ and $K(0) = C_4 + C_6$ (C_{1-6} are arbitrary fitting parameters). The zero-shear viscosity of the two CNF dispersions at various concentrations is then estimated as $\eta/\eta_0 = 1 + K(0)c^{\lambda(0)}$. The expressions to describe the zero-shear viscosity for the two dispersions are:

$$\eta^{(HO)}/\eta_0 = 1 + 5372c^{3.20} \quad (3)$$

$$\eta^{(LO)}/\eta_0 = 1 + 6722c^{3.17}. \quad (4)$$

Using these expressions, we can also estimate the overlap concentrations c^* where CNF interactions dominate the viscosity scaling through $c^* = K(0)^{-1/\lambda(0)}$. This is found to be $c^* = 0.068$ and 0.062 wt% for the HO and LO CNF, respectively. This also indicates that the lowest concentration in the experiment of $c = 0.08$ wt% is only slightly above this overlap concentration.

Pore sizes in random fiber networks

The probability of a randomly placed sphere in a fiber network to not be in contact with a fiber is called the unrestricted pore volume fraction (UPV) and is calculated through the theory by Ogston^{S2} using expressions by Chatterjee:^{S3}

$$UPV = (1 - \Phi)^{(R_{\text{sphere}}/R_{\text{fiber}})(R_{\text{sphere}}/R_{\text{fiber}}+2)} \quad (5)$$

where Φ is the volume fraction of fibers. Fig. S2 shows the theoretical UPV at various concentrations c of the fiber network assuming the CNFs as long rigid cylinders with radius R_{fiber} determined from the mean equivalent cross-sectional size of the CNFs found with SAXS (Fig. 1C in main manuscript). Here, $R_{\text{fiber}} = 2.1$ and 2.3 nm for HO and LO CNF, respectively. The black vertical dashed lines indicate the concentrations used in the XPCS study ($c = 0.08, 0.16$ and 0.24 wt%). Note that $UPV > 90\%$ for 50 nm GNPs at 0.08 wt%, *i.e.* that GNPs are almost moving freely in the network. In contrast, 200 nm GNPs at 0.24 wt% are practically always in contact with the network ($UPV < 5\%$).

Assessment of various fitting methods of XPCS data

The square first order autocorrelation $c(\tau)$ from one representative XPCS experiment of 200 nm GNPs in HO CNF at 0.24 wt% ($q = 0.0025 \text{ nm}^{-1}$) was used to compare various fitting methods (see Fig. S3A). Three methods were assessed:

1. The correlation is assumed the form:

$$c(\tau) = \sum_i G_i^{(d)} \exp(-2\Gamma_i^{(d)} \tau), \quad (6)$$

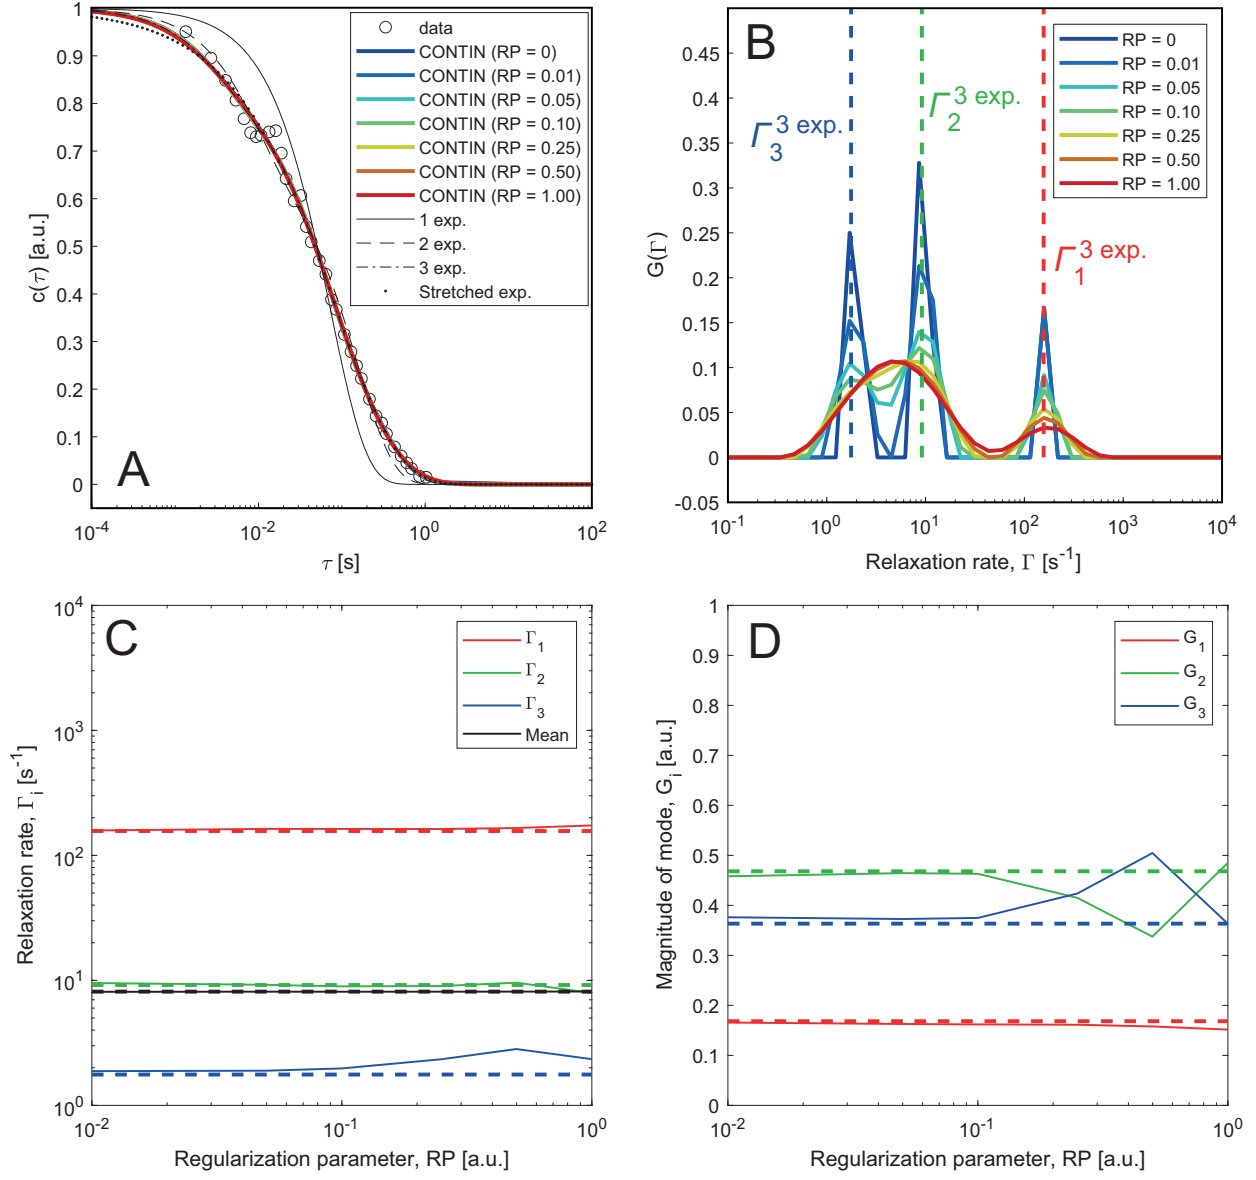

Figure S3: Assessment of various fitting methods applied to a dataset of $c(\tau)$ for 200 nm GNPs in 0.24 wt% HO CNF at $q = 0.0025 \text{ nm}^{-1}$; (A) The data $c(\tau)$ with curves of the various fits; (B) relaxation rate distributions $G(\Gamma)$ from the CONTIN fit at various regularization parameters (RP) with dashed lines showing the relaxation rates found by fitting 3 exponentials; (C) and (D) the relaxation rates and magnitude of dynamic modes at various RP, respectively.

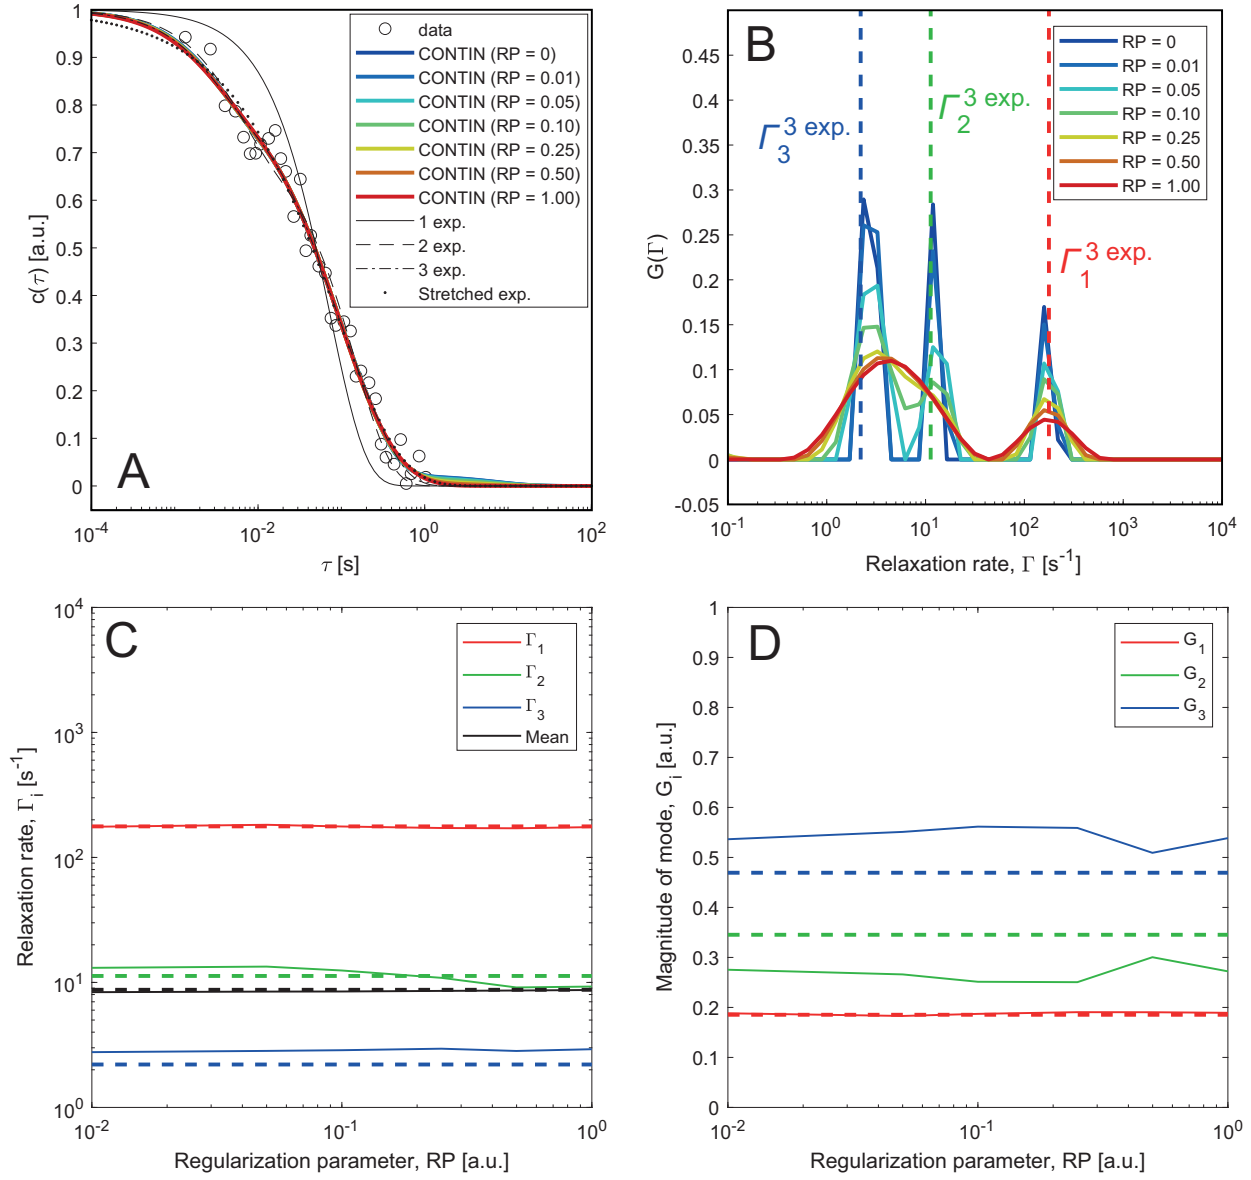

Figure S4: The figure shows exactly the same assessment done to the same data as in Fig. S3, but with added random noise $c_\epsilon \in [-0.05, 0.05]$ to the original data.

Table S1: Table of parameters from the various types of fitting methods applied to the data of 200 nm GNPs in HO-CNF at 0.24 wt% and $q = 0.0025 \text{ nm}^{-1}$. Values in parenthesis are results when adding random $\pm 5 \%$ noise to the data (see Fig. S4A).

	$\bar{\Gamma} [\text{s}^{-1}]$	$\Gamma_1 [\text{s}^{-1}]$	$\Gamma_2 [\text{s}^{-1}]$	$\Gamma_3 [\text{s}^{-1}]$	PDI	γ	R^2

CONTIN (RP=0) (w. log-normal deconv.) $c = \sum_{i=1}^N G_i \exp(-2\Gamma_i\tau)$	8.06 (8.35)	158.3 (173.0)	9.71 (11.9)	1.94 (2.73)	6.56 (6.06)	- -	0.9971 (0.9845)
CONTIN (RP=0.01) (w. log-normal deconv.)	8.10 (8.36)	158.3 (175.9)	9.53 (13.1)	1.88 (2.77)	6.56 (6.22)	- -	0.9971 (0.9845)
CONTIN (RP=0.05) (w. log-normal deconv.)	8.12 (8.45)	162.9 (182.4)	9.21 (13.4)	1.89 (2.83)	7.09 (6.53)	- -	0.9971 (0.9844)
CONTIN (RP=0.1) (w. log-normal deconv.)	8.11 (8.46)	162.8 (176.8)	8.95 (12.5)	1.97 (2.87)	7.16 (6.48)	- -	0.9970 (0.9842)
CONTIN (RP=0.25) (w. log-normal deconv.)	8.12 (8.55)	162.4 (171.9)	9.01 (10.9)	2.34 (2.95)	7.81 (6.97)	- -	0.9969 (0.9840)
CONTIN (RP=0.5) (w. log-normal deconv.)	8.13 (8.62)	165.5 (171.1)	9.59 (9.12)	2.82 (2.83)	8.52 (7.49)	- -	0.9969 (0.9839)
CONTIN (RP=1.0) (w. log-normal deconv.)	8.15 (8.70)	173.5 (174.8)	7.93 (9.27)	2.34 (2.92)	9.90 (8.38)	- -	0.9967 (0.9837)

where the distribution $G_i^{(d)}$ of pre-determined log-spaced relaxation rates $\Gamma_i^{(d)}$ is found using the CONTIN-algorithm with various values of the regularization parameter (RP) using the constraint that $\sum_{i=1}^N G_i^{(d)} = 1$. The value determines the level of smoothing of the distribution (see Fig. S3B). The distribution is used to extract the relaxation rates Γ_{1-3} and magnitudes G_{1-3} of the three dynamic modes according to the lognormal deconvolution described in the main manuscript (see Fig. S3C-D).

2. The correlation is assumed a similar form as the one above:

$$c(\tau) = \sum_{i=1}^N G_i \exp(-2\Gamma_i \tau), \quad (7)$$

but here both G_i and Γ_i are fitting constants. We assess the fits using $N = 1, 2, 3$ and 4 exponential functions with the constraint $\sum_{i=1}^N G_i = 1$. The values of G_{1-3} and Γ_{1-3} for the fit with 3 exponential functions is compared with the values from the lognormal deconvolution with dashed lines in Figs. S3B-D.

3. The correlation is assumed the form of a stretched exponential:

$$c(\tau) = \exp(-2[\Gamma\tau]^\gamma), \quad (8)$$

with γ as a stretching coefficient.

The results from the fits are illustrated in Fig. S3 and Table S1. Fig. S4 shows the same analysis for the same correlation curve but with added random noise $c_\epsilon \in [-0.05, 0.05]$ to the original data, *i.e.* $c(\tau) + c_\epsilon$. The corresponding parameters from the different fitting methods are noted with parenthesis in Table S1.

A couple of observations are done with respect to this assessment:

- A simple exponential is not good enough to describe the data.
- Using 2 exponentials, we already get a very good fit, but it is further improved by using 3 exponentials. There is no improvement of the fit with 4 exponentials.
- The quality of the fit with 3 exponentials is equally good as the non-regularized CONTIN result ($RP = 0$). The results of the three dynamic modes are practically identical for both methods. We could thus qualitatively reproduce the results in the manuscript by just considering a fit with 3 exponentials. However, we find that the CONTIN-approach gives us more flexibility since it does not require a pre-determined number of dynamic modes.
- The values from the CONTIN fit followed by lognormal deconvolution are not very sensitive to RP. The only issue that is observed is if there is too much smoothing applied (high RP) and the three peaks are thus difficult to distinguish. Here a value of $RP \leq 0.1$ seems to yield results independent of RP.
- The stretched exponential provides almost as good fit as 3 exponentials and CONTIN, but it is clear that the relaxation rate $\bar{\Gamma}$ does not correspond to the relaxation rates from any of the methods using sums of regular exponentials and is thus also difficult to relate to *e.g.* an average diffusion coefficient. The main difference with a stretched exponential is that it has an infinite derivative at $\tau = 0$ when $\gamma < 1$, and thus has a very quick initial decay compared to sums of exponentials. Since there are no indications of such behavior at low τ , we find that the stretched exponential form is not suitable for our study.
- Neither fitting method shows any significant sensitivity to noisy data, apart from some slight differences in the magnitude of the dynamic modes. In terms of relaxation rates, they provide similar results both with and without noise, which indicates that there are no problems of overfitting the data.

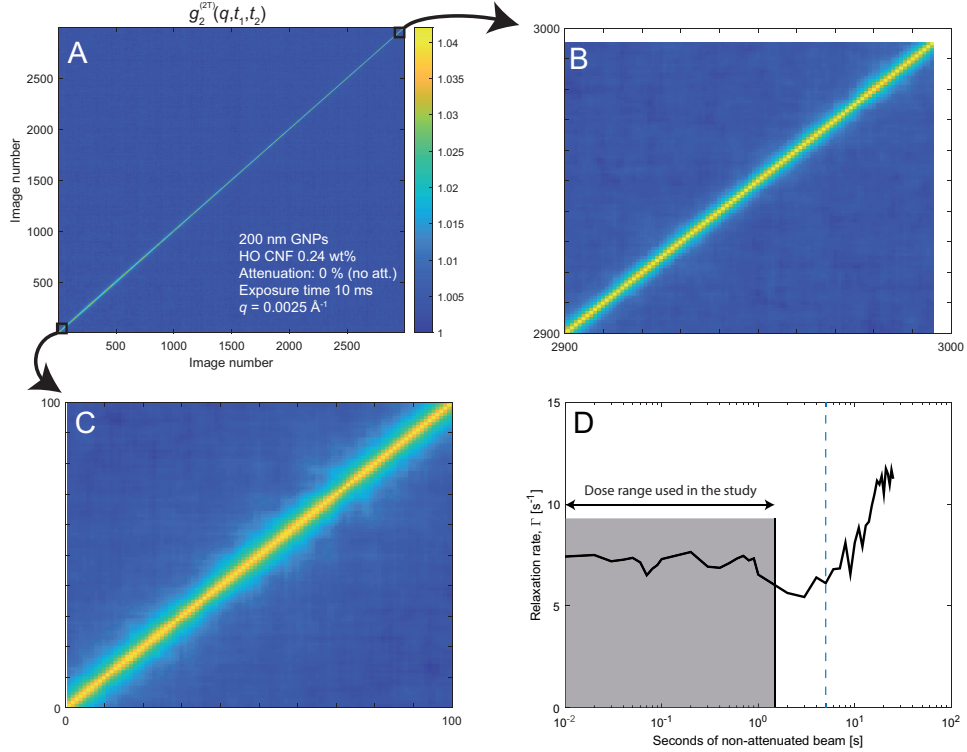

Figure S5: Study to assess the influence of the X-ray radiation on the system dynamics in a system of 200 nm GNPs in HO CNF at 0.24 wt%; (A) the two-time correlation $g_2^{(2T)}(q, t_1, t_2)$ of speckle intensities at $q = 0.0025 \text{ \AA}^{-1}$ between images at times t_1 and t_2 provided as image numbers; (B) zoom-in at the end of the experiment (last 1 s of radiation exposure); (C) zoom-in at the beginning of the experiment (first 1 s of radiation exposure); (D) relaxation rate Γ as function of seconds of radiation dose.

Influence of X-ray radiation during experiments

To study the influence of X-ray radiation on the dynamics, we perform a long-time experiment on the system of 200 nm GNPs in HO CNF at 0.24 wt%. Here, the experiment is performed with no attenuation to the beam using an exposure time of 10 ms and measuring 3000 subsequent images (30 seconds). To analyze the time-dependent dynamics, we use the two-time correlation function $g_2^{(2T)}(q, t_1, t_2)$ at $q = 0.0025 \text{ \AA}^{-1}$, which can provide us directly with the autocorrelations between two detector images at time t_1 and t_2 (see Fig. S5A-C). From this, we can derive correlation curves at various starting times t_0 through $c(\tau) = (g_2(q, t_0, t_0 + \tau) - 1)/\beta$, which is fitted to a simple exponential function $c(\tau) = \exp(-2\Gamma(t_0)\tau)$. This provides us with a relaxation rate dependent on the experimental time, *i.e.* dependent on the total exposure to the non-attenuated beam, illustrated in Fig. S5D.

The main influence of the radiation is a significant increase in relaxation rates above 5 s of exposure to the non-attenuated beam (above vertical dashed line in Fig. S5D). In the present study, the maximum dose is 1.3 s of exposure to the non-attenuated beam, which seems to have negligible effect on the system dynamics (shaded region) as the relaxation rate is fairly constant.

Influence of gravity during experiments

To be able to exclude any gravity-induced effects, we divide the detector into four 90° sectors to separate horizontal data (left and right sector on the detector) with vertical data (upper and lower sector on the detector). The square first order auto-correlations $c(\tau)$ for two repeated experiments of freely diffusing 200 nm GNPs are shown in Figs. S6A-B, where the data is separated into vertical and horizontal directions (crosses and circles in figure). Using CONTIN fits to extract the mean relaxation rate $\bar{\Gamma}$ (solid and dashed curves), we obtain the direction-specific diffusion coefficients D_V in vertical direction and D_H in horizontal

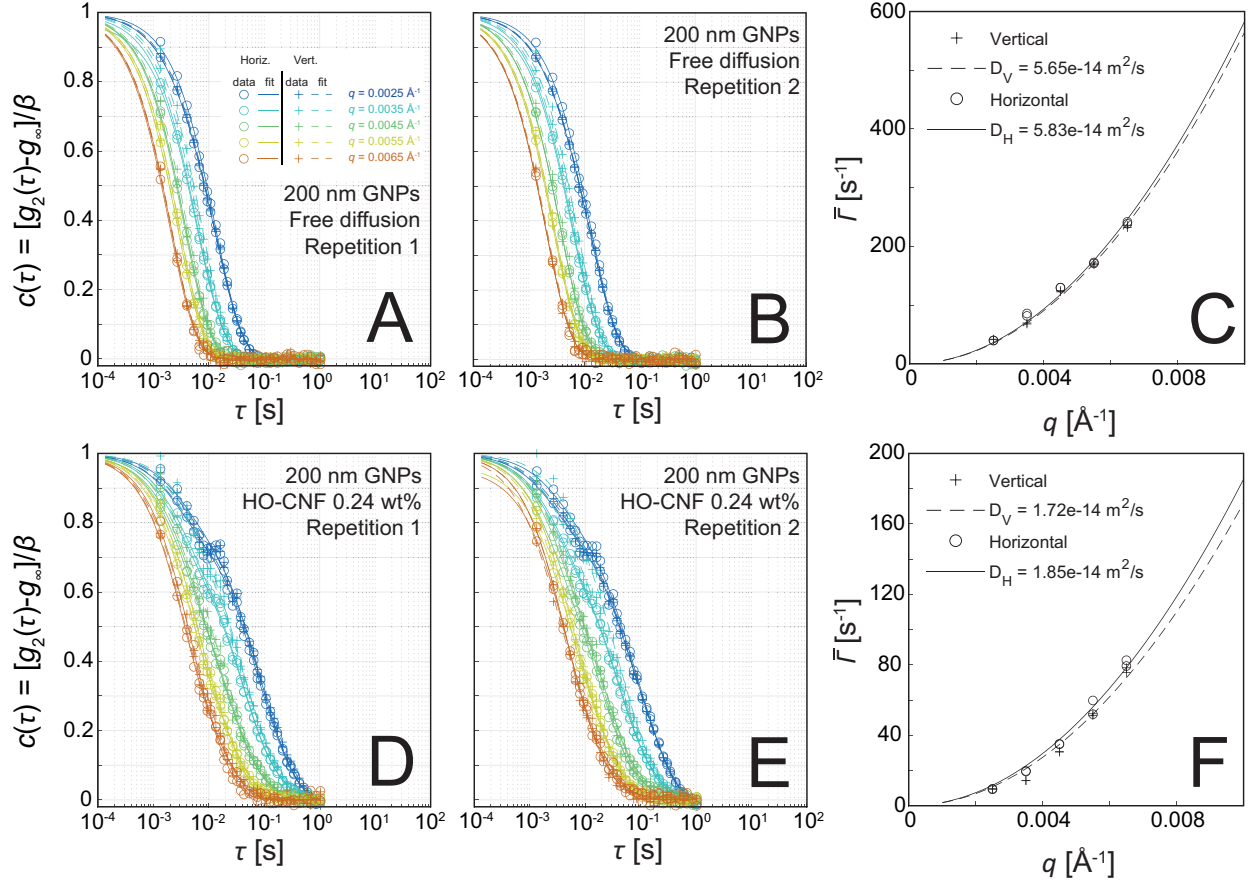

Figure S6: Assessment of direction dependent dynamics due to gravity-induced sedimentation; (A) and (B) the autocorrelation curves $c(\tau)$ for 200 nm GNPs freely diffusing in the solvent in two repeated experiments; the circles and crosses show horizontal and vertical data, respectively, with CONTIN fits provided with the solid and dashed curves; (C) the corresponding relaxation rates $\bar{\Gamma}$ in horizontal and vertical directions with corresponding fits of $\bar{\Gamma} = Dq^2$ to obtain diffusion coefficients in each direction; (D)-(F) the same assessment for 200 nm GNPs in 0.24 wt% HO CNF.

Figure S7: Results of SAXS measurements of freely moving GNPs (expected diameters $2R_{\text{expected}} = 50, 100$ and 200 nm) in the solvent; (A) the scattering intensity I as function of wave vector q (symbols) is fitted (black curves) assuming spherical particles with diameter $2R$ with polydispersity described by a log-normal distribution; (B) the resulting size distribution from the SAXS fitting.

Table S2: Table of parameters from SAXS and XPCS measurements of freely moving GNPs in the solvent.

	50 nm	100 nm	200 nm
$2R_{\text{SAXS}}$ [nm]	39.9	94.8	203.6
PD_{SAXS} [a.u.]	0.068	0.088	0.071
D_0 [10^{-14} m ² /s]	17.5	9.04	5.65
$2R_{\text{XPCS}}$ [nm]	57.5	111	178
PDI_0 [a.u.]	0.176	0.351	0.554

directions by assuming $\bar{\Gamma} = Dq^2$ (see Fig S6C). The same is then also done for two repeated experiments of 200 nm GNPs in 0.24 wt% HO CNF in Figs. S6D-F.

From these results, we find that there seems to be no significant difference between the results in horizontal and vertical directions and we can thus rule out any effect of gravity.

Sizes and dynamics of GNPs in pure solvent

The static and dynamic properties of the GNPs were studied in pure dispersions of propylene glycol (PG) using both the static (SAXS) and dynamic (XPCS) data from the experiments.

Figure S8: Results of XPCS measurements of freely moving GNPs (expected diameters $2R_{\text{expected}} = 50, 100$ and 200 nm) in the solvent; (A) the geometric mean radius from SAXS compared to the hydrodynamic radius from XPCS; (B) polydispersity index PDI ; (C) dynamic scaling exponent (assuming $\Gamma = (Dq^2)^{1/n}$).

In Fig. S7, we find the SAXS curves of the three GNP sizes with circle symbols. The data is fitted in SasView using a sphere-model with lognormal polydispersity.^{S4} The resulting distributions are illustrated in Fig. S7B with the values of mean radius R_{SAXS} and polydispersity PD_{SAXS} given in Table S2. Here we can see that the geometric size of the smaller particles is smaller than the expected diameter of 50 nm.

The dynamics of the freely moving GNPs in the solvent was measured with XPCS and the Brownian diffusion coefficient D_B was extracted according to the procedure in the manuscript. Through the Stokes-Einstein relationship $D_B = k_B T / (6\pi\eta R_H)$ (temperature $T = 298$ K and viscosity of PG determined by Sagdeev *et al.*^{S1}), the diffusion coefficient is used to determine the hydrodynamic radius R_H for different attenuation levels as illustrated in Fig. S8A.

Firstly, it should be noted that the comparison with the expected value (assumed at $T = 298$ K) is highly dependent on an accurate measurement of the effective temperature in the beam, which was not possible to do in the experiment. Just a 1-2 °C error in the effective temperature can cause a 10 % difference between hydrodynamic radii due to the temperature dependence of the solvent viscosity. This is the likely cause for the apparent decrease of hydrodynamic radii with a stronger dose as it is likely that a 5 times stronger

beam could result in a slight local heating of the irradiated sample. It should also be added that a 5 times smaller dose adds more noise to the data and larger error to the extracted diffusion coefficient. The error is also larger for the smaller particles, owing to their faster dynamics and therefore less usable autocorrelation data at higher q .

Despite these uncertainties, there are some interesting trends when comparing the geometric and hydrodynamic radii. The geometric radius is lower than the expected value for smaller GNPs but close to the expected size for the larger ones. On the other hand the hydrodynamic radius has a decreasing trend and a larger difference to the geometric radius for smaller GNPs. This is likely due to the polymer coating of approximately 1-5 nm covering the particle for steric stabilization, causing the particle to move slower than expected from its geometric size. This is naturally more prominent for the smallest particles as the relative thickness of the polymer layer is smaller for the larger GNPs.

The polydispersity index (PDI) describing the non-uniformity of dynamics in the systems is illustrated in Fig. S8B and determined with expressions in the main manuscript. We find slightly higher PDI for the larger GNPs, but they still show fairly high uniformity of dynamics with values of $PDI < 1$. Note that the values of PDI cannot be directly compared with the PD_{SAXS} as they have different definitions. The dynamic scaling exponent assuming $\Gamma = (Dq^2)^{1/n}$ is illustrated in Fig. S8C, where values are close to (albeit a bit larger than) 1 and thus little anomalous diffusion in the systems, *i.e.* the GNPs have a mean square displacement that is linearly proportional to time.

The mean of the data at 0% and 81% attenuation levels is used as the reference values D_0 (related to mean hydrodynamic radius R_{XPCS}) and PDI_0 in the main manuscript and summarized in Table. S2.

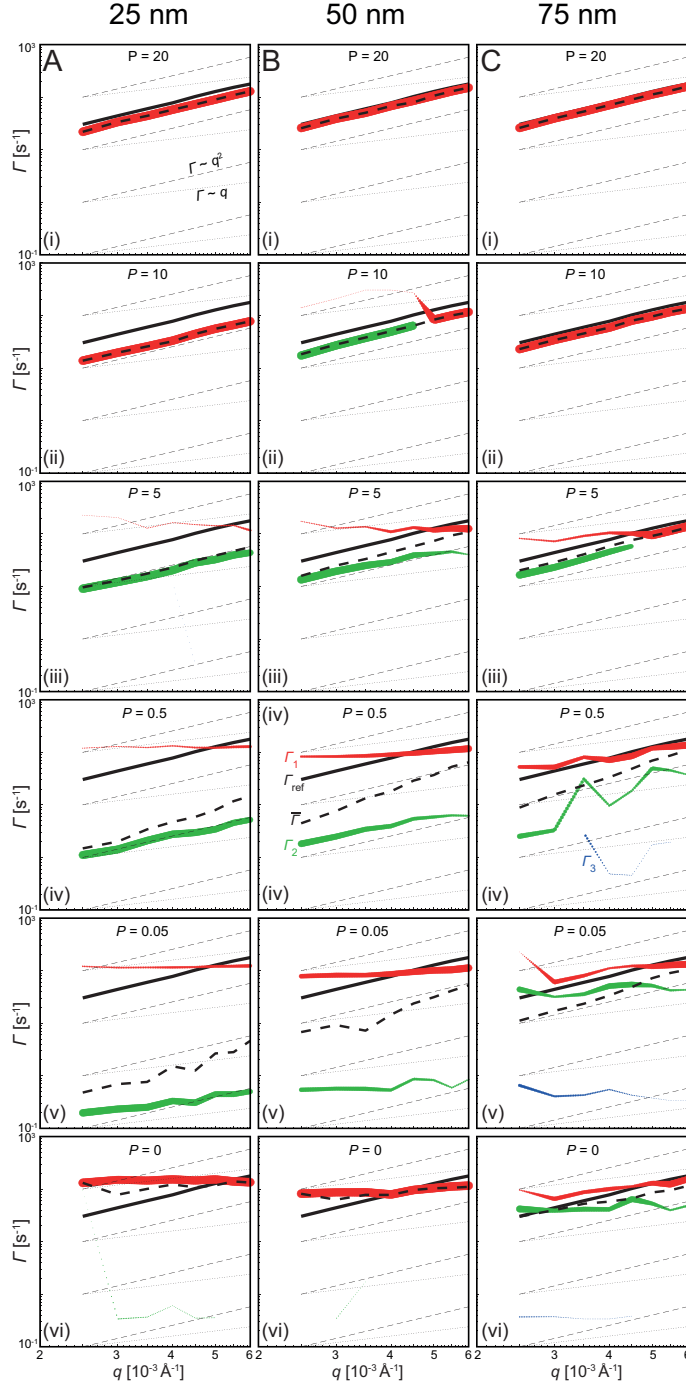

Figure S9: Results from the numerical simulations of confined Brownian motion of 200 nm spherical nanoparticles; the evolution of the relaxation rates Γ_1 , Γ_2 and Γ_3 as function of q are drawn with the line width scaled with the magnitude of the modes and linear interpolation between the q -values; the thin dashed and dotted lines indicate expected scaling behavior for Brownian ($\Gamma \propto q^2$) and ballistic ($\Gamma \propto q$) dynamics, respectively; the thick black solid and dashed lines show the free diffusion of GNPs (Γ_{ref}) and mean relaxation rate ($\bar{\Gamma}$), respectively; (A)-(C) shows the results using cell sizes of 25, 50 and 75 nm, respectively; panels (i)-(vi) show the results for various values of permeability P .

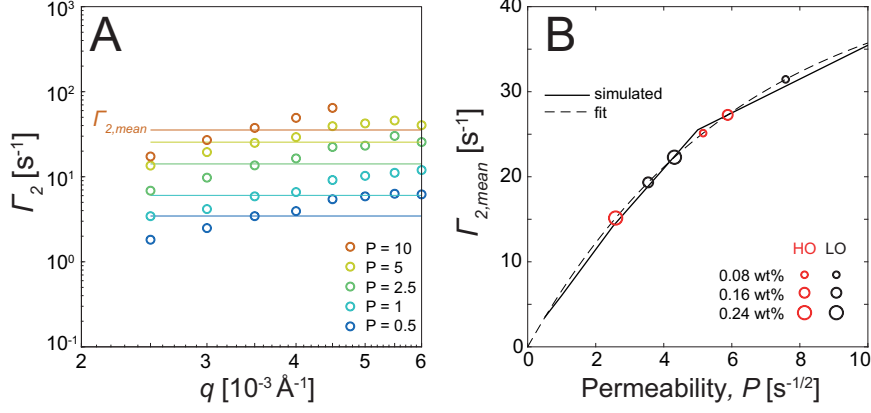

Figure S10: Quantification of permeability P in the CNF networks for 200 nm GNPs using the digital twin to compare relaxation rates $\Gamma_{2,\text{mean}}$; (A) Relaxation rate of second dynamic mode Γ_2 as function of q at various permeabilities from the digital twin; (B) the weighted mean $\Gamma_{2,\text{mean}}$ (illustrated with solid lines in A) as function of permeability P is fitted and used to obtain values of P for the experimental systems.

Results from the digital twin using various cell sizes

The same procedure to study evolution of dynamic modes in the simulated system, as described in the main manuscript, was performed for two other cell sizes 25 and 75 nm (the results for 50 nm was shown in the main manuscript). The results are shown in Fig. S9, illustrating different transition scenarios for the extracted modes. This indicates that the trends can be matched to the experimental trends to find an average cell size, corresponding to the undisturbed "wiggle-room" for the GNPs in the CNF network.

Quantification of permeability using the digital twin

As observed from the results in the digital twin in Fig. S9B, the dynamic modes in (ii)-(iv) corresponding to permeabilities between $P = 0.5$ and 10 for 50 nm cell size match the experimental trends qualitatively (Fig. 4 in main manuscript). The characteristic P -dependent feature is the decrease of the mean relaxation rate of the second dynamic mode $\Gamma_2(q)$ with decreasing P . Using the mean relaxation rate $\Gamma_{2,\text{mean}}$ (mean taken over q weighted with magnitude $G_2(q)$) from the digital twin at various P , illustrated in Fig. S10A, we fit

an exponential function $\Gamma_{2,\text{mean}}(P) = C_1[\exp(-C_2P) - 1]$ illustrated with dashed line in Fig. S10B. By extracting the same quantity $\Gamma_{2,\text{mean}}$ from the experimental systems we thus can use this function to find the permeability P of the CNF networks (values in Fig. 6 in main manuscript).
