Abstract

Causal set theory is a discrete model of spacetime that retains a notion of causal structure. We understand how to construct causal sets that approximate a given spacetime, but most causal sets are not at all manifold-like, and must be dynamically excluded if something like our universe is to emerge from the theory. Here we show that the most common of these “bad” causal sets, the Kleitman-Rothschild orders, are strongly suppressed in the gravitational path integral, and we provide evidence that a large class of other “bad” causal sets are similarly suppressed. It thus becomes plausible that continuum behavior could emerge naturally from causal set quantum theory.

1 Introduction

To build a discrete model of spacetime, one must first choose which aspects of spacetime structure to keep. In causal set theory, the choice is the causal structure, the relativistic picture of time in which each event has a past, present, and future. A causal set is essentially a discrete, causally ordered collection of events, with an added prohibition of closed timelike curves [1].

The appeal of this approach comes in part from theorems of Hawking, King, McCarthy, and Malament [2, 3], who show that if an ordinary continuum spacetime obeys suitable causality conditions, its geometry is completely determined by its causal structure and volume element. A causal set embodies the discrete version of this information: the causal structure is built in, and the volume of any region is proportional to the number of points it contains.

This is not quite enough, though; we must still ask how well the discrete structure approximates the continuum. There are actually two questions:

1. Given a spacetime, can we construct a causal set that approximates it at some scale, and use that causal set to reconstruct the properties of the spacetime?
2. If we start with an arbitrary causal set, can we find a spacetime it approximates?

A good deal is known about the first question. Given a spacetime M , there is a well understood procedure, “Poisson sprinkling,” for producing a causal set that approximates M . From such a causal set, we can reconstruct the dimension of M , its coarse-grained topology and geometry, and such structures as d’Alembertians and Greens functions. While important open issues remain, the answer to question 1 is largely “yes.”

For question 2, much less is known, and on the face of it the situation seems dire. Most causal sets fail to approximate any manifold at all. In fact, if one chooses a large random causal set, one is overwhelmingly likely to find a Kleitman-Rothschild (KR) order, a “three-layer” set with large spatial extension but only three moments of time [4]. If one discards the KR orders, one is overwhelmingly likely to be left with a two-layer set, followed by an infinite sequence of higher layered but still non-manifoldlike sets [5, 6]. If causal sets are fundamental, something profound must happen to eliminate these “bad” sets and leave us with an approximate continuum.

A first step towards addressing this problem was taken in [7], where it was shown that for a large range of coupling constants, the gravitational path integral very strongly suppresses the two-layer causal sets. In [8], this result was extended to a larger class of multi-layer sets, including the KR orders. To show this, though, the authors of [8] had to use a “wrong” action, which is a truncated version of the full Einstein-Hilbert action.

Here, we complete the proof for KR orders, showing that they are superexponentially suppressed in the gravitational path integral with the full Einstein-Hilbert action. In a subsequent work we will explore this question for the subset of all higher layered causal sets that are subdominant compared to the KR orders [5, 6]. While this does not settle the question—there are certainly other types of “bad” non-manifoldlike causal sets—these results makes it much more plausible that our observed continuum spacetime could emerge from a discrete causal set path integral.

2 Causal sets

A causal set is a locally finite, irreflexive partially ordered set. The partial ordering is interpreted as causal ordering: $x \prec y$ means “ x is to the causal past of y ,” where the irreflexive condition

Figure 1: An example of a KR order.

forbids $x \prec x$. Local finiteness means that for any x and y , the number of points z for which $x \prec z \prec y$ is finite; this is a discreteness condition. Irreflexivity implies that there are no points x, y for which both $x \prec y$ and $y \prec x$ (if there were, this would imply $x \prec x$); this is a causality condition, excluding closed causal curves.

We will need several causal set structures that have continuum analogs.

- A chain is an ordered set of elements $x_1 \prec x_2 \prec \dots \prec x_n$. This is an analog of a causal path.
- An antichain is a set of unrelated elements $\{x_1, x_2, \dots, x_n\}$ (that is, $x_i \not\prec x_j$ for any i, j). This is an analog of a spacelike hypersurface.
- Given two points x, y with $x \prec y$, the order interval $I(x, y)$ is the set of points z such that $x \prec z \prec y$. This is an analog of a causal diamond or Alexandrov open set, the region within the future light cone of x and the past light cone of y .
- A pair $x \prec y$ for which $I(x, y)$ is empty—that is, a pair of “nearest neighbors”—is called a link. Note that linked points are “near” in the Lorentzian sense: their *proper* distance is small, but they may have large separations in coordinate space or time.

Given a finite volume region M of a causal spacetime of dimension d , there is a standard way to construct a corresponding causal set. In a Poisson sprinkling, points from M are chosen randomly and independently at a density ρ , with causal relations induced from the causal structure of the manifold. One then “forgets” the manifold, keeping only the selected points and their causal relations, which naturally form a causal set. The density ρ determines a characteristic discreteness scale $\ell = \rho^{-\frac{1}{d}}$, below which the causal set contains little information about M . But on scales large compared to ℓ , the dimension and much of the topology and geometry of (M, g) can be reconstructed from the causal set [9].

Most causal sets, however, are nothing like these manifold-like sets. If one picks a random causal set with n points, for n large enough one is overwhelmingly likely to obtain a Kleitman-Rothschild (KR) order [4]. This is a causal set with three layers (see Fig 1), in which

- layer 1 and layer 3 each have $\frac{n}{4} + \mathcal{O}(n^{1/2} \log n)$ elements
- layer 2 has $\frac{n}{2} + \mathcal{O}(\log n)$ elements
- each element in layer 1 and layer 3 links with $\frac{n}{4} + \mathcal{O}(n^{7/8})$ elements in layer 2
- each element in layer 2 links with $\frac{n}{8} + \mathcal{O}(n^{7/8})$ elements in layer 1 and in layer 3

The number of n -element causal sets grows as $\sim 2^{\frac{n^2}{4} + \frac{3}{2}n + o(n)}$. By “overwhelmingly likely” we mean that the ratio [4]

$$\frac{\text{number of } n\text{-element KR orders}}{\text{number of all } n\text{-element causal sets}} \sim 1 + O\left(\frac{1}{n}\right),$$

i.e., the number of n -element KR orders also grows as $\sim 2^{\frac{n^2}{4} + \frac{3}{2}n + o(n)}$.

The full picture is even worse. If the KR orders are removed by hand, the remaining sets are overwhelmingly likely to be two-layer sets. If those are removed, one is left with four-layer sets, followed by an infinite hierarchy of higher layered sets [5, 6]. The “nice” manifoldlike causal sets obtained from Poisson sprinklings are apparently vanishingly rare.

3 Path integrals and the Benincasa-Dowker action

The fact that “physical” causal sets are so rare may be a cause for concern, but it is not such a strange situation. Even in a system as simple as a free point particle, the space of smooth paths is of measure zero. In that case, we understand what happens: the “bad” paths are suppressed by destructive interference in the path integral, leaving only a tiny subset of physical trajectories. It is natural to ask whether the same happens for causal sets.

To answer this, we would ideally construct a causal set action from first principles and then evaluate the path integral (technically, in view of discreteness, the path sum). We do not know how to do this. We can, however, use our knowledge of manifoldlike causal sets obtained from Poisson sprinklings to construct the causal set analog of the Einstein-Hilbert action.

For a causal set C with n elements, let N_J be the number of J -element order intervals,[‡] that is, the number of pairs $x \prec y$ for which there are exactly J elements z such that $x \prec z \prec y$. N_0 is the number of links, and has a maximum value $N_0^{\max} = \frac{n^2}{4}$. As Benincasa and Dowker have shown, for causal sets obtained from a Poisson sprinkling of a four-dimensional spacetime M , the Einstein-Hilbert action is then well approximated by the quantity

$$\frac{I_{BD}(C)}{\hbar} = 2\sqrt{\frac{2}{3}} \left(\frac{\ell}{\ell_p}\right)^2 (n - N_0 + 9N_1 - 16N_2 + 8N_3), \quad (3.1)$$

where ℓ_p is the Planck length and ℓ is a discretization scale [10]. More precisely, if one takes the expectation value of (3.1) over Poisson sprinklings, the difference between that expectation value and the Einstein-Hilbert action for M goes to zero as the sprinkling density ρ goes to infinity. Intuitively, (3.1) counts causal diamonds of varying volumes, and those volumes depend on curvature; the alternating signs are needed to cancel contributions from points that are “near” in proper distance but lie far down the light cone.

We can now write the path sum

$$\mathcal{Z}(\Omega) = \sum_{C \in \Omega} \exp \left\{ \frac{i}{\hbar} I_{BD}(C) \right\} \quad (3.2)$$

over some collection Ω of n -element causal sets, and ask whether it is suppressed. This is not easy, since the number of distinct n -element causal sets increases as $2^{\frac{n^2}{4} + \frac{3}{2}n + o(n)}$. But as shown

[‡]Note that conventions vary in the literature; our N_J is sometimes called N_{J+1}

in [7], if we take Ω to be the set of two-layer causal sets, the sum (3.2) can be evaluated. The simplification comes from the fact that in a two-layer set, the only order intervals are links, so the action (3.1) depends only on n and N_0 . A combinatoric argument then tightly bounds the number of sets with a given value of $p = N_0/N_0^{\max}$. For large n , the sum (3.2) can then be approximated by an integral over p and evaluated by steepest descent. The result is that for

$$\tan \left[\sqrt{\frac{2}{3}} \left(\frac{\ell}{\ell_p} \right)^2 \right] > \left(\frac{27}{4} e^{-1/2} - 1 \right)^{1/2} \quad (3.3)$$

$\mathcal{Z}(\mathcal{C}_{2\text{-layer}})$ goes as 2^{-cn^2} for some positive constant c . If the discreteness occurs near the Planck scale, this is a truly enormous suppression: a spacetime region of one cubic centimeter times one nanosecond already contains $n \sim 10^{133}$ Planck volumes.

The two-layer sets are the second most common “bad” causal sets, so this is a hopeful sign. As a next step, these results were partially generalized in [8] to the KR orders, the most common “bad” sets. To do so, though, the authors of [8] had to restrict themselves to the “link action”

$$\frac{I_{\text{link}}(C)}{\hbar} = 2\sqrt{\frac{2}{3}} \left(\frac{\ell}{\ell_p} \right)^2 (n - N_0) \quad (3.4)$$

rather than the full Benincasa-Dowker action (3.1). The action then again depends only on the ratio $p = N_0/N_0^{\max}$, and a similar combinatoric argument bounds the number of sets with a given value of p . In the end, one obtains exactly the same condition (3.3) on the couplings, and the same superexponential suppression. This is already very interesting since it suggests that the calculation of [7] for bi-layer orders contains a crucial nugget relevant to all k -layer orders.

In the remainder of this paper, we will show that the simplification (3.4) is harmless. For KR orders, and probably all layered causal sets, the difference between the link action and the full Benincasa-Dowker action is negligible in the large n limit.

4 KR Counting and combinatorics

Let us start with an intuitive sketch of our argument. Note first that for the dominant layered causal sets, the link term N_0 in the Benincasa-Dowker action (3.1) goes as n^2 for large n [6]. In the calculations of [7] and [8], subleading terms of order n in the action were discarded. Such terms could perhaps be treated perturbatively at large n , but they should not be relevant for the question at hand. In order for the N_1 , N_2 , and N_3 terms in the Benincasa-Dowker action to not be similarly negligible, they, too, must grow as n^2 .

For causal sets obtained from sprinklings in flat spacetime, it is indeed the case that the ratio N_J/N_0 remains finite as n goes to infinity [11], so the N_J in the Benincasa-Dowker action remain comparable. Layered sets, though, behave differently. Figure (2a) shows a one-element interval $I(x, y)$ in a three-layer set, which contributes to N_1 . As figure (2b) shows, though, if there is a second path from x to y , $I(x, y)$ becomes a two-element interval, which contributes to N_2 but *not* to N_1 . In figure (2c), the addition of a third path changes $I(x, y)$ to a three-element interval, contributing only to N_3 . For small causal sets, this is not an issue. But for large sets, with many points in intermediate layers, typical pairs $x \prec y$ are connected by a great many paths, so N_J is small for small J .

4.1 The link matrix

To make this argument quantitative, we need one more ingredient. The link matrix \mathcal{L} of a causal set with elements x_i is essentially a directed adjacency matrix: $\mathcal{L}_{ij} = 1$ if $I(x_i, x_j)$ is a link and $x_i \prec x_j$, and zero otherwise. For a three-layer set, with layers L_1, L_2, L_3 , the matrix \mathcal{L} has the structure

$$\mathcal{L} = \begin{pmatrix} L_1 & L_2 & L_3 \\ 0 & P & Q \\ 0 & 0 & R \\ 0 & 0 & 0 \end{pmatrix} \begin{matrix} L_1 \\ L_2 \\ L_3 \end{matrix}, \quad \mathcal{L}^2 = \begin{pmatrix} L_1 & L_2 & L_3 \\ 0 & 0 & PR \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{matrix} L_1 \\ L_2 \\ L_3 \end{matrix} \quad (4.1)$$

In general, the (ij) entry in \mathcal{L}^r is equal to the number of directed r -step walks from x_i to x_j . For a three-layer causal set, such a walk is necessarily either a link or a two-step walk, so $r \leq 2$. Each two-step directed walk between x_i in layer 1 and x_j in layer 3 must include a point in layer 2, which is then a point in the order interval $I(x_i, x_j)$. In figure (2a), for instance, the single directed walk from x to y corresponds to a one-element order interval; in figure (2b), the two directed walks correspond to a two-element interval. In general, for $J > 0$, the number N_J of J -element order intervals—the number that appears in the Benincasa-Dowker action—is equal to the number of entries in \mathcal{L}^2 for which $(\mathcal{L}^2)_{ij} = J$.

Our strategy for computing N_J will be to find the probability $Pr(N_J = K)$ for a random three-layer causal set, and then to use the fact that the total number of such sets goes as $2^{n^2/4}$. We will assume that the number of points in each layer is proportional to n —that is, that layers don't disappear as n becomes large—and that there are fixed probabilities for links between layer 1 and layer 2, and between layer 2 and layer 3. Specifically, denoting by $|L_i|$ the number of points in layer i , let

$$|L_1| = \gamma_1 n, \quad |L_2| = \gamma_2 n, \quad |L_3| = \gamma_3 n \quad (\text{with } \gamma_1 + \gamma_2 + \gamma_3 = 1) \quad (4.2)$$

$$\text{Probability } p \text{ of a link from a point in } L_1 \text{ to a point in } L_2 \quad (4.3)$$

$$\text{Probability } q \text{ of a link from a point in } L_2 \text{ to a point in } L_3 \quad (4.4)$$

Next look more carefully at the link matrix (4.1). In \mathcal{L}^2 , PR is an $|L_1| \times |L_3|$ matrix, whose (ij) entry is a dot product of two vectors of length $|L_2| = \gamma_2 n$, namely $\mathbf{P}_{(i)} = P_{(i)k}$ and $\mathbf{R}_{(j)} = R_{k(j)}$, where k designates the component while i and j are treated as fixed labels. So the problem is to

- (i) compute the probability P_J that this dot product is J for a random causal set;
- (ii) compute the probability $Pr(N_J = K)$ that exactly K such products appear in PR ;
- (iii) find the number of causal sets with $N_J = K$, and see how it behaves in the large n limit.

4.2 Computing P_J

We are looking at the product of the vectors $\mathbf{P}_{(i)} = P_{(i)k}$ and $\mathbf{R}_{(j)} = R_{k(j)}$. Now, P_{ik} is 1 if e_i in layer 1 links to e_k in layer 2, which occurs with a probability p , while R_{kj} is 1 if e_k in layer 2 links to e_j in layer 3, which occurs with a probability q . Thus the probability that a *fixed* set of J components in $\mathbf{P}_{(i)} \cdot \mathbf{R}_{(j)}$ have value 1 and the remainder have value 0 is

$$(pq)^J (1 - pq)^{\gamma_2 n - J}.$$

But there are $\binom{\gamma_2 n}{J}$ ways of choosing these J components, so

$$P_J = \binom{\gamma_2 n}{J} (pq)^J (1 - pq)^{\gamma_2 n - J} \quad (4.5)$$

Note that the leading behavior of P_J for fixed J and large n is

$$P_J \sim A_J n^J \alpha^{\gamma_2 n} \quad (4.6)$$

with $\alpha = 1 - pq < 1$, so for fixed J , $P_J \rightarrow 0$ as $n \rightarrow \infty$.

4.3 Computing $Pr(N_J = K)$

The matrix PR has $|L_1| \times |L_3| = \gamma_1 \gamma_3 n^2$ entries, each having a probability P_J of equaling J . Thus the probability that a *fixed* set of K entries have value J and the remainder do not is

$$P_J^K (1 - P_J)^{\gamma_1 \gamma_3 n^2 - K}$$

But there are $\binom{\gamma_1 \gamma_3 n^2}{K}$ ways of choosing such entries. Hence

$$Pr(N_J = K) = \binom{\gamma_1 \gamma_3 n^2}{K} P_J^K (1 - P_J)^{\gamma_1 \gamma_3 n^2 - K} \quad (4.7)$$

4.4 Large n asymptotics

For a three-layer set, the maximum value of N_1 is achieved when there is exactly one path between each point in layer 1 and each point in layer 3. Since there are $\gamma_1 n$ points in layer 1 and $\gamma_3 n$ points in layer 3, $N_1^{\max} = \gamma_1 \gamma_3 n^2$. N_2^{\max} and N_3^{\max} take the same value, although the maxima can't be reached simultaneously. Since we are interested in the question of whether the N_J grow as n^2 , let us take

$$K = s N_J^{\max} = s \gamma_1 \gamma_3 n^2 \quad (4.8)$$

and look at the large n behavior of $Pr(N_J = K)$.

Begin with the last term in (4.7). For large n , P_J is exponentially small, so by (4.6),

$$\ln(1 - P_J)^{\gamma_1 \gamma_3 n^2 - K} \sim -(1 - s) \gamma_1 \gamma_3 n^2 P_J \sim -(1 - s) \gamma_1 \gamma_3 A_J n^{J+2} \alpha^{\gamma_2 n} \quad (4.9)$$

which goes to zero exponentially for large n . Hence

$$(1 - P_J)^{\gamma_1 \gamma_3 n^2 - K} \sim 1 - \text{exponentially small corrections} \quad (4.10)$$

Inserting back into (4.7),

$$Pr(N_J = K) \sim \binom{\gamma_1 \gamma_3 n^2}{s \gamma_1 \gamma_3 n^2} (A_J n^J \alpha^{\gamma_2 n})^{s \gamma_1 \gamma_3 n^2} \quad (4.11)$$

The binomial coefficient in (4.11) is maximum when $s = \frac{1}{2}$, where

$$\binom{\gamma_1 \gamma_3 n^2}{s \gamma_1 \gamma_3 n^2} \sim 2^{\gamma_1 \gamma_3 n^2}$$

But the term that follows has a leading behavior

$$\alpha^{s \gamma_1 \gamma_2 \gamma_3 n^3} = 2^{-s \gamma_1 \gamma_2 \gamma_3 |\log_2 \alpha| n^3}$$

which clearly dominates for large n . Thus the asymptotic behavior is

$$Pr(N_J = s N_J^{\max}) \sim 2^{-s \gamma_1 \gamma_2 \gamma_3 |\log_2 \alpha| n^3} \quad (4.12)$$

4.5 Implications for the action

The Benincasa-Dowker action (3.1) and the link action (3.4) differ by terms proportional to N_1 , N_2 , and N_3 . For KR orders, or more generally three-layer causal sets, we can now answer the question of whether this difference matters. As noted earlier, the leading term in both actions is proportional to N_0 , which for layered causal sets goes as n^2 for large n . For the N_1 , N_2 , and N_3 terms in the Benincasa-Dowker action to give more than subleading corrections, they, too, must grow as n^2 . We can now see that they do not.

Indeed, pick arbitrarily small constants ε_J , and ask how many three-layer causal sets have $N_J > \varepsilon_J n^2$. From (4.8) and (4.11), the probability that any particular causal set satisfies this condition is

$$Pr(N_J > \varepsilon_J n^2) \sim \int_{\varepsilon_J / \gamma_1 \gamma_3}^1 ds \, 2^{-s \gamma_1 \gamma_2 \gamma_3 |\log_2 \alpha| n^3} \sim 2^{-\varepsilon_J \gamma_2 |\log_2 \alpha| n^3} \quad (4.13)$$

where the integral is dominated by its lower limit. But the total number of three-layer set with n elements increases only as $2^{n^2/4}$. Thus for large enough n , the expected number of three-layer sets that contribute more than subleading corrections to the Benincasa-Dowker action is zero.

We can further strengthen this result. Let us ask a weaker question: how many three-layer sets have $N_J > \beta_J n$ for some fixed constants β_J ? From (4.7),

$$Pr(N_J = \beta_J n) = \binom{\gamma_1 \gamma_3 n^2}{\beta_J n} P_J^{\beta_J n} (1 - P_J)^{\gamma_1 \gamma_3 n^2 - \beta_J n} \quad (4.14)$$

As before, the last term is very nearly one, while the binomial coefficient is now

$$\binom{\gamma_1 \gamma_3 n^2}{\beta_J n} \sim \left(\frac{\gamma_1 \gamma_3 e}{\beta_J} n \right)^{\beta_J n}$$

For large enough n , the leading behavior of $Pr(N_J = \beta_J n)$ is again controlled by the term

$$P_J^{\beta_J n} \sim 2^{-\beta_J \gamma_2 |\log_2 \alpha| n^2}$$

Thus

$$Pr(N_J > \beta_J n) \sim \int_{\beta_J}^{\gamma_1 \gamma_3 n} d\beta' 2^{-\beta' \gamma_2 |\log_2 \alpha| n^2} \sim 2^{-\beta_J \gamma_2 |\log_2 \alpha| n^2} \quad (4.15)$$

Again, the number of three-layer causal sets goes as $2^{n^2/4}$, so for large n , the expected number of such sets is

$$\#(N_J > \beta_J n) \sim 2^{(\frac{1}{4} - \beta_J \gamma_2 |\log_2 \alpha|) n^2} \quad (4.16)$$

For

$$\beta_J > \frac{1}{4\gamma_2 |\log_2 \alpha|} \quad (4.17)$$

this number falls to zero very quickly as n becomes large.

We conclude that for three-layer sets, including KR orders, the terms $N_{J>0}$ in the Benincasa-Dowker action (3.1) increase at large n at most as

$$N_J \sim \frac{n}{4\gamma_2 |\log_2 \alpha|} \quad (4.18)$$

This makes them subleading corrections to the link action. The superexponential suppression of KR orders found in [8] is therefore not just a feature of the link action, but holds for the full Benincasa-Dowker action, the causal set analog of the Einstein-Hilbert action. The gravitational path integral suppresses KR orders.

5 Conclusion

We have seen that for a large range of couplings, the gravitational path sum with the discretized Einstein-Hilbert action strongly suppresses the two largest classes of “bad” causal sets, the KR orders and the two-layer sets. An obvious question is whether these results can be generalized to the whole hierarchy of layered causal sets described in [5,6]. To show this would require two steps: a generalization of this work to justify using the link action, and an extension of the results of [8] beyond the KR case.

The first step is almost certainly possible. While the combinatorics becomes more complicated, the qualitative argument of section 4 continues to hold for sets with more than three layers. Work on the details is in progress. As for the second step, the results of [8] are in fact stronger than stated. For a fixed number of links the leading order contribution to all k -layer orders comes from the link maximizing configurations, which are precisely the KR and symmetric two-layer orders. Thus, even when the k -layers are included in the sum, they do not contribute to leading order.

Of course, even if one can show that all layered causal sets are suppressed, this is not quite enough to show the emergence of a continuum from the gravitational path integral. There are certainly other non-manifoldlike causal sets that do not have a simple layered structure. More generally, while we have an explicit construction of manifoldlike causal sets, we do not yet have a good intrinsic characterization of such sets. Still, though, the layered sets make up such an enormous share of the “bad” causal sets that their elimination is a major step forward.

Finally, if causal sets are primary and the continuum is emergent, a deeper question remains. The Benincasa-Dowker action (3.1) came from the continuum, starting with causal sets that

were constructed by hand to be manifoldlike and looking for an approximation of the continuum Einstein-Hilbert action. The most obvious tie to the continuum and classicality is the dimension, which we have assumed to be 4 in the Benincasa-Dowker action (3.1). In arbitrary dimensions as well, the Benincasa-Dowker-Glaser action [12, 13] is an alternating sum over the N_J , where J ranges from 0 to a dimension dependent J_{\max} . Thus our results show more generally that the link action suffices to suppress KR orders in any dimension. At a more fundamental level, however, what is really needed is a derivation of the action from first principles, entirely within the context of causal sets.
