ABSTRACT

We use the BayeSN hierarchical probabilistic SED model to analyse the optical–NIR (*BVriYJH*) light curves of 86 Type Ia supernovae (SNe Ia) from the Carnegie Supernova Project to investigate the SN Ia host galaxy dust law distribution and correlations between SN Ia Hubble residuals and host mass. Our Bayesian analysis simultaneously constrains the mass step and dust R_V population distribution by leveraging optical–NIR colour information. We demonstrate how a simplistic analysis where individual R_V values are first estimated for each SN separately, and then the sample variance of these point estimates is computed, overestimates the R_V population variance σ_R^2 . This bias is exacerbated when neglecting residual intrinsic colour variation beyond that due to light curve shape. Instead, Bayesian shrinkage estimates of σ_R are more accurate, with fully hierarchical analysis of the light curves being ideal. For the 75 SNe with low-to-moderate reddening (peak apparent $B - V \leq 0.3$), we estimate an R_V distribution with population mean $\mu_R = 2.59 \pm 0.14$, and standard deviation $\sigma_R = 0.62 \pm 0.16$. Splitting this subsample at the median host galaxy mass ($10^{10.57} M_\odot$) yields consistent estimated R_V distributions between low- and high-mass galaxies, with $\mu_R = 2.79 \pm 0.18$, $\sigma_R = 0.42 \pm 0.24$, and $\mu_R = 2.35 \pm 0.27$, $\sigma_R = 0.74 \pm 0.36$, respectively. When estimating distances from the full optical–NIR light curves while marginalising over various forms of the dust R_V distribution, a mass step of $\gtrsim 0.06$ mag persists in the Hubble residuals at the median host mass.

Key words: supernovae: general – cosmology: distance scale – ISM: dust, extinction – methods: statistical

1 INTRODUCTION

One of the most well-known correlations between Type Ia supernovae (SNe Ia) and their host galaxies is the so-called “mass step”. This is an empirical effect whereby SNe Ia in high mass galaxies are observed to be systematically brighter, post-standardisation, than their counterparts in lower mass hosts (Kelly et al. 2010; Sullivan et al. 2010). Many past studies (e.g. Sullivan et al. 2010; Childress et al. 2014; Kim et al. 2018; Rigault et al. 2020; Briday et al. 2022) have linked this to a difference in the populations of SN Ia progenitors between more and less massive host galaxies, something that could arise from a “prompt/delayed” progenitor model (à la Mannucci et al. 2005, 2006; Scannapieco & Bildsten 2005). Such a host-dependent progenitor scenario could also explain observed correlations between light curve shape and host properties (see e.g. Hamuy et al. 1996, 2000; Sullivan et al. 2006; Childress et al. 2014; Nicolas et al. 2021). Alternatively, it has recently been proposed that the mass step can be explained by a difference in host galaxy properties, based on analyses at optical wavelengths (Brout & Scolnic 2021; Popovic et al. 2021). However, recent findings that the mass step may extend to the near-infrared (NIR) would seem to be in tension with this (Ponder et al. 2021; Uddin et al. 2020; Jones et al. 2022), although the strength

of any NIR mass step is currently uncertain (Ponder et al. 2021; Johansson et al. 2021; Jones et al. 2022). The interplay between dust and host mass (see e.g. Brout & Scolnic 2021; González-Gaitán et al. 2021; Thorp et al. 2021; Johansson et al. 2021; Popovic et al. 2021; Meldorf et al. 2022; Wiseman et al. 2022), and the distribution of dust properties in SN Ia hosts more broadly, remains controversial, and the problem of accurately estimating the effect of dust on SN Ia observations is a challenging one. In this paper, we use our BAYESN model (Thorp et al. 2021; Mandel et al. 2022) for the optical–NIR spectral energy distributions (SEDs) of SNe Ia to place constraints on the SN Ia host galaxy dust law distribution via an analysis of optical and NIR data from the Carnegie Supernova Project. In parallel to this, we investigate the sensitivity of the mass step to a variety of assumptions about the distribution of host galaxy dust laws. We also present an argument for the importance of high quality optical and NIR data, and a simulation-based study demonstrating some of the challenges inherent in estimating the dust law distribution, and how these can be overcome using hierarchical Bayes.

The SN Ia mass step (Kelly et al. 2010; Sullivan et al. 2010) is an observed tendency for SNe Ia in high mass galaxies to have brighter post-standardisation magnitudes (or more negative Hubble residuals) than those in low-mass host galaxies. In optical magnitudes (or in Hubble residuals derived from optical light curves), a step of ~ 0.04 – 0.1 mag has typically been observed (Kelly et al. 2010; Sullivan et al.

2010; Childress et al. 2013; Betoule et al. 2014; Roman et al. 2018; Scolnic et al. 2018; Jones et al. 2018, 2019; Smith et al. 2020; Kelsey et al. 2021), located at host masses between $\sim 10^{10} M_{\odot}$ (e.g. Sullivan et al. 2010) and $10^{10.8} M_{\odot}$ (e.g. Kelly et al. 2010). Magnitude steps versus other host galaxy properties – particularly (local) specific star formation rate (Lampeitl et al. 2010; Rigault et al. 2013, 2015, 2020; Jones et al. 2018; Kim et al. 2018; Briday et al. 2022) – have also been observed. Although empirically well studied in the optical, the possibility of a NIR mass step has only been investigated in a small number of recent works (Ponder et al. 2021; Uddin et al. 2020; Johansson et al. 2021; Jones et al. 2022).

Ponder et al. (2021) assembled a sample of 143 SNe Ia with NIR light curves, based on a compilation (Weyant et al. 2014) sourced from the CfA/CfAIR Supernova Survey (Wood-Vasey et al. 2008; Friedman et al. 2015), Carnegie Supernova Project (CSP-I; Contreras et al. 2010; Stritzinger et al. 2011), SweetSpot (Weyant et al. 2014, 2018), the Barone-Nugent et al. (2012) sample, and elsewhere (Jha et al. 1999; Hernandez et al. 2000; Krisciunas et al. 2000, 2003, 2004a,b, 2007; Valentini et al. 2003; Phillips et al. 2006; Pastorello et al. 2007a,b; Stanishev et al. 2007; Pignata et al. 2008). They find that the peak H -band magnitudes of their sample tend to be brighter for the supernovae in more massive host galaxies. For a step in H -band magnitude at a host stellar mass of $10^{10.43} M_{\odot}$ (preferred based on the Akaike Information Criterion), they find a magnitude difference of 0.13 ± 0.04 . Omitting prominent outliers reduces this to 0.08 ± 0.04 mag, at a preferred step location of $10^{10.65} M_{\odot}$. For the same set of supernovae, they find that the Hubble residuals computed from stretch- and colour-corrected optical data favour a step at $10^{10.65} M_{\odot}$, with a size of 0.14 ± 0.04 mag (and at $10^{10.43} M_{\odot}$, they estimate an optical mass step of 0.10 ± 0.03 mag).

Uddin et al. (2020) observe a similar effect in a sample of 113 SNe Ia taken from CSP-I (Krisciunas et al. 2017). Fitting their light curves using SNooPy (Burns et al. 2011), they infer a distance estimate (and thus a Hubble residual) for each supernova in each passband (of $uBgVriYJH$). Then, assuming a step in Hubble residual located at their median host stellar mass ($\sim 10^{10.48} M_{\odot}$), they compute step sizes by taking the weighted average of the Hubble residuals either side of their step. This yields a step of $\geq 2\sigma$ across all passbands, including in the NIR. Their H -band step is of size 0.093 ± 0.043 mag, consistent with that of Ponder et al. (2021). In the J -band, they estimate a step of 0.090 ± 0.046 mag.

In their NIR mass step analysis, Johansson et al. (2021) combine a sample of ~ 200 literature SNe Ia (mainly CfA/CfAIR and CSP-I, plus others from Barone-Nugent et al. 2012; Stanishev et al. 2018; Amanullah et al. 2015) with ~ 40 more observed as part of their own survey using the intermediate Palomar Transient Factory (iPTF; Rau et al. 2009) and Reionization and Transients InfraRed Camera (RATIR; Butler et al. 2012). They split their sample at $10^{10} M_{\odot}$, and used SNooPy (Burns et al. 2011) to fit the optical and NIR light curves. With a fixed host galaxy dust law $R_V = 2.0$ (close to the weighted sample mean of $\mu_R = 1.9$ that they estimate from individual SNooPy fits to all $0.06 < E(B - V) < 0.5$ SNe), they estimate NIR mass steps of 0.021 ± 0.033 mag in the J -band, and -0.020 ± 0.036 mag in the H -band – both consistent with zero (although also within 1.2 and 2.0σ , respectively, of the J - and H -band steps estimated by Uddin et al. 2020). This is contrasted with a step of 0.070 ± 0.030 mag estimated from the optical ($BgVri$), and a step very similar in size to this in the Y -band (see their fig. 13). When using an individually-fitted host galaxy R_V for every supernova, they claim a mass step consistent with zero across the full optical–NIR ($BgVriYJH$) range (see Johansson et al. 2021, fig. 13).

Most recently, Jones et al. (2022) combined a sample of 42 low-

redshift ($z < 0.1$) SNe Ia from CSP-I, with 37 higher-redshift ($0.2 < z < 0.7$) SNe Ia with rest frame NIR observations obtained for the RAISIN programme using the *Hubble Space Telescope* (*HST*). Using the NIR light curves of their combined sample of 79 SNe, they estimate a mass step of 0.072 ± 0.041 mag at $10^{10} M_{\odot}$. Placing the step instead at a host mass of $10^{10.44} M_{\odot}$ (the best-fitting step location reported by Ponder et al. 2021), they estimate a slightly smaller step of 0.057 ± 0.035 mag. They find similar sized steps when using the high- z *HST* data alone, but these are more uncertain. From optical data, they find a Hubble residual step of 0.11 ± 0.03 mag using SNooPy (Burns et al. 2011), and 0.08 ± 0.03 mag using SALT2 (Guy et al. 2007, 2010; Betoule et al. 2014) or SALT3 (Kenworthy et al. 2021).

The possible extension of the mass step into the NIR has important implications for the underlying physical cause of SN–host correlations. It has been suggested by Brout & Scolnic (2021) and Popovic et al. (2021) that differing distributions of the host galaxy dust law R_V in galaxies greater or less massive than $10^{10} M_{\odot}$ can explain the conventional optical mass step. However, the detection of a significant mass step in the NIR, where sensitivity to dust extinction (and particularly to the value of R_V) is reduced, would seem at odds with such an explanation (Ponder et al. 2021; Uddin et al. 2020)¹. If the variation of dust properties with host galaxy mass cannot adequately explain the mass step, it would suggest that host mass traces (perhaps imperfectly) something about the intrinsic properties of SNe Ia. Whatever the case, any physical explanation for the mass step must be able to explain the fact that such steps have been observed in the literature following a variety of different SN Ia standardisation approaches, and when splitting at a range of different host masses between $\sim 10^{10}$ and $10^{10.8} M_{\odot}$ (e.g. Kelly et al. 2010; Sullivan et al. 2010; Childress et al. 2013; Uddin et al. 2020; Smith et al. 2020; Kelsey et al. 2021; Ponder et al. 2021).

The interpretation of the mass as a tracer of intrinsic SN Ia properties has recently been supported by Briday et al. (2022), in their analysis of 110 low redshift SNe Ia observed by the Nearby Supernova Factory (SNfactory; Aldering et al. 2002, 2020; Rigault et al. 2020). They found that the data were well modelled as coming from two underlying populations, best traced by local specific star formation rate (lsSFR) or total host galaxy stellar mass, and differing in post-standardization magnitude by ≥ 0.12 mag. Additionally, they combine literature reports of magnitude steps versus different host properties (lsSFR; Rigault et al. 2020; UV – optical colour; Roman et al. 2018; Kelsey et al. 2021; global mass; Roman et al. 2018; Smith et al. 2020; local mass; Jones et al. 2018; Kelsey et al. 2021; morphology; Pruzhinskaya et al. 2020) with their own equivalent results, concluding that the different step sizes follow naturally from their estimates of how well different host properties delineate between underlying SN Ia populations. Given that they find lsSFR to be the strongest environmental tracer of a magnitude step, they surmise that progenitor age is likely the fundamental property separating the two SN Ia populations that give rise to the mass step. This agrees with previous magnitude step studies (e.g. Rigault et al. 2013, 2020; Roman et al. 2018; Kim et al. 2018), and would align well with a “prompt/delayed” progenitor model (see e.g. Mannucci et al. 2005, 2006; Scannapieco & Bildsten 2005).

¹ Although, it is worth acknowledging that the non-detection of a NIR mass step does not necessarily imply that dust *does* explain the mass step. It could simply be that intrinsic differences between SN Ia populations in low- and high-mass hosts are less prominent in the NIR. Such a result might not be surprising, given the generally lower intrinsic variation seen amongst normal SNe Ia observed in the NIR (see e.g. Avelino et al. 2019).

A point of contention in recent studies of correlations between SNe Ia and their hosts has been the impact of host galaxy dust – particularly the distribution of the dust law R_V parameter. Along sight lines within the Milky Way, R_V has been found to follow a nearly Gaussian distribution (Schlafly et al. 2016, fig. 15) with small dispersion ($\sigma_R \approx 0.2$) and a mean of $\mu_R \approx 3.3$. Along sight lines in SN Ia host galaxies, a definitive constraint on the R_V distribution has proven elusive. In their study of the mass step, Brout & Scolnic (2021) found that SN Ia survey simulations with wide ($\sigma_R = 1.3 \pm 0.2$) Gaussian population distributions of R_V (with means of 2.75 ± 0.35 and 1.50 ± 0.25 , respectively, in low- and high-mass hosts) provided the best match to the SALT2 (Guy et al. 2007, 2010) fits of the optical light curves of a sample of 1445 real SNe Ia (from CSP-I; the CfA; Hicken et al. 2009, 2012; Foundation; Foley et al. 2018; Jones et al. 2019; the Pan-STARRS-1 Medium Deep Survey Rest et al. 2014; Scolnic et al. 2018; Supernova Legacy Survey; Astier et al. 2006; Betoule et al. 2014; SDSS-II; Frieman et al. 2008; Sako et al. 2011, 2018; and the Dark Energy Survey; Dark Energy Survey Collaboration et al. 2016; Brout et al. 2019). A limitation of this approach lies in the use of SALT2’s c parameter (roughly equivalent to apparent $B - V$ colour at peak) as a single proxy for all the colour information in the full SN Ia light curves. When the data are reduced to such a summary, considerable care must be taken to avoid a confounding of the intrinsic colour distribution and the effect of dust (see Mandel et al. 2017). A related limitation is that SALT2 employs a single fixed colour law that translates the apparent colour parameter into an effect on the SED, and so it cannot properly accommodate the impact of variable dust laws on the SED.

The physical effect of dust in the narrow optical $B - V$ wavelength range also should produce effects consistent with dust over a wider span of wavelengths. Hence, for reliable inference of R_V , it is preferable to model the effect of dust on the full light curves and their underlying SEDs directly, ideally in both the optical and NIR, thereby leveraging a wider range of colour information across the full time-varying SED in order to break degeneracies (see e.g. Krisciunas et al. 2007; Mandel et al. 2011, 2022). This is the approach we take in this paper.

In their recent study, Johansson et al. (2021) also investigated the trade-off between the mass step and the distribution of R_V in SN Ia hosts. Their analysis used the SNooPY light curve model (Burns et al. 2011) to fit the full range of optical and NIR data. However, they estimate the population distribution of R_V from a collection of independent fits to their sample of SNe Ia, taking the best-fitting values of R_V for each individual and constructing a distribution from these. A statistical pitfall inherent in using a collection of individual R_V point estimates is that these will likely be over-dispersed, due to the individual estimation errors, compared to the underlying population distribution, meaning the width of the population distribution can easily be overestimated by taking the sample standard deviation of these. This can be remedied by adopting a hierarchical Bayesian approach (see e.g. Mandel et al. 2011, Burns et al. 2014, Thorp et al. 2021, for examples in this context; or Loredo & Hendry 2010, 2019, for a pedagogical discussion). However, difficulty can still arise if the diversity of SN Ia intrinsic colours is not included within the model used to estimate R_V (e.g. the SNooPY `color_model` used by Johansson et al. 2021 does not account for any residual intrinsic colour variation beyond the stretch–colour relationship inferred in Burns et al. 2014). Not allowing for the intrinsic colour scatter of SNe Ia is known to bias R_V estimates (see Mandel et al. 2017), and could easily lead one to overestimate the amount of apparent colour dispersion that should be attributed to a range of R_V values (see discussion in Thorp et al. 2021, §4.3.2). We will explore these chal-

lenges in more depth later in this paper (in §5), and will demonstrate how they can be alleviated.

A hierarchical Bayesian approach to the modelling and inference of the dust law R_V distribution in SN Ia host galaxies was first developed, and applied to a sample of optical and NIR light curves, by Mandel et al. (2011). The BAYESN light curve modelling framework of Mandel et al. (2009, 2011) was recently generalised to the modelling of SN Ia SEDs by Mandel et al. (2022), and applied by Thorp et al. (2021) to constrain the distribution of dust laws in the host galaxies of 157 SNe Ia from the Foundation Supernova Survey (Foley et al. 2018; Jones et al. 2019). In that analysis, Thorp et al. (2021) allowed for different R_V population distributions in low- and high-mass host galaxies, including this within their hierarchical model alongside a conventional host galaxy mass step. Unlike Brout & Scolnic (2021), Thorp et al. (2021) concluded that the distribution of dust laws was not significantly different in low- and high-mass hosts, and that a scenario where a large offset in mean R_V replaced the conventional mass step was not favoured. Their results also favoured an overall small dispersion in R_V across their sample (with population standard deviation $\lesssim 0.6$ with 95 per cent posterior probability). Their analysis was able to leverage all available photometry from the g -through to the z -band ($3500 \lesssim \lambda \lesssim 9500 \text{ \AA}$), within their hierarchical Bayesian framework, to inform the dust constraints. However, the inclusion of data further into the NIR, and the consideration of SNe Ia with redder apparent colours ($B - V > 0.3$), has the potential to yield much stronger constraints and new insights.

In this work, we build on the advances made by Thorp et al. (2021) and present an analysis of 86 SNe Ia from CSP-I (Krisciunas et al. 2017). We investigate the strength of the host galaxy mass step in the Hubble residuals for this sample. Our analysis is carried out using BAYESN fits to the full optical+NIR light curves, and to the NIR light curves alone. We focus particularly on whether the treatment of host galaxy dust laws impacts the mass step in Hubble residuals estimated from joint fits to the optical and NIR. We are able to draw conclusions about both the mass step, and the host galaxy dust law R_V population distribution. Using the CSP sample enables us to leverage a wider wavelength range ($BVriYJH$ passbands; $\approx 3500\text{--}18000 \text{ \AA}$) than was possible with the Foundation data ($griz$ passbands; $\approx 3500\text{--}9500 \text{ \AA}$) used in Thorp et al. (2021), enabling stronger constraining power for the dust law R_V values of individual SNe. Additionally, we are able to include more highly reddened supernovae, allowing us to explore the possibility that R_V evolves with reddening/extinction (also studied by Mandel et al. 2011; Burns et al. 2014). We also verify that our results are robust to the assumption of some non-Gaussian forms for the R_V population distribution.

In Section 2, we describe the sample of 86 CSP SNe Ia used in this work. In Section 3, we describe the BAYESN SN Ia SED model (§3.1), the different photometric distance fitting procedures we adopt (§3.2), the posterior distributions that we sample in each case (§3.3), our estimation of Hubble residuals from the photometric distances (§3.4), and our approach to estimating the size of the mass step in a set of Hubble residuals (§3.5). Before presenting our analysis of the CSP data, we include two sections motivating the benefit of combining optical and NIR data for constraining dust (§4), and the benefit of the hierarchical Bayesian approach (§5). In Section 6, we describe our results, with Section 6.1 focusing on the Hubble residual step, Section 6.2 covering our inferences about the R_V population distribution, Section 6.3 presenting results on a gold-standard SN Ia subsample with NIR data near maximum, and Section 6.4 discussing our R_V inferences for the most highly reddened SNe Ia. We offer final discussion and conclusions in Section 7.

2 DATA

In this work, we use a sample of 86 spectroscopically normal SNe Ia with optical and NIR light curves from CSP-I (Krisciunas et al. 2017). All have self-consistent mass estimates, obtained using Z-PEG (Le Borgne & Rocca-Volmerange 2002), from Uddin et al. (2020). Our sample of 86 is a subset of the 113 supernovae used in the analysis of Uddin et al. (2020). The Uddin et al. (2020) sample is the full CSP sample (134 SNe), minus 13 SNe deemed to be peculiar, 7 with ambiguous hosts, and 1 with a poor quality light curve (see Uddin et al. 2020, §2.1–2.2 for details). Of the 113 SNe in the Uddin et al. (2020) sample, 100 have near-infrared light curves (those without are: 2005W, 2005be, 2005bg, 2005bl, 2005bo, 2005ir, 2005mc, 2006ef, 2006fw, 2006py, 2007ol, 2008bz, 2008cd). We apply a stricter cut on spectroscopic normality, bringing this down to 86. Compared to the 100 SNe with NIR light curves in Uddin et al. (2020), we have eliminated 9 SNe (2004gu, 2005ke, 2006bd, 2006gt, 2006mr, 2007N, 2007ax, 2007ba, 2009F; mostly 91bg-like) identified as Iapec in Friedman et al. (2015, table 3), and 5 SNe identified as 91bg-like (2007al, 2008bi, 2008bt), 86G-like (2007jh), or not subtyped (2007cg) in Krisciunas et al. (2017). We analyse this sample of 86 SNe Ia, and its partitions, for the remainder of this work. Table 1 summarises the cuts leading to this sample.

For all of these supernovae, we estimate values of BAYESN’s light curve shape parameter, θ_1 (strongly correlated with optical decline rate; see section 3.1 for definition), that are within the range spanned by the original Mandel et al. (2022) training set. Unlike for the BAYESN training set (see Avelino et al. 2019; Mandel et al. 2022), we do not impose requirements on the temporal coverage of the light curves. We estimate that 75 out of the 86 SNe have apparent $B - V \leq 0.3$ (consistent with the cut typically applied in cosmological analyses), but we do not exclude the redder supernovae at this stage. The sample covers a redshift range of $0.00365 \leq z_{\text{CMB}} \leq 0.08353$, with 11 SNe at $z_{\text{CMB}} < 0.01$, and 15 SNe at $z_{\text{CMB}} > 0.04$. The median host galaxy stellar mass of the sample (using the masses from Uddin et al. 2020) is $10^{10.57} M_{\odot}$. Figure 1 shows the redshift distribution of the sample, broken down by apparent $B - V$ colour and host galaxy mass. From this, we see that the low- vs. high-mass split is reasonably even across the redshift range. However, the supernovae with redder apparent colours ($B - V > 0.3$) are concentrated towards the lower end on the redshift distribution. Figure 2 shows a scatter plot of apparent $B - V$ colour vs. host mass. From this we can see that there is a fairly wide range of apparent colours on both sides of the median host mass ($10^{10.57} M_{\odot}$). The SNe with apparent $B - V \leq 0.3$ are distributed fairly evenly across this mass split, with 36 SNe at lower masses, and 39 at higher masses. The middle apparent colour bin ($0.3 < B - V \leq 0.7$) leans towards the lower mass side, with 6/7 SNe in this range having host masses less than the median. Conversely, the reddest SNe tend towards higher masses, with 3/4 of these SNe being in hosts more massive than the median.

Figure 1. CMB-frame redshift distribution of the 86 SNe Ia used in this work. Bins have a width of 0.01. (top panel) Bins subdivided by apparent $B - V$ colour. (bottom panel) Bins subdivided by host galaxy stellar mass (at the sample median, $10^{10.57} M_{\odot}$).

Figure 2. Apparent $B - V$ colours vs. host galaxy stellar mass for the 86 SNe Ia in our sample. Host mass estimates are from Uddin et al. (2020). The median host galaxy stellar mass ($10^{10.57} M_{\odot}$) is marked with a vertical black line. Supernovae with an estimated $z_{\text{CMB}} < 0.01$ are indicated as triangles with a black outlines.

As well as our fiducial sample of 86, we also carry out a limited number of analyses (see Section 6.3) with a “gold” subset of 28 SNe Ia. These are selected as the 28 SNe out of our fiducial sample that overlap with the “NIR@max” cut of Avelino et al. (2019); Mandel et al. (2022) – i.e. SNe with at least one NIR observation 2.5 d or more before the time of NIR maximum. This includes 28 out of the

30 CSP SNe from the Mandel et al. (2022, fig. 15) Hubble diagram – two SNe from there (2007A and 2008bf) are not included in our fiducial sample here due to ambiguous host galaxies (Uddin et al. 2020). This “gold” subsample are all low reddening ($B - V < 0.3$) by construction, and are all at $z < 0.04$. Their median host galaxy mass is $10^{10.545} M_{\odot}$ – very close to that of our full sample – but we do not use this subset for any calculations with a mass split due to its small size. Nevertheless, dust constraints from this sample are of interest, as we would expect the residual intrinsic colour scatter to be smallest here (this can be seen in Fig. 3).

In this paper, we will use the *BVriYJH* photometry from Krisciunas et al. (2017), for consistency with the passbands used in training our BAYESN SED model (see §3 or Mandel et al. 2022 for more information about the model training). We do not include the CSP *u*- or *g*-band data in our fits. Our experience has shown that inclusion of the latter does not significantly influence our results, in the kind of analysis presented here, as the *g*-band tends to be somewhat redundant with the *B*- and *V*-band when all three of these bands are available. We did not include *u/U*-band data in the training of the current BAYESN model, which was restricted to *B*-band and longer wavelengths. Given the potential value of the UV to questions of dust, intrinsic diversity, and SN–host correlations (see e.g. Brown et al. 2010; Foley et al. 2012; Foley & Kirshner 2013; Burns et al. 2014; Amanullah et al. 2015; Foley et al. 2016; Brown et al. 2017, 2018, 2019), its inclusion is a priority for future extensions of our model. Nevertheless, we demonstrate in Section 4 that optical–NIR photometry already contains substantial information in this regard.

3 ANALYSIS METHODS

We obtain our photometric distance estimates using the M20 version of the BAYESN SED model, described in Mandel et al. (2022). This was trained on data from CSP-I (Krisciunas et al. 2017), the CfA/CfAIR Supernova Surveys (Jha et al. 1999; Hicken et al. 2009, 2012; Wood-Vasey et al. 2008; Friedman et al. 2015), and elsewhere (Krisciunas et al. 2003, 2004a,b, 2007; Stanishev et al. 2007; Pignata et al. 2008; Leloudas et al. 2009), compiled in Avelino et al. (2019). Our fits are carried out using Stan’s (Carpenter et al. 2017; Stan Development Team 2021) standard Hamiltonian Monte-Carlo routine (Hoffman & Gelman 2014; Betancourt 2016a) to sample the target posterior distributions defined mathematically in §3.3. To assess the quality of our MCMC chains, we use a number of standard diagnostics and procedures. We run multiple (4) independent chains in parallel starting from different initial locations in parameter space. We assess the mixing and convergence of the chains using the \hat{R} (Gelman–Rubin) statistic and assess the effective sample size (Gelman & Rubin 1992; Vehtari et al. 2021), check that the estimated Bayesian fraction of missing information is not problematically low (Betancourt 2016b), and confirm that our chains are free from divergent transitions (see e.g. Betancourt et al. 2014; Betancourt & Girolami 2015; Betancourt 2017). The final photometric distance estimate, and its error, for a given supernova is taken from the posterior mean and standard deviation of its distance modulus, marginalising over all other parameters. The full technical details of the BAYESN model and photometric distance estimation process are described in Mandel et al. (2022), with a summary included below in Section 3.1.

3.1 The BAYESN Model

BAYESN models the rest-frame phase- and wavelength-varying host-dust-extinguished SED, $S_s(t, \lambda_r)$ of an SN Ia, s , via

$$-2.5 \log_{10}[S_s(t, \lambda_r)/S_0(t, \lambda_r)] = M_0 + W_0(t, \lambda_r) + \delta M_s + \theta_1^s W_1(t, \lambda_r) + \epsilon_s(t, \lambda_r) + A_V^s \xi(\lambda_r; R_V^{(s)}) \quad (1)$$

where t is rest-frame phase (relative to time of *B*-band maximum) and λ_r is rest-frame wavelength (Mandel et al. 2022, eq. 12). The optical–NIR SN Ia spectral template, $S_0(t, \lambda_r)$, of Hsiao et al. (2007), and a constant normalisation factor, $M_0 \equiv -19.5$, are fixed a priori. The function $W_0(t, \lambda_r)$ warps the baseline spectral template to yield a mean intrinsic SED, whilst $W_1(t, \lambda_r)$ is a functional principal component (FPC) that captures the primary mode of intrinsic SED variation in the SN Ia population. Cubic spline representations (W_0, W_1) of $W_0(t, \lambda_r)$ and $W_1(t, \lambda_r)$ are common to all supernovae, inferred during training, and fixed during photometric distance estimation. The R_V parameter controlling the Fitzpatrick (1999) dust law, $\xi(\lambda_r; R_V)$, was fully pooled (i.e. assumed to be the same for the entire sample) during training of the M20 model. We explore different treatments of this parameter at the photometric distance estimation stage, as described in Section 3.2.

The latent parameters $A_V^s, \theta_1^s, \delta M_s, \epsilon_s(t, \lambda_r)$ take unique values for each supernova, s . These are, respectively, the host galaxy dust extinction in the *V*-band, A_V^s ; a coefficient quantifying the effect of the $W_1(t, \lambda_r)$ FPC on the SED, θ_1^s ; a time- and wavelength-independent intrinsic magnitude offset, δM_s ; and a time- and wavelength-varying function, $\epsilon_s(t, \lambda_r)$, representing residual variations in the intrinsic SED not captured by $\theta_1^s W_1(t, \lambda_r)$. This function models residual intrinsic colour variations across phase and wavelength beyond the effect of θ_1 . The population distributions of the latent parameters are modelled as:

$$A_V^s \sim \text{Exponential}(\tau_A), \quad (2)$$

$$\theta_1^s \sim N(0, 1), \quad (3)$$

$$\delta M_s \sim N(0, \sigma_0^2), \quad (4)$$

$$\mathbf{e}_s \sim N(\mathbf{0}, \Sigma_{\epsilon}), \quad (5)$$

where \mathbf{e}_s is a vector encoding a 2D cubic spline representation of the residual function $\epsilon(t, \lambda_r)$. The hyperparameters σ_0 and Σ_{ϵ} are inferred during training, and fixed at the photometric distance estimation stage. The hyperparameter τ_A representing the population mean of the dust extinction A_V is ordinarily fixed during photometric distance estimation (when supernovae are treated independently), but can also be inferred if the full sample is fit jointly (see Section 3.2 (ii)).

In our generative model for SN Ia photometry, the host-dust-extinguished SED, $S_s(t, \lambda_r)$, is dimmed by the distance modulus, μ_s , redshifted, and extinguished by Milky Way dust (using the Fitzpatrick 1999 dust law, and Schlafly & Finkbeiner 2011 reddening map). The resulting observer frame SED, now reddened by both host and Milky Way dust, is then integrated through photometric bandpasses to yield model photometry. This process mathematically defines a likelihood function that is used to compare the model to observed photometry. During training, this likelihood forms the outer layer of a hierarchical model under which all population-level ($W_0, W_1, \Sigma_{\epsilon}, \sigma_0, \tau_A, R_V$) and supernova-level parameters ($A_V^s, \theta_1^s, \delta M_s, \mathbf{e}_s, \mu_s$) are inferred simultaneously for a sample of SNe Ia (see Mandel et al. 2022 for complete specification). The latter parameters are marginalised over, to yield posterior estimates of the former that are carried forward into photometric distance estimation. During photometric distance

estimation, population-level parameters are ordinarily kept fixed, and external constraints on distance (from, e.g., redshift + an assumed cosmology, or a redshift-independent distance probe) are relaxed. Under this fitting mode, all supernovae are conditionally independent in the posterior (see [Mandel et al. 2022](#)). In this work, we conduct several variations of the photometric distance estimation process, as detailed in Section 3.2. For some of these, we include and marginalise over population level parameters (e.g. R_V , or hyperparameters defining its population distribution) during photometric distance estimation. In these cases, we sample from the joint posterior over all supernovae. Section 3.3 discusses this.

3.2 Fitting Configurations

We take a number of different approaches to our light curve fits, yielding several sets of photometric distance estimates for our sample. Our primary fitting configurations are:

(i) *Fixed R_V* : Fitting all available optical-only (*BVri*), NIR-only (*YJH*), or optical+NIR (*BVriYJH*) data with the default **M20** BAYESN model trained by [Mandel et al. \(2022\)](#). In this fitting mode, each supernova is fitted independently from the others, with a fixed $R_V = 2.89$ (the global R_V inferred by [Mandel et al. 2022](#)) assumed.

(ii) *Population R_V* : Fitting all *BVri* or *BVriYJH* data using the **M20** model and *partial pooling* of R_V . This means that each supernova s has its own individual R_V^s , drawn from a common population distribution described by hyperparameters that are estimated from the data². Under this configuration, we fit all 86 SNe Ia in our CSP-I sample jointly. BAYESN hyperparameters defining the intrinsic SED ($W_0, W_1, \Sigma_\epsilon, \sigma_0$) are kept fixed to the **M20** estimates. The hyperparameter, τ_A , specifying the mean of the A_V population distribution (Eq. 2) is inferred from the sample, along with the parameters (μ_R, σ_R) specifying a truncated normal³ R_V population distribution,

$$R_V^s \sim \text{Trunc-}N(\mu_R, \sigma_R^2, a = 0.5, b = \infty). \quad (6)$$

Hyperpriors on $(\tau_A, \mu_R, \sigma_R)$ are as specified in [Mandel et al. \(2022\)](#); [Thorp et al. \(2021\)](#). As in [Thorp et al. \(2021\)](#), our default σ_R hyperprior is a half-normal, $\sigma_R \sim \text{Half-}N(0, 2^2)$. This is close to flat across all possible σ_R values of practical interest (see Fig. 8), but avoids the hard boundary associated with a uniform prior over a finite range. We consider our sensitivity to this choice in Appendix A, where we also try $\sigma_R \sim \text{Half-}N(0, 1^2)$, $\sigma_R \sim U(0, 4)$, and an improper flat prior on positive σ_R , and a hierarchical inverse- χ^2 prior (inspired by [Burns et al. 2014](#)). We also explore two alternative forms for the R_V population distribution (a skew-normal or Student’s t) in Appendix B. The approach of partially pooling R_V allows for principled sharing

² In contrast, *complete pooling* would imply a single common R_V for all supernovae, whilst *no pooling* would remove the assumption of a common R_V , or population distribution thereof, and would imply that all supernovae are fit completely independently. For a review of these distinctions, consult [Gelman et al. \(2014, ch. 5\)](#).

³ We define $X \sim \text{Trunc-}N(\mu, \sigma^2, a, b)$ as a random variable drawn from a normal distribution with mean, μ , and standard deviation, σ , with lower and upper truncation at a and b , respectively. The probability density function for $a \leq X \leq b$ is

$$P(X|\mu, \sigma, a, b) = \frac{1}{\sigma} \frac{\phi(\xi)}{\Phi(\beta) - \Phi(\alpha)},$$

and is zero for $X < a, X > b$. Here, $\xi = (X - \mu)/\sigma$, $\alpha = (a - \mu)/\sigma$, $\beta = (b - \mu)/\sigma$, and $\phi(z)$ and $\Phi(z)$ are respectively the PDF and CDF of a standard normal random variable z .

of information between SNe. This leads to more reliable inference of the population distribution of R_V than one would get from a collection of individual R_V estimates obtained with no pooling. Our fully Bayesian approach also enables us to estimate distances whilst marginalising over the individual R_V^s and A_V^s of the sample, as well the hyperparameters of their population distributions – something previous mass step analyses have not been able to do.

(iii) *Binned population R_V* : A variation of the population R_V configuration (ii) where the sample of 86 SNe Ia is subdivided by either SN Ia apparent $B-V$ colour (à la [Mandel et al. 2011](#); [Burns et al. 2014](#)), or host galaxy stellar mass (à la [Brout & Scolnic 2021](#); [Thorp et al. 2021](#)). In each bin, an independent R_V population distribution is assumed, with the same form as Equation 6. When binning by host galaxy stellar mass, we use the mass estimates from [Uddin et al. \(2020\)](#), and divide the sample at either $10^{10} M_\odot$ (a conventional choice since [Sullivan et al. 2010](#); see discussion in [Ponder et al. 2021, §5.7](#)), or $10^{10.57} M_\odot$ (the median host mass for our sample of 86 SNe). When binning by apparent $B - V$ colour⁴, we use our own estimates of this quantity from fits in the fixed R_V configuration (i). We adopt either a 2-bin configuration, splitting at $B - V = 0.3$ (roughly equivalent to a typical $c_{\text{SALT2}} = 0.3$ cosmology cut), or a 3-bin configuration with bins of $B - V \leq 0.3$, $0.3 < B - V \leq 0.7$, and $B - V > 0.7$.

(iv) *Free R_V , BS21 prior*: Fitting all *BVri* or *BVriYJH* data using the **M20** model, with a free R_V for each supernova, and an R_V prior based on the ([Brout & Scolnic 2021, BS21](#)) model:

$$R_V^s \sim \begin{cases} \text{Trunc-}N(\mu_R = 1.50, \sigma_R^2 = 1.3^2) & \text{if } M_* \geq 10^{10} M_\odot \\ \text{Trunc-}N(\mu_R = 2.75, \sigma_R^2 = 1.3^2) & \text{if } M_* < 10^{10} M_\odot \end{cases}. \quad (7)$$

As in Eq. 6 (and consistent with [Brout & Scolnic 2021](#)), we adopt a lower R_V truncation of $a = 0.5$, with no upper truncation (i.e. $b = \infty$).

(v) *Free R_V , uniform prior*: Fitting all *BVri* or *BVriYJH* data using the **M20** model, with free R_V for each supernova and a uniform prior, $R_V^s \sim U(1, 6)$. The lower limit here is chosen to be around the theoretical minimum value of R_V (from the Rayleigh scattering limit, see [Draine 2003](#)). The upper limit is set to encompass the highest R_V values reported (see e.g. [Cardelli et al. 1989](#); [Fitzpatrick 1999](#); [Fitzpatrick & Massa 2007, 2009](#)) along sight lines in the Milky Way (although such extreme values are found to be vanishingly rare in our Galaxy – see [Schlafly et al. 2016](#)).

3.3 Posterior Distributions

In the standard BAYESN photometric distance estimation procedure (see [Mandel et al. 2022, §2.8](#)), all population-level parameters of the model are fixed to their training values, and every supernova can be treated independently. In this case, the posterior distribution is given by Eq. 30 in [Mandel et al. \(2022\)](#). Our *fixed R_V* fitting configuration (Section 3.2 (i)) is exactly equivalent to this. Our *free R_V* configurations are very similar, with every supernova being independent, albeit with its host galaxy R_V^s as a free parameter. In this case, the

⁴ Strictly speaking, we compute host-dust-extinguished rest-frame $B - V$ colour at the time of B -band maximum. This quantity is fairly “close to the data” and is quite insensitive to the exact fitting configuration used.

posterior distribution we sample for a supernova, s , can be written as

$$\begin{aligned} & P(\mu_s, \phi_s | \hat{f}_s, \hat{W}_0, \hat{W}_1, \hat{\Sigma}_\epsilon, \hat{\sigma}_0, \hat{\tau}_A) \\ & \propto P(\hat{f}_s | \mu_s, A_V^s, R_V^s, \theta_1^s, \delta M_s^s, e_s, \hat{W}_0, \hat{W}_1) \times P(\mu_s) \\ & \quad \times P(A_V^s | \hat{\tau}_A) \times P(R_V^s) \times P(\theta_1^s) \times P(e_s | \hat{\Sigma}_\epsilon) \times P(\delta M_s^s | \hat{\sigma}_0), \quad (8) \end{aligned}$$

where $(\hat{W}_0, \hat{W}_1, \hat{\Sigma}_\epsilon, \hat{\sigma}_0, \hat{\tau}_A)$ are population-level hyperparameter estimates from training⁵, $\phi_s = (\mu_s, A_V^s, R_V^s, \theta_1^s, \delta M_s^s, e_s)$ are supernova-level latent parameters, and \hat{f}_s are the observed fluxes for supernova s . The first factor on the right-hand side is the light curve data likelihood (c.f. §2.1 of Mandel et al. 2022), while the factors on the third line are population distributions. When estimating a photometric distance, $P(\mu_s) \propto 1$. Otherwise, it is based on the external distance constraint (see Section 3.4 for details of these). For our *free* R_V configuration with a uniform prior, $P(R_V^s) = U(R_V^s | 1, 6)$. When using the BS21 prior, $P(R_V^s)$ is dependent on the host galaxy mass of supernova s , and follows from Equation 7.

Equation 8 shows the construction of the posterior distribution for our *free* R_V fitting configurations where no pooling takes place (described in Section 3.2 (iv) and (v)). In our *population* R_V fitting configurations (described in Section 3.2 (ii) and (iii)), we must define a joint posterior over all supernovae. For the *population* R_V configuration without binning by mass or colour, we have

$$\begin{aligned} & P(\{\mu_s, \phi_s\}, \mu_R, \sigma_R, \tau_A | \{\hat{f}_s\}, \hat{W}_0, \hat{W}_1, \hat{\Sigma}_\epsilon, \hat{\sigma}_0) \\ & \propto \left[\prod_s P(\hat{f}_s | \mu_s, A_V^s, R_V^s, \theta_1^s, \delta M_s^s, e_s, \hat{W}_0, \hat{W}_1) \right. \\ & \quad \times P(\mu_s) \times P(A_V^s | \tau_A) \times P(R_V^s | \mu_R, \sigma_R) \times P(\theta_1^s) \\ & \quad \left. \times P(e_s | \hat{\Sigma}_\epsilon) \times P(\delta M_s^s | \hat{\sigma}_0) \right] \times P(\tau_A) \times P(\mu_R) \times P(\sigma_R). \quad (9) \end{aligned}$$

Our hyperpriors, $P(\mu_R)$, $P(\sigma_R)$, $P(\tau_A)$, are as specified in Mandel et al. (2022), Thorp et al. (2021), and Section 3.2 (ii).

For the binned population R_V fitting configurations (Section 3.2 (iii)), some or all of the population-level hyperparameters $(\mu_R, \sigma_R, \tau_A)$ are split by host mass or apparent colour and Eq. 9 is modified accordingly. When binning by mass, we assume that all three of these hyperparameters are split for the two mass bins. When binning by apparent colour, we maintain a common A_V population distribution across the colour bins (i.e. an exponential distribution parameterised by a single common τ_A).

3.4 Hubble Residuals

From each set of photometric distance moduli, we compute Hubble residuals by subtracting off external distance modulus estimates computed from the supernova host galaxy redshifts under a fiducial cosmology of $H_0 = 73.24 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.28$, and $\Omega_\Lambda = 0.72$ (Riess et al. 2016). The redshifts are corrected to the CMB rest frame and for local flows using peculiar velocities estimated using the Carrick et al. (2015) flow model⁶. We compute the uncertainty on an external distance estimate as in Avelino et al. (2019, eq. 8), assuming a peculiar velocity uncertainty of 150 km s^{-1} (Carrick et al. 2015). Where redshift-independent distance constraints are available for nearby SNe (e.g. from Cepheid variables, Tully–Fisher, or similar, as listed in Avelino et al. 2019, table 4), we use these

(and their uncertainties) instead. Uncertainties on the external distance estimates are added in quadrature to the posterior uncertainties on the BAYESN photometric distances to obtain the uncertainties on the Hubble residuals. The posterior uncertainties on the photometric distances naturally include the intrinsic scatter via marginalisation of the above posteriors.

3.5 Searching for a Mass Step

We use the best-fit estimates of host galaxy stellar mass reported in Uddin et al. (2020, table C1). For a given set of Hubble residuals, we estimate the step size at a given mass by taking the difference of the weighted means of the Hubble residuals either side of the chosen step. The weight of the Hubble residual is the inverse of the sum of the squares of its photometric distance uncertainty and external distance uncertainty. The quadrature sum of the errors on the weighted means gives the uncertainty in step size. We compute the step sizes at $10^{10} M_\odot$, and $10^{10.57} M_\odot$ (the median host mass for our sample of 86 SNe Ia).

We also compute the maximum likelihood estimate (MLE) of the step location for each set of Hubble residuals, and estimate the step size here. We do this following the methodology described in Thorp et al. (2021, appendix A), which finds the step location that maximises $P(\text{Hubble resids.} | \text{step loc.})$, having marginalised over the the residual Hubble diagram scatter and the mean Hubble residual on either side of the step. To avoid spurious maxima, we restrict the maximisation to step locations that fall within the interquartile range of the host galaxy masses of our sample ($\approx 10^{10.20} - 10^{10.82} M_\odot$).

4 WHY OPTICAL AND NIR DATA ARE NEEDED

Several past analyses have shown and exploited the fact that optical and NIR data combined can be used to obtain improved constraints on SN Ia host galaxy dust (e.g. Krisciunas et al. 2007; Folatelli et al. 2010; Mandel et al. 2011, 2022; Burns et al. 2014; Johansson et al. 2021). The unique advantage gained by adding NIR data to optical comes from the additional colour information provided – with a wider wavelength range, it becomes possible to disentangle total extinction (e.g. A_B or A_V) from R_V using colour information alone. When only optical colours are available, additional information is needed to obtain robust estimates (e.g. information about absolute magnitude, derived from an independent estimate of the SN Ia distance).

To see why optical and NIR data are so powerful when used in combination, we can look at the effect of dust on SN Ia colour curves for a range of optical and optical–NIR colours. Figure 3 shows $B - X$ colour curves (for $X \in VriYJH$), simulated using the M20 BAYESN model. In Figure 3, the black lines show the distribution of intrinsic colour curves, after correction for light curve shape. The yellow ($A_B = 0.75$, $A_V = 0.45$, $R_V = 1.5$) and red ($A_B = 1.2$, $A_V = 0.9$, $R_V = 3.0$) lines show two different combinations of reddening law and B -band extinction that yield the same reddening: $E(B - V) = 0.3$. The blue line ($A_B = 1.2$, $A_V = 0.72$, $R_V = 1.5$) shows a third dust configuration, with the same B -band extinction as the red line, the same dust law as the yellow line, but a higher reddening: $E(B - V) = 0.48$. From the closeness of the red and blue curves in the right hand panel of Figure 3, one can immediately see that the optical–NIR colours (i.e. $B - J$, $B - H$) are highly sensitive to the total B -band extinction, but almost unaffected by R_V . Conversely, the optical colour curves (i.e. $B - V$, $B - r$) are mostly sensitive to the reddening, $E(B - V)$. This can be seen from the closeness of the red and yellow curves in the left hand panel of Figure 3.

⁵ We use the M20 values of these, available at: <https://github.com/bayesn/bayesn-model-files>

⁶ <https://cosmicflows.iap.fr/>

Figure 3. Colour curves in the rest-frame CSP passbands simulated using the M20 BAYESN model. Solid and dashed black lines show the mean intrinsic colour and intrinsic colour scatter ($\pm 1\sigma$), after correcting the light curve shape to the population mean θ_1 . Coloured lines show how dust affects the mean colour curves. The yellow and red lines correspond to different dust configurations which give rise to $E(B-V) = 0.3$ mag. The blue lines correspond to a higher reddening of $E(B-V) = 0.48$ mag, but the same R_V as the yellow lines. Vertical offsets are (1.75, 3.25, 5.75, 0.0, 3.5, 5.5) for ($B-V$, $B-r$, $B-i$, $B-Y$, $B-J$, $B-H$).

Consequently, by constraining $E(B-V)$ using optical colours, and extinction (e.g. A_B) using optical–NIR colours, one can imagine directly estimating $R_V = A_B/E(B-V) - 1$. In practice, we do not directly estimate R_V from inferring extinction and reddening derived from colours in this way. Instead, our BAYESN hierarchical model (see Section 3.1) implicitly leverages the colour information from all available passbands at all observed times, weighting the data appropriately based on the embedded residual intrinsic scatter model to yield well motivated uncertainties on the dust extinction and dust law R_V .

5 WHY HIERARCHICAL BAYES IS NEEDED

To motivate our hierarchical Bayesian methodology, we present here a simulation-based exercise illustrating the challenges of correctly estimating the R_V population distribution from a sample of supernovae. To do this, we simulate several sets of CSP-like light curves from the M20 BAYESN forward generative model. For each simulation, we generate 86 light curves with the same redshifts, light curve shapes (θ_1^s), host galaxy dust extinction (A_V^s), and observation patterns (observation times and passbands) as the real supernovae in our fiducial CSP sample. The intrinsic residuals (δM_s and $\epsilon_s(t, \lambda_r)$) are randomly realised for each simulated supernova from the population distributions inferred during training of the M20 model. We generate

three variations of this simulation with different input R_V distributions, all with population mean $\mu_R = 2.7$, and with population standard deviations of $\sigma_R = 0.0, 0.5$, and 1.0 . For each simulation we generate random realisations of the true $\{R_V^s\}$.

We perform several sets of fits to each of these simulated samples, using the M20 BAYESN model. First, we fit all of the light curves independently, assuming a uniform prior on each individual R_V^s – this corresponds to the free R_V fitting configuration, as described in Section 3.2 (v), although here our exact prior is $R_V^s \sim U(0.5, 6.0)$ ⁷. We then repeat these individual light curve fits, but with the BAYESN residual intrinsic scatter model switched off during fitting (i.e. δM_s and e_s are fixed to zero). This forces all apparent colour variation to be explained by a combination of the principal SED shape parameter (θ_1^s), and dust extinction (A_V^s, R_V^s), and ignores any possible variation arising from residual intrinsic colour scatter. This should be somewhat analogous to the SNOOPy color_model (Burns et al. 2011, 2014). From each of these fits, one might take the posterior means, \hat{R}_V^s , and standard deviations, $\hat{\sigma}_s$, as point estimates of each supernova’s R_V^s . We then use these to perform two different estimates of the parameters (μ_R, σ_R) population’s R_V distribution:

⁷ This is chosen for consistency with the simulations, where a lower truncation of $R_V^s > 0.5$ was applied to the Gaussian population distributions

(A) *Naive*: The simple sample mean and sample standard deviation of $\{\hat{R}_V^s\}$ are taken as estimates ($\hat{\mu}_R, \hat{\sigma}_R$) of the population mean and standard deviation, respectively.

(B) *Shrinkage*: We perform a shrinkage estimate of (μ_R, σ_R) by assuming a simple normal–normal model for our set of point estimates, $\{\hat{R}_V^s, \hat{\sigma}_s\}$. The posterior is

$$P(\mu_R, \sigma_R | \{\hat{R}_V^s\}) \propto P(\mu_R, \sigma_R) \prod_{s=1}^{N_{\text{SN}}} N(\hat{R}_V^s | \mu_R, \hat{\sigma}_s^2 + \sigma_R^2), \quad (10)$$

as in Gelman et al. (2014, eq. 5.18). We maximize Eq. 10, assuming a flat prior on the parameters – i.e. $P(\mu_R, \sigma_R) \propto 1$ – to obtain a MAP estimate of μ_R, σ_R .

Finally, we compare our population distribution estimates from methods (A) and (B) to our preferred approach:

(C) *Full hierarchical Bayes (H.B.)*: Estimating μ_R and σ_R from a hierarchical Bayesian analysis of all light curves simultaneously, under an R_V population model. This is equivalent to the population R_V fitting configuration with partial pooling in Section 3.2 (ii).

We expect the full hierarchical Bayesian method (C) to give the most reliable estimates of the population distribution. When the fits are carried out with the residual scatter model included, we would expect the shrinkage estimator (B) to provide a good estimate of the population standard deviation, σ_R , but the naive approach (A) to overestimate the R_V dispersion as it does not account for the extra scatter induced by the uncertain individual \hat{R}_V^s estimates. When the fits are carried out with the residual scatter model turned off, we expect the uncertainties on the individual \hat{R}_V^s estimates to be underestimated, and these estimates to be over-dispersed (since the apparent colours of all supernovae with a given light curve shape are forced to map back to the same intrinsic colours, e.g. the solid black line in Fig. 3). We therefore expect the shrinkage estimator (B) to overestimate σ_R in this case, as the widely dispersed and over-confident \hat{R}_V^s estimates will cause the required level of shrinkage to be underestimated. We expect the naive method (A) to perform even worse.

Table 2 reports the full set of results from our simulation-based tests. For the naive method (A), the estimate of the population mean, $\hat{\mu}_R$, is consistently biased towards the mean of the individual R_V^s prior used in the fits, i.e. $\mathbb{E}(R_V^s) = 3.25$ for $R_V^s \sim U(0.5, 6.0)$. When analysing the individual fits results with the shrinkage estimator (B), this remains true for fits where residual scatter was ignored. However, for the fits where residual scatter was accounted for, the population mean estimate from method (B) is much closer to the truth. From the fully hierarchical analysis (C), the $\hat{\mu}_R$ estimates are within one posterior standard deviation of the truth for all three simulations.

The estimates of the population standard deviation conform well to our expectations. When the residual scatter is ignored during the fits, the estimate of the population standard deviation, $\hat{\sigma}_R$ is poor when using the naive method (A) or shrinkage estimator (B). For all three simulations, the estimate is close to the standard deviation one would expect from the individual R_V^s prior used in the fits (Std. Dev. (R_V^s) = 1.59 for $R_V^s \sim U(0.5, 6.0)$). This reflects the poor estimates of the individuals' R_V^s when residual scatter is neglected. When residual scatter is included in the individual fits, our $\hat{\sigma}_R$ estimate is still biased high for the two simulations with narrower population distributions when using the naive method (A). When using the shrinkage estimator (B), the $\hat{\sigma}_R$ estimates are close to the truth for all three simulations. The fully hierarchical analysis (C) performs well, as expected. For the two simulations with non-zero input population variance, the recovered $\hat{\sigma}_R$ values are consistent with the

^a Input values of the true R_V population parameters.

^b Method used to estimate parameters (see text in §5).

^c If Yes, BAYESN's residual intrinsic scatter model was included and marginalised over when fitting light curves.

^d For the full H.B. method (C), reported estimates are either posterior mean ± std. dev. or 68 (95) % upper bounds.

truth. For the simulation with input $\sigma_R = 0$, the posterior from the full hierarchical Bayesian approach peaks at zero, and places a 95 per cent upper bound of 0.20. Figure 4 shows a comparison of the different methods for estimating the population mean and standard deviation, for the simulation with input parameters $\mu_R = 2.7$ and $\sigma_R = 0.5$.

Figure 5 compares the individual R_V^s estimates from the individual fits and the full hierarchical Bayesian analysis to the true input values of the simulated population. This comparison is made for the simulation with true $\mu_R = 2.7$ and $\sigma_R = 0.5$. We can see from this figure that the R_V^s point estimates from the individual light curve fits (orange points in the second panel) are visibly overdispersed in comparison to the true population distribution (blue points in the leftmost panel), even when BAYESN's residual scatter model is turned on. For low A_V^s , the R_V^s estimates are more weakly constrained, and are biased slightly high (towards the prior mean). The individual uncertainties are large, though, except for the more highly extinguished individuals where the recovered R_V^s estimates deviate less from the true values. When the fits are carried out with the residual intrinsic colour scatter turned off (red points in the third panel), the level of overdispersion is much greater, and the uncertainties on the individuals' R_V^s and A_V^s point estimates are much smaller in most cases.

In the fully hierarchical Bayesian analysis (C), we obtain a set of posterior draws where the i th MCMC sample corresponds to a set of population hyperparameters (μ_R^i, σ_R^i), and an associated realisation, $\{R_V^s\}_i$, of individual R_V^s values. In the fourth panel of Figure 5, we show a hexagonally-binned probability density plot derived from the posterior samples of every individual's (A_V^s, R_V^s), with overlaid blue circles showing the truth. At high extinction, the clusters of posterior samples corresponding to individual supernovae can be distinguished, whilst at lower extinction the samples blend together into a continuum that visually traces the true (A_V, R_V) distribution of the sample. The rightmost panel of the plot shows the distribution of true R_V^s (blue histogram), compared to the distribution of

Figure 4. Visual comparison of different approaches for estimating the R_V population distribution hyperparameters of a simulated population of 86 SNe Ia. The simulation was generated with a population mean of $\mu_R = 2.7$, and population standard deviation of $\sigma_R = 0.5$ (indicated by the blue crosshairs). The green contours show the 2D marginal posterior distribution (68 and 95 per cent credible intervals) obtained from a full hierarchical Bayesian analysis of the simulated data, with the green star showing the posterior mean for each hyperparameter. The orange and red crosses show the naive sample mean and standard deviation of the $\{R_V^s\}$ point estimates made by fitting each supernova individually with BAYESN, both with (orange cross) and without (red cross) BAYESN’s residual scatter model turned on. Orange and red stars show the result of applying a simple shrinkage estimator to the same sets of R_V^s point estimates. Numerical results are summarised in Table 2.

individual point estimates obtained with and without BAYESN’s intrinsic scatter model (orange and red histograms, respectively). The orange histogram is clearly broader than the blue, and is biased towards the prior mean of 3.25. The red is very overdispersed, with spurious overdensity near the prior bounds. The pale yellow/green histogram is a marginalisation of the density plot from one panel to the left – i.e. the marginal density of all individuals’ R_V^s posterior samples obtained from the hierarchical Bayesian analysis. This traces the true R_V distribution much better than the distribution of point estimates obtained from the supernova-by-supernova fits. Also shown in the rightmost panel is the Gaussian population distribution implied by the posterior mean estimate of the population hyperparameters ($\hat{\mu}_R = 2.80$, $\hat{\sigma}_R = 0.63$) obtained from the hierarchical Bayesian analysis. As expected, this traces the true population distribution very well, being very close to the input values of the population hyperparameters ($\mu_R = 2.7$, $\sigma_R = 0.5$). The hierarchical Bayesian analysis provides the best estimate of the true underlying R_V population distribution.

6 RESULTS

In this section, we present the results of our analysis applied to the sample selected as described in §2. In §6.1, we describe results for the Hubble residuals and mass step for the SNe Ia within the apparent $B - V \leq 0.3$ colour cut. This colour cut is consistent with typical cosmological analyses, and is applied using apparent colour estimates from fits to the light curves. Eleven SNe are removed under this cut, yielding a low-to-moderate reddening sample of 75. Conclusions about the mass step are not strongly sensitive to this colour cut. In §6.2, we investigate the inferred distribution of host galaxy dust laws over the full apparent colour range. For the full sample, NIR

data near maximum are not required. In §6.3, results for a “gold-standard” subset with NIR near maximum light are described. In §6.4, we discuss the most highly-reddened individual objects in the sample.

6.1 Hubble Residual Step

6.1.1 Using NIR Data

Our NIR Hubble residuals, obtained using the fixed R_V fitting configuration, have a total root mean square (RMS) scatter of 0.137 mag (without correcting for any possible mass step), for the subset with apparent $B - V \leq 0.3$. Estimated mass steps are included in Table 3. Correcting for the expected dispersion that would be contributed by peculiar velocity uncertainty (assuming $\sigma_{\text{pec}} = 150 \text{ km s}^{-1}$), we estimated a Hubble diagram scatter of $\sigma_{-pv} = 0.121$ mag (using equation 33 of Mandel et al. 2022). Note that for this sample of 75 SNe Ia with apparent $B - V \leq 0.3$, NIR data near maximum are not required. Results for a “gold-standard” subset with NIR near maximum light are described in Section 6.3.

At a host galaxy stellar mass of $10^{10} M_{\odot}$, we estimate a Hubble residual step of 0.020 ± 0.052 mag, consistent with zero. At the median mass of the full sample ($10^{10.57} M_{\odot}$), we estimate a similar Hubble residual step of 0.050 ± 0.032 mag, consistent both with zero as well as a larger value, as seen by, e.g., Uddin et al. (2020). Using the maximum likelihood estimator detailed in Appendix A of Thorp et al. (2021), we estimate a preferred step location of $10^{10.77} M_{\odot}$. This is towards the higher end of reported estimates in the literature (although the sample being studied here favours high-mass hosts in general), and is similar to the step locations reported by, e.g., Ponder et al. (2021) and Kelly et al. (2010). At this step location, our estimated NIR Hubble residual step size is 0.084 ± 0.035 mag, somewhat larger than the step at the median host mass.

6.1.2 Using Optical Data

When fitting the samples’ optical ($BVri$) light curves under the fixed R_V configuration, the Hubble diagram RMS (σ_{-pv}) is 0.150 (0.137) mag, within the colour cut, somewhat larger than for the equivalent NIR fits. At $10^{10} M_{\odot}$, our estimate of the Hubble residual step is 0.080 ± 0.041 mag, larger than our equivalent estimate of the step size in the NIR Hubble residuals. At the sample median mass ($10^{10.57} M_{\odot}$) and maximum likelihood step location ($10^{10.77} M_{\odot}$), we estimate step sizes of 0.078 ± 0.028 mag and 0.112 ± 0.030 mag, respectively. A representative set of results are included in Table 3.

Under the free R_V fitting configurations, we allow R_V^s to be a free parameter in each fit (with one of two choices of fixed prior, and no pooling across the sample – see Section 3.2 (iv) and (v) for details), and marginalise over it when estimating distances. For both choices of prior, the Hubble diagram RMS is ~ 0.16 – 0.18 mag under a $B - V \leq 0.3$ colour cut – larger than the equivalent results under the configuration where a fixed $R_V = 2.89$ was used. Our estimated Hubble residual magnitude steps for both prior choices are broadly consistent with one another. The estimated step sizes (≥ 0.06 mag at the median, ≥ 0.1 mag at the MLE) are consistent with estimates made using the fixed R_V fitting configuration. Detailed results are listed in Table 3. The two choices of R_V prior we adopt are both only weakly constraining – even though the BS21 population distributions (Eq. 7) are more informative than the $U(1, 6)$ prior, they still permit a wide range of R_V for both mass bins due to their large σ_R values. The combination of broad priors, and the limited R_V constraining power of the optical data alone, contribute to more uncertain distance

Figure 5. Estimation of R_V and its population distribution for a simulated set of 86 SNe Ia. Blue points show the true simulated R_V^s values for the individuals in the sample, with population mean $\mu_R = 2.7$ and standard deviation $\sigma_R = 0.5$. Orange points show R_V^s estimates obtained from fitting each SN independently whilst assuming a uniform prior $R_V^s \sim U(0.5, 6.0)$. These fits were carried out with BAYESN’s residual scatter model turned on. Red points show R_V^s estimates obtained from fitting each SN independently with BAYESN’s residual scatter model turned off. Points are sorted by extinction, A_V^s , and estimates for a given individual are connected by faint lines. The yellow–green hexagonally-binned density plot shows the combined density of all individuals’ (A_V^s, R_V^s) posterior samples from the full hierarchical Bayesian analysis. The true R_V^s values (same as in the leftmost panel) are overlaid as open blue circles. The rightmost panel shows several representations of the population distribution: a histogram of the sample’s true R_V^s values (blue line), a histogram of the individual point estimates made without considering intrinsic scatter (orange line), the marginal density of the individual R_V^s posterior samples (yellow/green histogram), and the Gaussian PDF implied by the posterior mean estimate of the population hyperparameters ($\hat{\mu}_R, \hat{\sigma}_R$) from the hierarchical Bayesian analysis (green curve). From this, it is clear that the hierarchical Bayesian approach does the best job of capturing the true population distribution, whereas the point estimates from the individual fits are overdispersed, especially when intrinsic scatter is neglected in the fit.

Table 3. Hubble residual magnitude steps for different fitting configurations and step locations, computed for the 75 SNe Ia within the $B - V \leq 0.3$ colour cut^a. The dust parameters are determined from colours alone, without external distance information.

^a RMS, σ_{-pv} , and step sizes are computed from the subsample of 75 SNe with apparent $B - V \leq 0.3$. The population R_V model configurations (ii) and (iii) are fit to the full sample of 86 SNe, but only the Hubble residuals of the $B - V \leq 0.3$ are used in evaluating the mass step.

^b Fitting configuration (as listed in Section 3.2).

^c Estimated Hubble residual step size at different host galaxy stellar masses.

^d Root mean square (RMS) scatter of the Hubble residuals (without correction for a mass step).

^e Hubble diagram scatter with expected contribution from peculiar velocity uncertainty ($\sigma_{pec} = 150 \text{ km s}^{-1}$) removed (Mandel et al. 2022, eq. 33).

^f RMS of Hubble residuals of the part of the sample (67 SNe) with $z_{CMB} > 0.01$. Presented as an alternative to σ_{-pv} for mitigating the effect of peculiar velocity uncertainty. Conclusions about the Hubble residual step size do not change substantially under this cut.

^g Step size computed at the MLE step location (estimated to be $10^{10.77} M_\odot$ for all *BVriYJH* configurations).

Figure 6. Mass step in Hubble residuals derived from photometric distance fits to optical+NIR CSP data under the population R_V configuration with partial pooling, as per Section 3.2 (ii). (lower panel) Hubble residuals are shown in blue. Error bars are from quadrature sum of photometric distance uncertainty and uncertainty on external distance estimate (see Section 3.4). Mass step shown is at maximum likelihood step location. (upper panel) Black line and left hand axis show Hubble residual step significance vs. host mass. Grey line and right hand axis show marginal likelihood of Hubble residual step as a function of host mass.

estimates, and the large Hubble residual scatter that we see here. It is noticeable that when optical and NIR data are combined (c.f. Section 6.1.3), the free R_V fitting configurations are competitive with the others.

6.1.3 Using Optical + NIR Data

When estimating Hubble residuals from the full optical + NIR light curves, we adopt a variety of fitting configurations differing mainly in their treatment of R_V . Using the default M20 BAYESN model with a fixed $R_V = 2.89$, we estimate a Hubble diagram RMS (σ_{pV}) of 0.123 (0.108) mag within the $B - V \leq 0.3$ colour cut. At a host galaxy mass of $10^{10} M_\odot$, we estimate a Hubble residual step of 0.071 ± 0.037 mag. At the median host mass ($10^{10.57} M_\odot$) and MLE step location ($10^{10.77} M_\odot$), we find Hubble residual steps of 0.062 ± 0.026 and 0.092 ± 0.028 mag, respectively. These results are summarised in the first row of Table 3.

For the population R_V fitting configurations, the individual R_V values are partially pooled: either across the full sample, or subsamples binned by host galaxy mass or SN Ia apparent colour (see Section 3.2 for full details). Across all different assumptions about the R_V population distribution, the results are highly consistent. The Hubble residual RMS (σ_{pV}) is typically ~ 0.12 (0.10) mag. At $10^{10} M_\odot$

we estimate a Hubble residual step of ~ 0.06 mag. At the sample median host mass, we estimate Hubble residual steps of ~ 0.06 mag ($2.2\text{--}2.5\sigma$) depending on the exact configuration considered. The most significant (0.064 ± 0.026) occurs when the R_V population is modelled as a Gaussian distribution for the full sample, and its hyperparameters are inferred. The least (0.056 ± 0.026) corresponds to the case where the sample was divided equally into two bins of host galaxy stellar mass, and the R_V population distribution in each is modelled as an independent Gaussian distribution, whose hyperparameters are inferred. For all population R_V configurations, the preferred step location is at $10^{10.77} M_\odot$, where the step size is consistently ≥ 0.08 mag ($\geq 2.9\sigma$). The lower panel of Figure 6 shows (within an apparent $B - V \leq 0.3$ colour cut) the Hubble residuals and estimated mass step resulting from the unbinned population R_V fitting configuration. The upper panel shows the estimated step significance at different masses (à la Roman et al. 2018, fig. 19; Kelsey et al. 2021, fig. 8), along with the marginal likelihood of the Hubble residuals conditional on a step at a particular mass.

In free R_V fitting configurations, we fit every supernova independently, with one of two choices of prior – either uniform, or a mass dependent prior motivated by BS21. For both choices of prior, the results are very similar to the population R_V configuration results, where R_V was partially pooled. The Hubble diagram RMS is around 0.12–0.13 mag for both choices of prior, under the $B - V \leq 0.3$ cut. At the median host galaxy mass, we estimate a Hubble residual step of $\sim 0.06 \pm 0.03$ mag. At the MLE mass step location, our estimated Hubble residual steps are $\sim 0.08 \pm 0.03$ mag. The Hubble diagram scatter is very close to the scatter achieved with all other optical + NIR configurations.

Results for all fitting configurations and step locations are presented in Table 3.

6.2 Distribution of Dust Laws: Using Optical + NIR Data

6.2.1 Constraints from Optical-NIR Colours: Fitting without External Distance Information

From the population R_V fitting configurations with partial pooling, we can make inferences about the R_V population distribution in the CSP sample. We marginalise over all distances and other supernova-level parameters (including the R_V values for the constituent individuals of the sample) to estimate the posterior distribution of the hyperparameters defining the R_V population distribution(s). Table 4 lists posterior estimates of these hyperparameters (μ_R and σ_R ; population mean and standard deviation, respectively) for the model configurations where a truncated normal R_V population distribution is assumed across either the full sample, or subsamples binned by colour or host galaxy mass. Our results for non-Gaussian population distributions are discussed in Appendix B.

From the optical and NIR data of our full sample of 86 SNe Ia, we fit a truncated Gaussian population distribution for R_V (Eq. 6) with mean $\mu_R = 2.48 \pm 0.08$, and standard deviation $\sigma_R = 0.34 \pm 0.11$. These parameters are inferred simultaneously with individual R_V^s and A_V^s values for the 86 SNe in our sample. The left hand panels of Figure 7 show our constraints on the A_V^s and R_V^s of the population's constituent individuals, in the space of derived reddening, $E^s(B - V) = A_V^s/R_V^s$, vs. extinction, A_V^s . These estimates were obtained under the population R_V fitting configuration with partial pooling. The right hand panels contrast these with the constraints obtained under the free R_V configuration with no pooling and a uniform prior, $R_V^s \sim U(1, 6)$. In the latter case, the individual estimates show

Table 4. Inferred dust R_V population distribution parameters from $BVriYJH$ data.

^a Constraints on R_V distribution parameters from optical and NIR data without using external distance information.

^b Constraints with external distance information applied.

^c Binning strategy adopted (see Section 3.2 (iii)). When binned by host galaxy stellar mass, the value in parentheses is the chosen split point. “Unbinned” corresponds to the population R_V fitting configuration described in Section 3.2 (ii).

^d Subsample to which the parameters in columns 4 and 5 pertain. When binned by mass, “low” and “high” denote, respectively, the subsamples above and below the split point indicated in column 1.

^e Number of supernovae in each subsample.

^f Values quoted are posterior mean and standard deviation.

^g Values quoted are either posterior mean ± standard deviation, or 68 (95)% upper bounds.

^h These rows correspond to the $B - V \leq 0.3$ bin of a fitting configuration where mass and colour binning was applied.

more apparent dispersion⁸ at low extinction, where the ability to constrain an individual’s R_V^s is poor. Hence, a significant portion of this apparent dispersion is likely due to individual estimation errors rather than true R_V variation, as demonstrated in §5.

For the free R_V configuration results, one could take the posterior means, \hat{R}_V^s , and standard deviations, $\hat{\sigma}_s$, as estimates of each supernova’s R_V^s (as in Section 5 (A)). If one then takes the standard deviation of the individuals’ point estimates, one would naively estimate a population standard deviation of $\hat{\sigma}_R = 0.81$, and a population mean of $\hat{\mu}_R = 3.1$. This is similar to the approach taken by Johansson et al. (2021), and yields a similar estimate of the population standard deviation (they estimate $\hat{\sigma}_R = 0.9$, on a sample which includes our own as a subset). An estimate of a population distribution width based on point estimates is likely to be an overestimate, however, as discussed in Section 5 (see also Loredo & Hendry 2010, 2019). The optimal approach is to use a fully hierarchical model for the data. However, we can also apply the normal–normal model used in Section 5 (B) (Equation 10) post-hoc to the $\{\hat{R}_V^s, \hat{\sigma}_s\}$ estimates from the free R_V fits, to estimate the population parameters (μ_R, σ_R). From this, we estimate $\hat{\mu}_R = 2.58$ and $\hat{\sigma}_R = 0.31$, closer to the results from the fully hierarchical analysis under the population R_V fitting configuration.

The marginal posterior distribution of the population distribution parameters (μ_R, σ_R), obtained using the unbinned population R_V fitting configuration, is shown in the upper left panel of Figure 8. Our population hyperparameter estimates are consistent with the estimates made by Thorp et al. (2021) for SNe Ia from Foundation DR1 (Foley et al. 2018; Jones et al. 2019). As in Thorp et al. (2021),

our inferences show preference for a fairly small dispersion in R_V ($\sigma_R < 0.52$ with 95 per cent posterior probability). However, for the CSP sample considered here, we find much less posterior probability at $\sigma_R = 0$ – i.e. a preference for small but non-zero dispersion in R_V .

When the sample is split into either two or three bins by apparent $B - V$ colour, our estimates of the R_V population mean μ_R are consistent between all colour bins (and with the unbinned result). There is a preference in the posterior for slightly lower μ_R for the SNe in the redder ($B - V > 0.3$) bins, as reported by e.g. Mandel et al. (2011) and Burns et al. (2014), although the difference here is not statistically significant. However, our sample has relatively few (eleven) SNe Ia with $B - V > 0.3$, so our estimates of the R_V population distribution in the higher colour bin(s) should be interpreted with this in mind. The lower left hand panels of Figure 8 show the posterior distributions of (μ_R, σ_R) in different colour bins for 3-bin model. Summaries of our posterior estimates of the population parameters are reported in Table 4.

The most important part of the colour-binning exercise is the behaviour of the low–moderate reddening bin $B - V \leq 0.3$ where the bulk of the sample (75 SNe) falls. The reddest SNe (even if they are few in number) exert considerable “pull” on the inferred R_V distribution for a sample of SNe Ia (see, e.g. Folatelli et al. 2010; Mandel et al. 2011). This is due to their larger lever arm distance from the intrinsic colour locus, which gives them much greater sensitivity to small changes in R_V . Splitting the sample by colour isolates the less reddened ($B - V \leq 0.3$) supernovae from the influence of their highly reddened counterparts. Because of this, the strategy of binning by colour has the greatest effect on the R_V distribution amongst the least reddened supernovae. For $B - V \leq 0.3$, we estimate an R_V population distribution with population mean $\mu_R = 2.59 \pm 0.14$ and standard deviation $\sigma_R = 0.62 \pm 0.16$. The estimated population mean

⁸ Note that this does not translate into a significantly greater Hubble diagram dispersion (see Table 3), as the sensitivity of distance to misestimated R_V is small when the dust extinction is low.

Figure 7. Constraints on the dust latent parameters (A_V^S , R_V^S) for the 86 SNe in our sample. Blue markers show marginal posterior estimates (medians and 68 per cent credible intervals) from the population R_V fitting configuration with an inferred Gaussian population distribution, $R_V^S \sim N(\mu_R, \sigma_R^2)$. Black markers show estimates from the free R_V fitting configuration, with no pooling and independent uniform priors of $R_V^S \sim U(1, 6)$. Orange solid and dashed lines show the $E(B-V)$ vs. A_V relations (mean \pm std. dev) implied by the population distribution parameters ($\hat{\mu}_R = 2.48$, $\hat{\sigma}_R = 0.34$) we estimate under partial pooling. (bottom panels) Constraints visualised in the space of derived $E_S(B-V) = A_V^S/R_V^S$ vs. A_V^S . (top panels) Residuals about the estimated population mean, i.e. the line $E(B-V) = A_V/\hat{\mu}_R = A_V/2.48$.

μ_R , for $B-V \leq 0.3$, is consistent with the value estimated for the full sample without colour binning. The estimated population standard deviations, σ_R , for $B-V \leq 0.3$ and the unbinned sample are not inconsistent. For the colour-restricted subsample, however, there is greater posterior probability towards larger standard deviations, with the 95th percentile falling at $\sigma_R \approx 0.9$ (c.f. the unbinned result, where we estimate that $\sigma_R \lesssim 0.5$ with 95 per cent posterior probability). This is likely driven by the fact that the restriction to $B-V \leq 0.3$ removes the ability of the highly reddened supernovae (which seem to show fairly small R_V dispersion in this sample – see Table 4, or red/purple contours in lower left panel of Fig. 8) to pull the entire population distribution tighter.

When the sample is divided by host galaxy stellar mass, we estimate consistent R_V distributions between the two mass bins when splitting at either 10^{10} or $10^{10.57} M_\odot$. When the sample is divided at the latter (the median host galaxy mass), we estimate population means of $\mu_R = 2.60 \pm 0.12$ for lower-mass hosts, and $\mu_R = 2.35 \pm 0.14$ for the higher-mass hosts. We estimate similar population standard deviations (0.33 ± 0.12 and 0.41 ± 0.20 for low- and high-mass hosts, respectively) in the two mass bins, also. The upper right panel of Figure 8 overlays the (μ_R, σ_R) posterior distributions for the two mass bins. When dividing the sample at $10^{10} M_\odot$, the consistency between the two bins is even stronger (see Table 4), albeit with the caveat that there are only 15 SNe Ia in the sample with a host mass $< 10^{10} M_\odot$. The preference for similar R_V population distributions for low- and high-mass host galaxies aligns with the results of Thorp et al. (2021) for the Foundation DR1 (Foley et al. 2018; Jones et al. 2019) SN Ia sample.

This result also holds when we repeat our analysis with both host mass and colour binning. In this mode, we focus on the $B-V \leq 0.3$ bin, as it is most cosmologically relevant, and most comparable to previous analyses (e.g. Brout & Scolnic 2021; Thorp et al. 2021). Additionally, it is even more difficult to draw conclusions about the sparsely populated $B-V > 0.3$ bin when this is further divided by host mass. Our R_V distribution inferences are consistent when splitting the $B-V \leq 0.3$ subsample at either $10^{10} M_\odot$ or $10^{10.57} M_\odot$, and the results are consistent with those obtained without the colour cut. Using the split at $10^{10.57} M_\odot$, we find a population mean R_V of $\mu_R = 2.79 \pm 0.18$ for low-mass hosts and $\mu_R = 2.35 \pm 0.27$ for high-mass hosts, with population standard deviations of $\sigma_R = 0.42 \pm 0.24$ and $\sigma_R = 0.74 \pm 0.36$, respectively. The lower right panels of Figure 8 show the joint posterior distributions over (μ_R, σ_R) for the two mass bins in the case. Our estimates of the population means are consistent to within 1.4σ , and are consistent with the results obtained by Thorp et al. (2021) on the completely independent Foundation dataset. Our complete results for the $10^{10} M_\odot$ and $10^{10.57} M_\odot$ mass splits, with $B-V \leq 0.3$ colour cut can be found in Table 4.

Although these analyses were carried out without any external constraints on the distance moduli of individual SNe, repeating our fits with external distance constraints imposed makes very little difference to the conclusions about the dust law population distribution(s). The next section 6.2.2 discusses this. Our R_V distribution inferences using optical data only are presented in Appendix C.

6.2.2 Constraints from Optical–NIR Colours and Luminosity: Using External Distance Information

In Section 6.2.1, the dust law population parameters are inferred during photometric distance estimation, in which the photometric distances are marginalised over without external distance constraints being imposed. Under that mode of analysis, information about R_V comes from colours (i.e. the relative brightness differences between photometric passbands). In this section, we repeat our R_V population distribution analysis, but with external distance constraints (see Section 3.4) imposed. When the distance moduli are strongly constrained externally, information about R_V comes from from colours and absolute magnitudes, rather than colours alone⁹. As such, this approach is closer to that of Mandel et al. (2022) and Thorp et al. (2021), where R_V (or its population distribution) was constrained during training of the BAYESN model, with external distance constraints imposed.

Imposing external distance constraints makes very little difference to our R_V population distribution inferences when conditioning on the full $BVriYJH$ light curves. The two rightmost columns of Table 4 list our estimates of the population distribution parameters (μ_R, σ_R) from this analysis (c.f. the adjacent columns, listing the results when no external distance constraints were used). The consistency of these results indicates that when optical and NIR data are available, the colour information alone is highly informative about the distribution of R_V .

⁹ Figure 12 of Mandel et al. (2022) provides a helpful low-dimensional visualisation of how SN Ia colour–colour information can be used to infer R_V (see, also, e.g. Folatelli et al. 2010, fig. 13). Similarly, figure 5 of Thorp et al. (2021) visualises how colour–magnitude information can be used to similar effect.

Figure 8. Two-dimensional marginal posteriors of R_V population distribution parameters, μ_R and σ_R (as defined in Eq. 6), under partial pooling. Axis limits are the same for all quadrants. (upper left panels) Inferences from the population R_V model with no binning by colour or mass, as per Section 3.2 (ii). (upper right panels) Inferences for the model with a population R_V distribution within each of two separate bins of host galaxy stellar mass (above and below the sample median of $10^{10.57} M_\odot$), as per Section 3.2 (iii). (lower left panels) Same as upper right, but split into three bins of $B - V$ colour instead of two bins of host mass. (lower right panels) Same as upper right, but with the sample restricted to apparent $B - V \leq 0.3$.

6.3 A “Gold-Standard” Subsample with NIR at Maximum

In this section, we present a limited set of results on a “gold-standard” subset of the CSP sample – namely the 28 SNe Ia that were identified by Avelino et al. (2019) as having NIR data around maximum light (“NIR@max”). This subset is of particular interest, as we expect it to have the highest quality NIR light curves. Moreover, NIR observations near maximum light are of particular value for the study of

host galaxy dust, as the intrinsic optical–NIR colour dispersion is particularly small here (see Fig. 3, and discussion in Section 4). This makes it easiest to separate the effect of dust from the intrinsic colour variation.

We perform a joint fit to the optical and NIR light curves of these 28 SNe, under the population R_V fitting configuration, where R_V is partially pooled across the sample. From this gold-standard

Table 5. Hubble residual scatter for the “gold-standard” NIR@max subsample of 28 SNe Ia.

Config. ^a	Passbands	RMS	σ_{-pv}	RMS _{$z>0.01$} ^b
Fixed R_V ^c	<i>BVriYJH</i>	0.087	0.075	0.089
	<i>BVri</i>	0.113	0.099	0.115
	<i>YJH</i>	0.091	0.074	0.084
Pop. R_V ^d	<i>BVriYJH</i>	0.087	0.074	0.087

^a Fitting configuration (see §3.2).^b Computed for the 25 SNe with $z_{\text{CMB}} > 0.01$.^c Fixed $R_V = 2.89$.^d R_V partially pooled across the 28 SNe Ia. In this configuration, we infer a population mean of $\mu_R = 2.88 \pm 0.22$, and std. dev. of $\sigma_R = 0.46 \pm 0.26$.

subsample, we estimate a population mean R_V of $\mu_R = 2.88 \pm 0.22$, and a population standard deviation of $\sigma_R = 0.46 \pm 0.26$. This population mean estimate is highly consistent with the global R_V estimate ($R_V = 2.89 \pm 0.20$) made in Mandel et al. (2022), whose training set included these 28 SNe Ia as a significant subset. It is also consistent with the population mean estimate ($\mu_R = 2.70 \pm 0.25$) obtained by Thorp et al. (2021) on the completely independent Foundation supernova sample. The population distribution we infer for the gold-standard subset of 28 SNe Ia is consistent with our inference for our full $B - V \leq 0.3$ subsample of 75 SNe, where we estimate $\mu_R = 2.59 \pm 0.14$ and $\sigma_R = 0.62 \pm 0.16$.

As one would expect, we estimate a very small Hubble diagram scatter on this subsample. Table 5 summarizes these results. Using the full optical and NIR light curves, and a fixed $R_V = 2.89$ we estimate Hubble residual RMS (σ_{-pv}) of 0.087 (0.075) mag – very similar to the Hubble diagram scatter found in Mandel et al. (2022), which included these 28 SNe as a significant subset of their fiducial sample. The RMS is almost exactly the same when using the NIR light curves only, indicating the power of having NIR data at peak where SNe Ia are very close to standard candles (see e.g. Avelino et al. 2019). Using only the optical light curves, the RMS (σ_{-pv}) is slightly higher (0.113 (0.099) mag) but still small, reflecting the fact that this subset generally has the highest quality light curves in all passbands. The Hubble diagram scatter from population R_V fits with partial pooling is almost identical to the fits where R_V was fixed. This is unsurprising, since we estimate that this subsample is highly consistent with a population mean $\mu_R \approx 2.9$, with a narrow estimated R_V distribution. Moreover, since this sample has $B - V \leq 0.3$ (and thus low–moderate dust reddening) by construction, the sensitivity of distance estimates to small deviations of R_V from the population mean will be fairly limited – especially when NIR data are available.

6.4 Individual Highly Reddened Objects

In this section, we investigate the four most highly reddened SNe Ia in the sample: 2005A, 2006X, 2006br, and 2009I. These supernovae constitute the reddest subsample (apparent $B - V > 0.7$) in our colour-binned analyses. Given their extremely high dust extinction, we expect precise inference of R_V for these SNe, independently from the dust population distribution or prior, and will thus focus on the results where each supernova was fitted separately (i.e. no pooling) with a uniform prior, $R_V \sim U(1, 6)$. These results made use of the full *BVriYJH* light curves. Table 6 lists our inferred A_V and R_V values for the four highly reddened SNe Ia. Also listed are the intrinsic $B - V$ colours that we estimate at maximum light, and a derived estimate of colour excess due to reddening: $E(B - V) = A_V / R_V$.

Table 6. Dust inferences^a for the four most highly reddened SNe Ia.

SN	$(B - V)_{\text{int}}$ ^b	A_V ^c	R_V ^d	$E(B - V)$ ^e
2005A	0.16 ± 0.03	2.18 ± 0.06	2.21 ± 0.10	0.99 ± 0.03
2006X	0.09 ± 0.03	2.67 ± 0.05	2.24 ± 0.07	1.19 ± 0.03
2006br	0.06 ± 0.04	2.36 ± 0.10	2.46 ± 0.14	0.96 ± 0.04
2009I	-0.01 ± 0.04	2.06 ± 0.08	2.63 ± 0.18	0.78 ± 0.04

^a All values quoted are posterior mean \pm standard deviation.^b Estimated in the CSP B - and V -bands at the time of B -band maximum.^c Inferred under an exponential prior: $A_V \sim \text{Exponential}(\tau_A = 0.33)$.^d Inferred under a uniform prior: $R_V \sim U(1, 6)$.^e Derived from $E(B - V) = A_V / R_V$.

We can compare our estimates from Table 6 to other A_V , R_V , and $E(B - V)$ estimates for these supernovae, when these are available in the literature. Burns et al. (2014) carried out an extensive study of the CSP data available at the time, including three of the four highly-extinguished SNe Ia included here (2005A, 2006X, 2006br). When assuming the Fitzpatrick (1999) reddening law and a uniform prior on R_V , they estimate $R_V = (1.9 \pm 0.1, 1.8 \pm 0.1, 2.5 \pm 0.2)$ and $E(B - V) = (1.129 \pm 0.029, 1.360 \pm 0.026, 0.896 \pm 0.050)$ for supernovae (2005A, 2006X, 2006br). For 2006br, our estimates of $E(B - V)$ and R_V agree very closely with those of Burns et al. (2014). For 2005A, our estimate of $E(B - V)$ is lower, and our estimate of $R_V = 2.21 \pm 0.10$ is somewhat higher than that of Burns et al. (2014). For 2006X, our estimated $E(B - V) = 1.17 \pm 0.05$ is significantly lower than the $E(B - V) = 1.360 \pm 0.026$ estimated by Burns et al. (2014), and our estimated $R_V = 2.24 \pm 0.07$ is significantly higher than the Burns et al. (2014) estimate of $R_V = 1.8 \pm 0.1$.

Elsewhere in the literature, Folatelli et al. (2010) also present estimates of R_V based on optical and NIR CSP photometry for supernovae 2005A and 2006X, finding values of 1.68 ± 0.10 and 1.55 ± 0.07 , respectively. Also using CSP photometry, Phillips et al. (2013) estimate $A_V = 1.88^{+0.09}_{-0.13}$ and $R_V = 1.31^{+0.08}_{-0.10}$ for 2006X. From their own optical and NIR photometry, taken on a variety of telescopes, Wang et al. (2008) estimate $R_V = 1.48 \pm 0.06$ and $A_V = 2.1$. By comparing the optical spectra of 2006X to the spectroscopically similar unreddened supernova 2004eo, Elías de la Rosa (2007, ch. 5) estimate $R_V = 1.74 \pm 0.11$ and $A_V = 2.08 \pm 0.57$ – a slightly higher R_V value than the photometric analyses of Wang et al. (2008), Folatelli et al. (2010), and Phillips et al. (2013), but still lower than our own estimate. Spectropolarimetric observations of 2006X (see e.g. Patat et al. 2009, 2015) have also been used to constrain its line of sight R_V . Patat et al. (2015) report an upper limit of $R_V \lesssim 2.2$, based on empirical linear relations (Serkowski et al. 1975; Whittet & van Breda 1978; Clayton & Mathis 1988) between R_V and the wavelength of maximum polarisation (estimated to be $\lambda_{\text{max}} \lesssim 0.4 \mu\text{m}$). Inserting the estimate of $\lambda_{\text{max}} = 0.365 \pm 0.02 \mu\text{m}$ for 2006X (Patat et al. 2015) directly into the R_V vs. λ_{max} relations from Serkowski et al. (1975), Whittet & van Breda (1978), and Clayton & Mathis (1988) gives $R_V = 2.01 \pm 0.11, 2.04 \pm 0.15, \text{ and } 2.15 \pm 0.86$, respectively. All of these would be consistent with our own estimate for 2006X ($R_V = 2.24 \pm 0.07$).

In common between Wang et al. (2008), Folatelli et al. (2010), and Phillips et al. (2013) is their use of the Cardelli et al. (1989) dust law (or the update due to O’Donnell 1994), rather than the Fitzpatrick (1999) law that we use here. The Cardelli et al. (1989) law typically yields lower R_V estimates on a supernova-by-supernova basis than the Fitzpatrick (1999) law, as discussed by Burns et al. (2014)¹⁰. This

¹⁰ Indeed, for supernovae 2005A and 2006X, Burns et al. (2014) estimate

could be the source of some of the discrepancy between our own R_V estimate and these other works. A further cause for the discrepancy could be due to the assumptions about the intrinsic colours from which colour excess is determined. Wang et al. (2008), Folatelli et al. (2010), and Phillips et al. (2013) all primarily rely on an assumed or fitted linear relation between mean intrinsic colour and light curve decline rate ($\Delta m_{15}(B)$), à la Phillips et al. (1999). As noted by Wang et al. (2008), a significant deviation of a supernova’s intrinsic colour from the population mean $(B - V)_{\text{int}}$ vs. $\Delta m_{15}(B)$ relation could compromise one’s ability to correctly estimate the level of dust reddening. The BAYESN SED model we have used here ought to be guarded against such an issue, as it incorporates a residual scatter model, inferred during model training, that naturally allows for realistic variation about the mean intrinsic colours associated with a given light curve shape (see the black curves in Figure 3 for a visualisation of this).

It is noticeable that we estimate that 2005A and 2006X are both intrinsically very red, with $(B - V)_{\text{int}} > 0.1$. This could be a possible cause for the discrepancy we see between our results and other photometric studies in the literature. In Mandel et al. (2022), the inferred distribution of intrinsic $B - V$ colour at peak had a population mean of -0.028 ± 0.007 mag, and population standard deviation of 0.065 ± 0.005 mag. This intrinsic colour distribution is implicitly embedded in the M20 BAYESN model (via the population distribution of the $\epsilon_s(t, \lambda)$ functions) we have used throughout the present work. Based on the intrinsic colour estimates in Table 6, 2005A and 2006X would both fall fairly far into the red tail of the M20 population distribution – both beyond the 95th percentile of said distribution. Our estimated intrinsic colours for 2006br and 2009I are less extreme – both within the 95th percentile – but still in the redder half of the M20 distribution.

Supernovae 2005A, 2006X, and 2006br have all been identified as having high ejecta velocities ($\gtrsim 11800 \text{ km s}^{-1}$), as measured by the Si II line at maximum light (Wang et al. 2009; Foley et al. 2011; Blondin et al. 2012; Folatelli et al. 2013; Dettman et al. 2021). Supernova 2009I, on the other hand, was identified by Krisciunas et al. (2017) as being “normal” (i.e. having Si II velocity $< 11800 \text{ km s}^{-1}$ at maximum light) based on the Wang et al. (2009) subclassification scheme. Reported Si II velocities for 2005A (based on the line at 6355 Å) range between $13790 \pm 350 \text{ km s}^{-1}$ (Dettman et al. 2021), and $14976 \pm 279 \text{ km s}^{-1}$ (Folatelli et al. 2013). For 2006X, Si II estimates are typically $\approx 16000 \text{ km s}^{-1}$ (Foley et al. 2011; Blondin et al. 2012; Folatelli et al. 2013), although Dettman et al. (2021) find a lower value of $13790 \pm 220 \text{ km s}^{-1}$. For 2006br, Foley et al. (2011), Blondin et al. (2012), Folatelli et al. (2013), and Dettman et al. (2021) all report ejecta velocity estimates of $\approx 14000 \text{ km s}^{-1}$. It has been reported by various past studies (e.g. Foley & Kasen 2011; Foley 2012; Blondin et al. 2012; Mandel et al. 2014) that SNe Ia with higher ejecta velocities may be intrinsically redder. Additionally, Siebert et al. (2020) report a Hubble residual vs. ejecta velocity step, that would be consistent with a velocity–colour relation. Such an effect could explain the very red colours estimated for 2005A, 2006X, and 2006br. All three of these SNe have estimated Si II velocities $\gtrsim 14000 \text{ km s}^{-1}$ – this puts them towards the fastest tail of the velocity distributions that are typically observed (see e.g. fig. 1 in Foley et al. 2011). In a scenario where Si II velocity and

R_V values of 1.4 ± 0.1 and 1.3 ± 0.1 , respectively. However, they also note that for these two supernovae, a CSM-motivated power-law in the style of Goobar (2008) fits the data better than either of the Cardelli et al. (1989) or Fitzpatrick (1999) dust laws. Whilst noting this caveat, we will defer a thorough investigation of dust-law functional form to future work.

intrinsic colour are correlated (à la Foley et al. 2011; Foley 2012; Mandel et al. 2014), one would thus expect these SNe to lie towards the redder tail of the intrinsic $B - V$ colour distribution, qualitatively consistent with our estimates in Table 6. Our inference that 2009I has an intrinsic colour closer to the population mean would also seem to align with this picture, as this SN is identified as having a normal Si II velocity (Krisciunas et al. 2017). A more quantitative investigation of this effect is beyond the scope of the present work, but could be an interesting topic for future investigation.

It is possible that these SNe are not as intrinsically red as our inferences suggest, so we consider the sensitivity of these results to the extinction prior. The results presented in Table 6 were carried out using an exponential prior on extinction, $A_V \sim \text{Exponential}(\tau_A = 0.33)$, inferred during the training of the M20 BAYESN model. A Bayesian calculation under such a prior will naturally penalise higher A_V values, meaning it may be easier to make a supernova more intrinsically red to explain some of its apparent colour. To investigate whether these intrinsically red colours can be traced to the dust prior, we repeated our fits with an improper flat prior, $A_V \sim U(0, \infty)$, on positive dust extinction. We found that our inferences were essentially unchanged under this alternative prior.

It is worth noting that, whilst we estimate $R_V \approx 2.2\text{--}2.7$ for these four very highly reddened SNe Ia in the CSP-I sample, this may not be characteristic of all such SNe (see e.g. SN 2012cu with $E(B - V) \approx 1$, $R_V \approx 2.8\text{--}3.0$; Amanullah et al. 2015; Huang et al. 2017).

7 CONCLUSIONS

In this paper, we have conducted a detailed investigation into the dust law R_V distribution in SN Ia host galaxies, and tested the sensitivity of the mass step to a variety of Bayesian treatments of this distribution. As a precursor to our main analysis, we have argued for the importance of leveraging colour information across the full optical–NIR wavelength range in order to effectively separate the effects of dust from intrinsic SN Ia colour variation (§4). Moreover, we have presented a simulation-based demonstration of several of the statistical challenges inherent in inferring the host galaxy dust law R_V distribution from a sample of SN Ia photometry (§5). In particular, we have shown that:

- fitting SNe Ia one-by-one, first obtaining point estimates of R_V for each individual with a uniform prior, and then inferring the population distribution by taking the simple standard deviation of the point estimates, will lead to a biased (high) inference of the R_V dispersion within the population;
- if SN Ia residual intrinsic colour scatter is not accounted for in the fit, R_V estimates for individual supernovae will be overconfident (individual uncertainties underestimated) and overdispersed (sample variance larger than the true population variance);
- a shrinkage estimator based on a simple hierarchical Bayesian approach can be used to obtain a more robust constraint on the R_V distribution from a collection of point estimates, but *only* if these have appropriate individual uncertainties (obtained by robustly accounting for intrinsic colour scatter); and
- a fully hierarchical Bayesian approach is the ideal solution, with the distribution of dust laws being constrained whilst fitting the full sample of light curves simultaneously.

We emphasize that these statistical effects will generally apply for any method of estimating dust properties from light curves or colour curves. However, we demonstrate and address them here using the

BAYESN SED model since it uniquely contains a quantitative description of the time-dependent optical–NIR residual intrinsic colour scatter that can be used both for simulation and fitting of SN Ia light curves with variable dust laws. Furthermore, BAYESN has the unique capability of jointly fitting ensembles of SN Ia light curves in a hierarchical configuration.

Motivated by these lessons, we have applied our BAYESN model for the SEDs of SNe Ia (Mandel et al. 2022) to the optical and NIR light curves of 86 supernovae from CSP-I (Krisciunas et al. 2017). Using our hierarchical Bayesian framework to leverage the wide wavelength range covered by the CSP data (B – H band; ~ 3500 – 18500 Å), we have been able to place strong constraints on the population distribution of host galaxy dust law R_V values. Additionally, we have found that the Hubble residuals from distances estimated using the full optical and NIR light curves of the sample show evidence of a step with host galaxy stellar mass, and that this is insensitive to a variety of treatments of R_V and its population distribution.

From the optical and NIR data of the low-to-moderate reddening SNe Ia (peak apparent $B - V \leq 0.3$, consistent with the standard cut used in cosmological analyses), we infer an R_V distribution with a population mean of $\mu_R = 2.59 \pm 0.14$, and a population standard deviation of $\sigma_R = 0.62 \pm 0.16$. Our estimate of the population mean is highly consistent with the estimate ($\mu_R = 2.70 \pm 0.25$) obtained in Thorp et al. (2021), who used the BAYESN model to study a completely independent cosmological SN Ia sample (Foundation DR1; Foley et al. 2018; Jones et al. 2019). Our estimate of the population standard deviation is not large, but is significantly different from zero, and indicates moderate scatter in SN Ia host galaxy R_V . This result is also consistent with the findings of Thorp et al. (2021), who estimated that $\sigma_R \leq 0.61$ with 95 per cent posterior probability. Here, the advantage of the near infrared data generally allows us to place stronger constraints on the small, but likely non-zero, size of the R_V population distribution than Thorp et al. (2021), who were only able to obtain upper limits.

Like Thorp et al. (2021), we do not find strong evidence for a substantial mass dependence of the R_V distribution. Restricting ourselves to the $B - V \leq 0.3$ subset, we estimate $\mu_R = 2.79 \pm 0.18$ for host galaxies less massive than the median ($10^{10.57} M_\odot$), and $\mu_R = 2.35 \pm 0.27$ for those more massive. A similar result is obtained when splitting the sample at $10^{10} M_\odot$. As well as investigating correlations between R_V and host mass, we also attempt to place constraints on the R_V distribution among SNe Ia with redder apparent colours. Although previous works (Mandel et al. 2011; Burns et al. 2014) have found evidence for an anti-correlation between R_V and reddening or apparent colour, we generally do not find a strong effect of this nature (c.f. also Rose et al. 2022). Whether splitting the sample into two ($B - V \leq 0.3$ and $B - V > 0.3$) or three ($B - V \leq 0.3$, $0.3 < B - V \leq 0.7$, $B - V > 0.7$) bins of apparent colour, we find consistency in the mean R_V across the range of apparent colours. However, this inference is based on 11 SNe at $B - V > 0.3$ (of which only 4 have $B - V > 0.7$), so these results should be treated with caution – a larger sample of highly reddened SNe Ia would be needed to properly characterise this effect. However, it is worth noting that this is the first study of optical–NIR colours that has been based on a continuous SED model – the discrete-passband light curve models of Mandel et al. (2011) and Burns et al. (2014) relied on colour-dependent K corrections to map the observed data to the rest-frame. If these were inaccurate at high-reddening, it could explain why our results differ from Mandel et al. (2011) and Burns et al. (2014) in this regime.

We have found that our inferences of the R_V distribution from the full optical and NIR light curves are almost unchanged when dis-

tance constraints based on redshifts and an assumed cosmology are imposed. This indicates that the rich colour information provided by the B through H -band data is sufficient for constraining host galaxy dust properties, independently from the luminosity information provided by external distance estimates to the SNe, and thus independently from the cosmological model. An inspection of the BAYESN model colour curves (§4) reveals why this is the case – when the full wavelength range is available, optical–optical colours provide information about reddening (i.e. $E(B - V)$), whilst optical–NIR colours are sensitive to extinction (i.e. A_V or A_B). In combination, this allows for robust inference of R_V . When only optical–optical colours (e.g. $B - \{V, r, i\}$) are available, constraining R_V with partial information is more challenging, and so the absolute magnitude information provided by independent, external estimates of distances must be invoked to break the degeneracy.

The sample we have analysed in this work is similar to that of Burns et al. (2014), albeit using a new release of the CSP data, and with slightly different cuts. Although we adopt slightly different binning strategies, our inferences about the population mean R_V are broadly consistent with the findings of Burns et al. (2014). When assuming the Fitzpatrick (1999) dust law and excluding fast decliners (SNooPY $s_{BV} < 0.5$), they estimate $\mu_R = 3.3 \pm 0.7$ and $\mu_R = 2.6 \pm 0.4$ for SNe with $0.1 < E(B - V) < 0.3$ and $0.3 < E(B - V) < 0.4$, respectively. Alternatively, when fitting a Gaussian mixture to the full population of SNe with $B - V < 0.5$, they estimate a dominant component with $\mu_R = 2.3 \pm 0.3$. These values are all broadly consistent with our estimate of $\mu_R = 2.59 \pm 0.14$ for our lowest-reddening bin (where $B - V \leq 0.3$). They seem to find a stronger trend of mean R_V with reddening (see also Mandel et al. 2011) than is seen in our own results, although given the uncertainties in the redder colour bins, the two sets of results are not inconsistent. That their Gaussian mixture model is dominated by a single component in all cases (see table 5 in Burns et al. 2014) agrees with our finding that the data do not show a strong preference for a non-Gaussian R_V distribution (see Appendix B). The most striking difference between our results and those of Burns et al. (2014) is in the inferred widths of our R_V population distributions. For all colour bins, Burns et al. (2014) find a preference for wide distributions with $\sigma_R \gtrsim 1$, although there is considerable uncertainty in some cases. Conversely our results point towards narrower distributions, with a high probability of $\sigma_R < 1$ for all colour bins. The reason for this difference is not completely obvious, but could be related to prior choice (although see our Appendix A), treatment of intrinsic colour, binning strategy, or differences in the sample selection and data.

A large number of CSP supernovae were also used in the more recent optical and NIR dust analysis of Johansson et al. (2021) (in combination with additional data from CfA/CfAIR, and their own iPTF sample). Taking the portion of their sample with $0.06 < E(B - V) < 0.5$, they estimate an R_V distribution with mean $\mu_R = 1.9$ and standard deviation $\sigma_R = 0.9$. Splitting their sample by host mass at $10^{10} M_\odot$, they estimate $\mu_R = 1.7$, $\sigma_R = 0.8$ for high-mass hosts, and $\mu_R = 2.2$, $\sigma_R = 0.9$ for low-mass hosts. Their mean R_V estimates are somewhat lower than our own in all cases, and their estimates of σ_R tend to be wider. Their lower mean R_V estimates may be due to their use of the Cardelli et al. (1989) dust law, which often seems to yield slightly lower estimates of R_V (see, e.g. Burns et al. 2014, particularly table 1 therein). Alternatively, it could arise from the fact that unphysically negative values of $E(B - V)$ seem to be allowed in their fits (although they omit SNe with estimated $E(B - V) < 0.06$ mag from their estimates of population mean). Allowing negative $E(B - V)$, whilst not allowing residual intrinsic colour scatter, could cause the $E(B - V)$ parameter to absorb a mixture

of intrinsic colour and dust, thus pushing the estimated R_V lower to capture an overall apparent colour–luminosity effect (similar to β in the Tripp 1998), rather than isolating a dust effect¹¹. Their estimated low vs. high mass $\Delta\mu_R = 0.5$ would not be inconsistent with our own results (e.g., for the $B-V < 0.3$ subsample, we estimate $\Delta\mu_R = 0.24 \pm 0.72$ when splitting at $10^{10} M_\odot$, or $\Delta\mu_R = 0.43 \pm 0.32$ when splitting at the sample median host mass). Since Johansson et al. (2021) estimate σ_R by taking the standard deviation of a collection of point estimates, their tendency towards larger estimates is unsurprising – we have demonstrated in this work (§5) that such a strategy can lead to overestimation. The lack of accounting of residual intrinsic colour scatter when fitting the SNooPy color_model (Burns et al. 2011, 2014) is likely to be a contributing factor.

As well as investigating the dust law distribution in the CSP sample, we also estimate the Hubble residual mass steps obtained from distances estimated using optical-only, NIR-only, and optical+NIR data. Within this sample that is tilted towards more massive hosts (median mass $10^{10.57} M_\odot$), we find that the Hubble residuals obtained from our optical+NIR distances show a step of $0.056\text{--}0.064 \pm 0.026$ mag at the median host galaxy mass (when limited to the $B-V \leq 0.3$ subset, and adopting a hierarchical treatment of R_V and its population distribution). Our Hubble diagram total RMS is typically $\lesssim 0.12$ mag. At $10^{10} M_\odot$ we estimate a similar sized, but more uncertain, mass step, whilst at the maximum likelihood step location ($\sim 10^{10.8} M_\odot$) we estimate a larger step $0.082\text{--}0.090 \pm 0.028$ mag. The step size is largely insensitive to the treatment of host galaxy R_V . We infer distances under fitting configurations where R_V is fixed to a fiducial value for all SNe ($R_V = 2.89$; Mandel et al. 2022), allowed to vary from SN to SN within an inferred population distribution (under various forms of this distribution), or is inferred independently for each SN under one of two weakly informative priors. Using Hubble residuals inferred from optical data only, we find similar or larger mass steps at all locations, and a larger Hubble diagram scatter that is more sensitive to the treatment of R_V . When the Hubble residuals are based on NIR-only estimates of distance, we estimate a step of 0.050 ± 0.032 mag at the median host mass, and 0.084 ± 0.035 mag at the MLE step location. For the full sample, the NIR-only Hubble diagram total RMS is 0.137 mag, smaller than for any of the optical-only results. For the subsample with NIR data at maximum, we obtain an even smaller Hubble diagram RMS of 0.091 mag. Like the results of Ponder et al. (2021) and Jones et al. (2022), we estimate a positive, but fairly uncertain, NIR mass step. Our step sizes’ credible intervals would be consistent with both the larger steps found by Uddin et al. (2020) in *YJH* and Johansson et al. (2021) in *Y*, or the smaller size estimated by Johansson et al. (2021) in *JH*. Larger samples of SN Ia in the NIR will provide more stringent constraints.

In summary, we have been able to leverage the high quality optical and NIR data from CSP-I to place strong constraints on the distribution of host galaxy dust law R_V values in SN Ia hosts. With this independent sample, we have upheld the conclusions of Thorp et al. (2021) – namely that the lines of sight to low reddening ($B-V \leq 0.3$) SNe Ia typical of a cosmological sample have an R_V distribution of small to moderate width, with limited dependence on host galaxy stellar mass. Contrary to other recent work (Johansson et al. 2021), we have found that a mass step persists in the Hubble residuals of SNe Ia distances estimated from the full optical and NIR light curves, and

that this is robust to a variety of Bayesian treatments of host galaxy R_V and its population distribution. When estimating distances from the NIR light curves alone, our results depend on the step location. We find a strong NIR-only step at the maximum likelihood step location, comparable to the equivalent steps in the optical+NIR or optical-only Hubble residuals. Our estimated NIR Hubble residual step at the median host galaxy mass is more tenuous. A weaker NIR mass step could be indicative of a wavelength-dependent correlation between intrinsic SN Ia luminosity and host mass, or an SN–host correlation that is driven by a combination of dust and intrinsic factors. Further work is needed to properly understand this. However, irrespective of the size of any NIR mass step, our finding that the optical+NIR Hubble residuals consistently show a step even when marginalising over the dust law distribution suggests that dust is unlikely to be the only driver of observed SN–host correlations.

We have affirmed here the value of combining optical and NIR data for investigating the dust in SN Ia host galaxies and understanding SN–host correlations. Of critical importance to future investigation is the growth of an SN Ia sample with NIR light curves, and a more representative host galaxy population than was observed by the CSP-I (Krisciunas et al. 2017) and CfAIR2 (Wood-Vasey et al. 2008; Friedman et al. 2015) surveys. Such data are beginning to become available from the RATIR followup of the iPTF survey (Johansson et al. 2021), with more on expected on the horizon from CSP-II (Phillips et al. 2019). The Dark Energy, H_0 , and peculiar Velocities using Infrared Light from Supernovae (DEHVILS; Konchady et al. 2022) survey on the UK Infrared Telescope (UKIRT), and y-band Pan-STARRS data from the Young Supernova Experiment (YSE; Jones et al. 2021) will further enable future investigations. Expanding the sample of high redshift SNe Ia with rest-frame NIR observations (e.g. Jones et al. 2022) will also be of great importance for constraining any potential redshift–evolution of SN Ia host galaxy dust properties.

The ongoing development of robust statistical techniques for modelling dust and SN–host correlations, combined with the continual expansion of the NIR dataset, and the investigation of novel approaches for constraining SN Ia dust and intrinsic properties (e.g. the use of SN Ia siblings; Biswas et al. 2022; Ward et al. in prep.), should enable us to finally address one of the outstanding questions of SN Ia cosmology. This will be vital to ensuring that our understanding of SN Ia dust, and correlations between SNe Ia and their hosts, do not limit our ability to capitalise on the data from the Vera C. Rubin Observatory and Nancy Grace Roman Space Telescope.

ACKNOWLEDGEMENTS

We thank the anonymous referee for their encouraging review and helpful comments. We thank Gautham Narayan for his valuable contributions to the development and implementation of the BAYESN model, and for supporting our access to the Illinois Campus Cluster. We thank Sam M. Ward and Suhail Dhawan for helpful discussions. This work made use of files and metadata compiled by David O. Jones, Andrew S. Friedman, and Arturo Avelino from public datasets. We thank the Carnegie Supernova Project team for making their SN Ia photometry and host galaxy mass estimates publicly available.

APPENDIX A: HYPERPRIOR SENSITIVITY OF DUST LAW POPULATION DISTRIBUTION

As in Thorp et al. (2021, appendix B), we consider here the sensitivity of our R_V population distribution inferences to our choice of prior. In particular, we focus on the choice of prior on the standard deviation parameter(s), σ_R . We rerun our partial pooling analyses, where R_V is either unbinned or binned by $B - V$ colour, using several alternative choices of prior on σ_R . As well as our default prior, $\sigma_R \sim \text{Half-}N(0, 2^2)$, we follow Thorp et al. (2021) in testing a tighter half-normal prior, $\sigma_R \sim \text{Half-}N(0, 1^2)$, and a uniform prior, $\sigma_R \sim U(0, 4)$. The former promotes a higher degree of shrinkage than our default choice, whilst the latter specifies equal preference for any $\sigma_R < 4$ (i.e. the range over which we place 95 per cent prior probability in our default choice). In addition to these, we expand on Thorp et al. (2021) to consider an improper flat prior, $\sigma_R \sim U(0, \infty)$, which should yield a proper posterior (see Gelman 2006; Gelman et al. 2014, §5.7) even for the smallest colour bin (where $N = 4$). We also test the hierarchical prior from Burns et al. (2014, B14)¹²,

$$w^2 \sim U(0, \infty), \quad (\text{A1})$$

$$\sigma_R^2 | w^2 \sim \text{Inv-}\chi^2(1, w^2), \quad (\text{A2})$$

where σ_R^2 has a scaled inverse- χ^2 prior with one degree of freedom, and a scale parameter, w , whose square has an improper uniform prior. Since the inverse- χ^2 distribution is zero-avoiding (i.e. places zero probability density at $\sigma_R = 0$ and therefore a priori excludes it and penalises small values of σ_R), and the improper prior on w^2 will concentrate at $w^2 \rightarrow \infty$, we expect this prior choice will encourage high estimates of σ_R . It will certainly prevent the estimates of σ_R from shrinking towards zero, even if the number of groups being considered (five colour bins in Burns et al. 2014) is enough to constrain w^2 . This prior choice may explain the results of Burns et al. (2014), who estimated wide R_V population distributions (with posterior mean $\sigma_R \gtrsim 1$) in all of their reddening bins (see their table 6).

Table A1 lists our posterior inferences on σ_R under the alternative prior choices. For the 1- or 2-bin models, the $\text{Half-}N(0, 1^2)$, $U(0, 4)$, and $U(0, \infty)$ priors have negligible impact on our σ_R posteriors compared to our default $\text{Half-}N(0, 2^2)$ choice. For the 3-bin model, there is some sensitivity in the tail of the posterior, but it is fairly small. For example, in switching from the $\sigma_R \sim \text{Half-}N(0, 2^2)$ to the $\sigma_R \sim \text{Half-}N(0, 1^2)$ prior, the 95th percentile of the posterior for the $0.3 < B - V \leq 0.7$ colour bin shifts inwards from $\sigma_R = 1.02$ to $\sigma_R = 0.56$. For the $B - V > 0.7$ bin, the 95th percentile shifts from $\sigma_R = 0.76$ to $\sigma_R = 0.62$ under the same change of prior. The shift in the 68th percentile is smaller, only $\lesssim 0.05$ for both colour bins. Under the B14 prior (Eq. A1, A2), the posterior estimates of σ_R are consistent with those from the other prior choices. However, the posteriors peak away from zero for all bins, something that isn't true for the other priors (which do not a priori exclude zero). The prior scale hyperparameter, w , has a very similar posterior for the model configurations with two or three colour bins. For the 3-bin configuration, we estimate that $0.09 \leq w \leq 0.82$ with 95 per cent

¹² Their appendix A.1.2 suggests that they adopt this prior for both their Gaussian mixture R_V population distribution model, and for their $E(B - V)$ binned model inspired by Mandel et al. (2011). However, it is not totally explicit that they adopt this prior in the latter case.

Table A1. Sensitivity analysis of the constraints on the dust R_V population std. dev. hyperparameter σ_R , from full optical and NIR light curves under alternative hyperprior choices.

Binning ^b	Subsample	σ_R^a				
		Half- $N(0, 2^2)^c$	Half- $N(0, 1^2)$	$U(0, 4)$	$U(0, \infty)$	B14 ^d
Unbinned	-	0.34 ± 0.11	0.33 ± 0.11	0.33 ± 0.11	0.34 ± 0.11	0.38 ± 0.10
2-bin	$B - V \leq 0.3$	0.62 ± 0.16	0.54 ± 0.16	0.55 ± 0.16	0.59 ± 0.16	0.51 ± 0.15
	$B - V > 0.3$	0.17 ± 0.10	0.17 ± 0.10	0.17 ± 0.10	0.18 ± 0.11	0.24 ± 0.12
3-bin	$B - V \leq 0.3$	0.57 ± 0.20	0.57 ± 0.15	0.58 ± 0.17	0.57 ± 0.16	0.52 ± 0.16
	$0.3 < B - V \leq 0.7$	$0.34 (1.02)$	$0.29 (0.56)$	$0.32 (0.68)$	$0.33 (0.72)$	0.30 ± 0.18
	$B - V > 0.7$	$0.31 (0.76)$	$0.28 (0.62)$	$0.28 (0.65)$	$0.31 (0.83)$	0.30 ± 0.21

^a Different columns correspond to different σ_R hyperprior choices. Values quoted are either posterior mean \pm standard deviation, or 68 (95)% upper bounds.

^b Colour binning strategy.

^c Default prior choice (reproduced from Table 4).

^d Burns et al. (2014, B14) hierarchical prior (Eq. A1, A2).

posterior probability. For the 1-bin configuration, the prior scale is less constrained, with the 95 per cent credible interval covering $0.16 \leq w \leq 1.34$.

Figure A1 shows the posterior distribution of σ_R in different colour bins (under the 3-bin model) for different choices of prior. The posteriors are depicted via histograms of the MCMC samples, rather than kernel density estimates, and with a more zoomed in σ_R axis than Figure 8. This is to highlight the behaviour at low σ_R . The lower left panel uses our fiducial prior, $\sigma_R \sim \text{Half-}N(0, 2^2)$, and is equivalent to the lower left panel of Figure 8. The zero-avoidance induced by the B14 prior is clearly visible in the upper right panel – none of the other prior choices yield posteriors that exhibit this behaviour.

Overall, the only slight differences resulting from the prior choices we have tried here indicate that our posterior results are relatively insensitive and robust to them.

APPENDIX B: ALTERNATIVE FORMS FOR THE DUST LAW POPULATION DISTRIBUTION

Here, we present results from photometric distance fits with partial pooling of R_V (Section 3.2 (ii)), but with alternative forms for the R_V population distribution than our fiducial choice of a truncated normal (Eq. 6). Specifically, we repeat our analysis assuming either a skew normal¹³ population distribution,

$$R_V^S \sim \text{Skew-}N(\xi_R, \omega_R, \alpha_R) \text{ for } R_V^S \geq 0.5, \quad (\text{B1})$$

or a Student's t ¹⁴ population distribution,

$$R_V^S \sim \text{Student-}t(\nu_R, \mu_R, \sigma_R) \text{ for } R_V^S \geq 0.5, \quad (\text{B2})$$

¹³ We define $X \sim \text{Skew-}N(\xi, \omega, \alpha)$ as a random variable drawn from a skew normal distribution, with location parameter ξ , scale parameter ω , and skewness parameter α . The probability density function is

$$P(X|\xi, \omega, \alpha) = \frac{2}{\omega} \phi\left(\frac{X - \xi}{\omega}\right) \Phi\left(\alpha \frac{X - \xi}{\omega}\right),$$

where $\phi(z)$ and $\Phi(z)$ are respectively the PDF and CDF of a standard normal random variable z .

¹⁴ We define $X \sim \text{Student-}t(\nu, \mu, \sigma)$ as a random variable drawn from a Student's t -distribution, with location parameter μ , scale parameter σ , and degrees-of-freedom ν . The probability density function is

$$P(X|\nu, \mu, \sigma) = \frac{\Gamma[(\nu+1)/2]}{\Gamma(\nu/2)\sqrt{\nu\pi}\sigma} \left[1 + \frac{1}{\nu} \left(\frac{X - \mu}{\sigma}\right)^2\right]^{-(\nu+1)/2},$$

where $\Gamma(z)$ is the gamma function.

both truncated to $R_V \geq 0.5$ ¹⁵. These distributions were chosen to probe specific kinds of non-Gaussianity (skewness, or heavy-tailedness, respectively). Both can revert to a normal distribution as a special case, with $\text{Skew-}N(\xi, \omega, \alpha) \rightarrow N(\xi, \omega^2)$ for $\alpha = 0$, and $\text{Student-}t(\nu, \mu, \sigma) \rightarrow N(\mu, \sigma^2)$ as $\nu \rightarrow \infty$.

When adopting these alternative R_V distributions, we use the same hyperpriors (from Thorp et al. 2021) on their location and scale parameters as we do when assuming a truncated normal R_V distribution, i.e. location $\sim U(1, 5)$, and scale $\sim \text{Half-}N(0, 2^2)$. For the skew normal distribution, we adopt a Gaussian prior on the skewness parameter, $\alpha_R \sim N(0, 2^2)$, since this allows a fairly substantial skew without preference for either direction. For the t -distribution's degrees-of-freedom parameter, we follow Juárez & Steel (2010) in adopting a Gamma distribution prior¹⁶, $\nu_R \sim \text{Gamma}(\alpha = 2.0, \beta = 0.1)$.

Under these two models, our constraints on any non-Gaussianity of the R_V distribution are limited. For the skew normal population distribution, we estimate a location parameter $\xi_R = 2.33 \pm 0.30$, and a scale parameter $\omega_R = 0.49 \pm 0.18$. The skewness parameter shows a weak preference for a positively skewed distribution, with $\alpha_R = 1.14 \pm 2.08$, although both directions of skew are permitted in the posterior with high probability. The upper panel of Figure B1 shows our joint posterior over the three parameters of the skew normal distribution. Although the posterior mean of the location parameter, ξ_R , is lower than the posterior estimate of μ_R for the Gaussian population distribution (c.f. Table 4, and the upper left panels of Fig. 8), it is worth noting that ξ_R does not equal the implied distribution mean unless $\alpha_R = 0$. In fact, for each MCMC sample, i , we can estimate the expected value of R_V , $\mathbb{E}(R_V | \xi_R^i, \omega_R^i, \alpha_R^i)$, implied

¹⁵ Let a random variable, X , follow an untruncated probability distribution with PDF $f(X)$ and CDF $F(X)$. Let a second random variable, Y , follows the same probability distribution, but truncated on its lower tail so $Y \geq a$. The probability density function for Y will be

$$P(Y) = \begin{cases} f(Y)/[1 - F(a)] & \text{for } Y \geq a \\ 0 & \text{elsewhere} \end{cases}.$$

¹⁶ This choice is weakly informative, and covers a wide range of possibilities, with the 1st and 99th percentiles falling at $\nu_R = 1.5$ (where the t -distribution will be nearly a Cauchy) and $\nu_R = 66.4$ (where the t -distribution will be practically Gaussian), respectively. We expect this simple choice will be sufficient for our purposes. For alternatives, see e.g. Fonseca et al. (2008); Juárez & Steel (2010); Frühwirth-Schnatter & Pyne (2010); Rubio & Steel (2015); Simpson et al. (2017).

Figure A1. Histograms of σ_R posterior samples under different choices of prior for the model configuration where an R_V population distribution is inferred within each of 3 colour bins. Axes are the same for all panels. Coloured lines depict the σ_R posteriors in different colour bins. Grey lines show the priors. For the B14 prior, the prior scale parameter, w^2 , is a free parameter, so no prior is plotted. The histogram bins have a width of 0.05.

by the population distribution parameters $(\xi_R^i, \omega_R^i, \alpha_R^i)$ under the skew normal population distribution. Doing this, we estimate that $\mathbb{E}(R_V | \xi_R, \omega_R, \alpha_R) = 2.50 \pm 0.09$. This is almost perfectly consistent with our posterior estimate of $\mu_R = 2.48 \pm 0.08$ for the mean of the Gaussian population distribution.

For the Student's t -distribution, we estimate a location parameter of $\mu_R = 2.47 \pm 0.08$, and a scale of $\sigma_R = 0.30 \pm 0.11$. These values are quite consistent with the population mean and standard deviation parameters we estimate when assuming a Gaussian population distribution (see Table 4 and Fig. 8). The degrees-of-freedom parameter, ν_R has a posterior very close to the prior, suggesting that there is little preference for any particular level of heavy-tailed-ness in this sample. The lower panel of Figure B1 shows the posterior distribution of the parameters of the Student's t R_V population distribution.

We find that marginalising over these alternative R_V population distributions when inferring distances has very little impact on the estimated mass step in the resulting Hubble residuals. Across the range of possible mass step locations, our estimated Hubble residual steps are highly consistent with those estimated when our fiducial choice of a Gaussian R_V population distribution was adopted.

Figure B1. Posterior inferences of dust R_V population distribution parameters for the two alternative distributional forms. Coloured lines depict the posteriors. Faint grey lines on the 1D marginals show the priors. (top panel) Skew normal R_V population distribution (Eq. B1). (bottom panel) Student's t population distribution (Eq. B2).

APPENDIX C: DISTRIBUTION OF DUST LAWS: USING OPTICAL DATA ONLY

The most reliable inference of R_V and its population distribution is achieved when leveraging the full optical and NIR ($BVriYJH$) light curves of our sample. Nevertheless, we can also attempt our analysis whilst using only the optical ($BVri$) light curves. This Appendix presents these results, with the use of external distance information. Without the use of external distance constraints, population R_V in-

Table C1. Same as Table 4, but dust R_V population constraints using optical-only ($BVri$) data with external distance information applied.

Binning	Subsample	N	μ_R	σ_R
Unbinned	-	86	2.53 ± 0.15	0.51 ± 0.14
Colour (2-bin)	$B - V \leq 0.3$	75	2.72 ± 0.17	0.40 ± 0.21
	$B - V > 0.3$	11	2.14 ± 0.30	0.60 ± 0.34
Colour (3-bin)	$B - V \leq 0.3$	75	2.73 ± 0.15	0.35 ± 0.19
	$0.3 < B - V \leq 0.7$	7	2.39 ± 0.36	0.74 ± 0.50
	$B - V > 0.7$	4	1.83 ± 0.29	0.55 ± 0.47
Mass ($10^{10} M_\odot$)	low	15	2.79 ± 0.49	1.29 ± 0.62
	high	71	2.47 ± 0.15	0.45 ± 0.14
Mass ($10^{10.57} M_\odot$)	low	43	2.76 ± 0.19	0.60 ± 0.18
	high	43	2.26 ± 0.23	0.52 ± 0.35

ferences are not very reliable, for the reasons discussed in Section 4. Under these conditions, R_V is constrained only by colour information (i.e. relative differences in magnitude between passbands). Optical colours by themselves do not effectively constrain individual R_V values nor their population distribution for most of the sample (c.f. Fig. 3). When external distance constraints are imposed, R_V is informed by colour–magnitude information, rather than colours alone. Stronger constraints are possible from the optical light curves under these circumstances.

Table C1 lists our posterior estimates of the R_V population distribution parameters (μ_R, σ_R) from fitting optical ($BVri$) data with external distance constraints imposed. For all configurations considered, our estimates of the population mean, μ_R , are consistent to within $\lesssim 2\sigma$ with the equivalent estimates made using the full $BVriYJH$ data. The same is true for our estimates of the population standard deviation parameter, σ_R .

The colour-binned results from fitting only the optical data would seem to suggest a stronger trend of mean R_V with colour/reddening (à la Mandel et al. 2011; Burns et al. 2014) than the results from the optical + NIR analysis. This is particularly apparent in the 3-bin configuration, where the population mean R_V estimates for the lowest- ($B - V \leq 0.3$) and highest-reddening ($B - V > 0.7$) supernovae are $\sim 2.8\sigma$ apart when only the $BVri$ data are considered. Although this appears to be drastically different to the conclusion from the analysis of the $BVriYJH$ data, where the same colour bins differ by only $\sim 1\sigma$ in estimated mean R_V , the actual parameter estimates from the two analyses differ by at most $\sim 1.4\sigma$ (with the biggest difference being between the μ_R estimates in the very sparsely populated $B - V > 0.7$ bin).

This paper has been typeset from a $\text{\TeX}/\text{\LaTeX}$ file prepared by the author.
