Abstract. The study of cosmic expansion history and the late time cosmic acceleration from observational data depends on the nuisance parameters associated with the data. For example, the absolute peak magnitude of type Ia supernova associated with the type Ia supernova observations and the comoving sound horizon at the baryon drag epoch associated with baryon acoustic oscillation observations are two nuisance parameters. The nuisance parameters associated with the gamma-ray bursts data are also considered. These nuisance parameters are constrained by combining the cosmological observations using the Gaussian process regression method with minimal model dependence. The bounds obtained in this method can be used as the prior for the data analysis while considering the observational data accordingly. Along with these nuisance parameters, the cosmic curvature density parameter is also constrained simultaneously. We find that the constraints on the cosmic curvature density parameter show no significant deviations from a flat Universe.

1 Introduction

The late time cosmic acceleration is one of the major discoveries in the late 20th-century [42, 43, 47, 61]. This acceleration has been confirmed by several cosmological observations such as type Ia supernova [10, 14, 34, 49], cosmic microwave background (CMB) [1–3], baryon acoustic oscillation (BAO) [4, 5, 25] etc. One of the possible explanations of the late time cosmic acceleration is the introduction of an exotic matter component, called dark energy, that has large negative pressure [18, 40, 62]. Another alternative to explain this acceleration is the modification of general relativity at large cosmological scales [16, 28, 31, 53]. Several dark energy and modified gravity models have been proposed in the literature and these models have been constrained and shaped by the cosmological observations [28, 37].

Alongside the type Ia supernova, CMB, and BAO observations, several other observations have been continuously developed to better understand the nature of the late time cosmic acceleration and the mechanisms to explain this acceleration. For example, such observations are the cosmic chronometers (CC) [27, 44] and gamma-ray bursts (GRB) [6, 30, 58] observations. All these recent observations are providing us with percent precision data which are helpful to understand the nature of dark energy or modification of gravity [39, 59] with high precision.

The simplest candidate for dark energy is considered to be the cosmological constant and the corresponding model is called the Λ CDM model [13]. This is the most successful model to study the evolution of the Universe in light of recent cosmological observations [1–3]. This model has theoretical problems like fine-tuning and cosmic coincidence problems

[38, 48, 56, 64]. Despite these theoretical problems, there are other inconsistencies with this model that arose from the percent precision observational data [8, 41]. One such example is the so-called Hubble tension [19, 32, 55]. Considering these caveats into account, it is necessary to go beyond the Λ CDM model. In this context, in literature, many dynamical dark energy and modified gravity models have been developed gradually [28, 37].

The background dynamics of the Universe are not only studied through different dark energy and modified gravity models but it has also been studied through different parametrizations to the different cosmological quantities without assuming any model [7, 15, 20, 21, 35, 52]. Even in recent times, background dynamics are studied from several observations with the minimal model or parametrization dependence by using various modern techniques [23, 33, 36, 54, 57, 63]. One such technique is the Gaussian process regression (GPR) and it has been used in the literature in several contexts [26, 50, 51]. The GPR method is the key ingredient in our analysis.

Most of the above-mentioned observations involve cosmological nuisance parameters like the peak absolute magnitude of the type Ia supernova [11, 24]. Because of this reason, both the model dependent and independent studies of the late time cosmic acceleration depend on these cosmological nuisance parameters [12, 17]. So, to study the late time cosmic acceleration, we need prior information on these parameters. However, without priors or with flat priors, these parameters can be constrained by combining different observations [22]. In our analysis, we constrain these nuisance parameters from the joint analysis of cosmological observations, mentioned above.

Constraints on the nuisance parameters degenerate to the cosmic curvature density parameter [9, 36]. Thus, it is also important to simultaneously constrain the cosmic curvature density parameter. For this reason, in our analysis, we keep the cosmic curvature density parameter as a free parameter and simultaneously constrain it with other parameters from different combinations of cosmological observations.

This paper is organized as follows: In Sec. 2, we mention the basic cosmological equations; in Sec. 3, we present the methodology to obtain bounds on several nuisance parameters from the combinations of different data; in Sec. 4, we present the results of our analysis; the concluding remarks are mentioned in Sec. 5.

2 Basics

In our entire analysis, we assume that the geometry of the Universe is described by the Friedmann-Lemaître-Robertson-Walker (FLRW) metric. In FLRW cosmology, the line of sight comoving distance, d_C is given as

$$d_C = cd_P, \quad (2.1)$$

where c is the speed of light in vacuum and d_P is given as

$$d_P = \int_0^z \frac{d\tilde{z}}{H(\tilde{z})}, \quad (2.2)$$

where H is the Hubble parameter, z is the redshift, and \tilde{z} is the dummy argument for the redshift.

In the presence of the cosmic curvature, the transverse comoving distance differs from the line of sight comoving distance. The transverse comoving distance, d_M is given as

$$d_M = \begin{cases} \frac{c}{\sqrt{W_{k0}}} \sinh(\sqrt{W_{k0}} d_P), & \text{for } \Omega_{k0} > 0, \\ cd_P, & \text{for } \Omega_{k0} = 0, \\ \frac{c}{\sqrt{|W_{k0}|}} \sin(\sqrt{|W_{k0}|} d_P), & \text{for } \Omega_{k0} < 0, \end{cases} \quad (2.3)$$

where Ω_{k0} is the cosmic curvature density parameter given as $\Omega_{k0} = -Kc^2/a_0^2 H_0^2$; K is the spatial curvature of the space-time; a_0 is the present value of the scale factor and it can be normalized as $a_0 = 1$ without loss of generalization; H_0 is the Hubble parameter at present or Hubble constant; W_{k0} is given as

$$W_{k0} = \Omega_{k0} H_0^2 = 10^4 (\Omega_{k0} h^2) [\text{KmS}^{-1} \text{Mpc}^{-1}]^2, \quad (2.4)$$

where Hubble constant is related to the dimensionless parameter, h given as $H_0 = 100h \text{KmS}^{-1} \text{Mpc}^{-1}$. The luminosity distance, d_L is related to the transverse comoving distance as

$$d_L = (1+z)d_M. \quad (2.5)$$

The angular diameter distance, d_A is also related to the transverse comoving distance given as

$$d_A = \frac{d_M}{1+z}. \quad (2.6)$$

For a type Ia supernova, the observed (apparent) peak magnitude, m is related to the luminosity distance given as

$$m - M_B = 5 \log_{10} \left(\frac{d_L}{\text{Mpc}} \right) + 25, \quad (2.7)$$

where M_B is the absolute peak magnitude of the type Ia supernova.

2.1 Hubble parameter from luminosity distance

In the subsequent sections, we will need the derivation of the Hubble parameter from the luminosity distance, because we will avoid any integral equation like in Eq. (2.2). To do this, we first take the derivative of Eq. (2.3) and we get

$$d'_M = \begin{cases} cd'_P \cosh(\sqrt{W_{k0}} d_P), & \text{for } \Omega_{k0} > 0, \\ cd'_P, & \text{for } \Omega_{k0} = 0, \\ cd'_P \cos(\sqrt{-W_{k0}} d_P), & \text{for } \Omega_{k0} < 0, \end{cases} \quad (2.8)$$

where prime denotes the derivative with respect to the redshift. The above equation is rewritten as

$$d'_P = \begin{cases} \frac{d'_M}{c \cosh(\sqrt{W_{k0}} d_P)}, & \text{for } \Omega_{k0} > 0, \\ \frac{d'_M}{c}, & \text{for } \Omega_{k0} = 0, \\ \frac{d'_M}{c \cos(\sqrt{-W_{k0}} d_P)}, & \text{for } \Omega_{k0} < 0. \end{cases} \quad (2.9)$$

We solve Eq. (2.3) to get d_P from d_M and putting these solutions in the above equation, we get

$$(d'_P)^2 = \begin{cases} \frac{(d'_M)^2}{c^2 + W_{k0}d_M^2}, & \text{for } \Omega_{k0} > 0, \\ \frac{(d'_M)^2}{c^2}, & \text{for } \Omega_{k0} = 0, \\ \frac{(d'_M)^2}{c^2 + W_{k0}d_M^2}, & \text{for } \Omega_{k0} < 0. \end{cases} \quad (2.10)$$

The above equation can be rewritten as

$$(d'_P)^2 = \frac{(d'_M)^2}{c^2 + W_{k0}d_M^2}, \quad (2.11)$$

and valid for all values of Ω_{k0} . Taking derivative of Eq. (2.2), we get $d'_P = 1/H$. Putting this in the above equation we get

$$H^2 = \frac{c^2 + W_{k0}d_M^2}{(d'_M)^2}. \quad (2.12)$$

Using Eq. (2.5) in the above equation, we get

$$H^2 = \frac{(1+z)^2 [c^2(1+z)^2 + W_{k0}d_L^2]}{[(1+z)d'_L - d_L]^2}. \quad (2.13)$$

Consequently, we get the Hubble parameter from the luminosity distance and its derivative given as

$$H = \left(\frac{(1+z)^2 [c^2(1+z)^2 + W_{k0}d_L^2]}{[(1+z)d'_L - d_L]^2} \right)^{\frac{1}{2}}. \quad (2.14)$$

2.2 d_L and d'_L from m and m'

The luminosity distance can be computed from m using Eq. (2.7) given as

$$d_L = 10^{\frac{1}{5}(m-25-M_B)} \text{ Mpc}. \quad (2.15)$$

Taking derivative of the above equation w.r.t redshift, we get d'_L from m and m' given as

$$d'_L = \frac{\log 10}{5} 10^{\frac{m-M_B-25}{5}} m' \text{ Mpc}, \quad (2.16)$$

3 Methodology

We combine different cosmological observations to obtain bounds on different cosmological nuisance parameters. To do this, we consider the Pantheon sample for type Ia supernova observations [49], the cosmic chronometers observations [27, 44], the baryon acoustic oscillation observations [5], and the Amati correlated gamma-ray bursts data [6, 30, 58]. For the methodology, here, we adapt the Gaussian process regression (GPR) analysis [26, 29, 45, 50, 51, 60]. Throughout this paper, we denote type Ia supernova, cosmic chronometers, baryon acoustic oscillation, and gamma-ray bursts data by 'SN', 'CC', 'BAO', and 'GRB' respectively. Any quantity having subscript or superscript with these keywords corresponds to the values of that quantity at data points of corresponding observations. For example, z_{SN} represents the redshift points corresponding to the SN data.

3.1 Reconstruction of m and m' from SN data using GPR

This work aims to combine the SN data with other data, for example, the CC data. Comparing any two data sets are not straightforward because two different observations have data for two different quantities and they are not at the same data points. For example, the SN data measures m (with error bars, Δm) [49] and the CC data measures H (with error bars, ΔH) [27, 44] at different redshift points. We consider the notation ΔX to represent the standard deviation in any quantity, X throughout this analysis.

For the solution of this problem, GPR is useful [26, 29, 45, 50, 51, 60]. To have the lower computational time cost, we choose the posterior GPR approach [45, 50, 51, 60]. With this GPR analysis, we reconstruct a function for $m(z)$ and the corresponding uncertainties from the SN data. The posterior approach of the GPR analysis takes the data and the uncertainties in the data as the inputs and predicts the function for the corresponding quantity and the associated uncertainty in it. For these predictions, GPR analysis also considers a kernel covariance function and a mean function as inputs. For this purpose, we choose the squared exponential kernel and the mean function for $m(z)$ corresponding to the Λ CDM model. For details of the GPR analysis, see Appendix A and for details of the kernel and mean functions, see Appendix B. We denote the predicted function for m as m_{GPR} and the corresponding uncertainties as Δm_{GPR} .

The GPR analysis not only predicts the function for a quantity corresponding to the observational data, but it can also predict the function for the derivatives of the quantity. We only need the first derivative prediction in our analysis. For the details of the first derivative prediction, see Appendix A. We denote the predicted function for the first derivative of m w.r.t z as m'_{GPR} and the corresponding uncertainties as $\Delta m'_{\text{GPR}}$. All these predicted functions will be used in the next steps.

3.2 Combination of SN and CC data: bounds on M_B and $\Omega_{k0}h^2$

From reconstructed m_{GPR} (obtained from the above subsection), we reconstruct d_L using Eq. (2.15) and the corresponding uncertainties. Similarly, from reconstructed m_{GPR} and m'_{GPR} (obtained from the above subsection), we reconstruct d'_L using Eq. (2.16) and the corresponding uncertainties. Note that, these reconstructed functions are dependent on the parameter, M_B . This can be seen through Eqs. (2.15) and (2.16).

From these reconstructed functions, next, we reconstruct the corresponding Hubble parameter using Eq. (2.14). From Eq. (2.14), we can see that reconstruction of H from d_L and d'_L depends on the W_{k0} parameter. So, ultimately, the reconstructed H and the corresponding uncertainties are dependent on both M_B and W_{k0} . We denote these as H_{GPR} and ΔH_{GPR} respectively.

We compare the reconstructed Hubble parameter with the Hubble parameter data obtained directly from the CC data to determine M_B and W_{k0} simultaneously. For this purpose, we define a log-likelihood ($\log L_{\text{CC}}$) given as

$$\begin{aligned} \log L_{\text{CC}}(M_B, W_{k0}) = & -\frac{1}{2} \sum_{z_{\text{CC}}} \frac{[H_{\text{GPR}}(z_{\text{CC}}, M_B, W_{k0}) - H_{\text{CC}}]^2}{\Delta H_{\text{tot}}^2(z_{\text{CC}}, M_B, W_{k0})} \\ & -\frac{1}{2} \sum_{z_{\text{CC}}} \log [2\pi \Delta H_{\text{tot}}^2(z_{\text{CC}}, M_B, W_{k0})], \end{aligned} \quad (3.1)$$

where ΔH_{tot}^2 is the total variance in the Hubble parameter given as $\Delta H_{\text{tot}}^2(z_{\text{CC}}, M_B, W_{k0}) = \Delta H_{\text{GPR}}^2(z_{\text{CC}}, M_B, W_{k0}) + \Delta H_{\text{CC}}^2$. H_{CC} and ΔH_{CC} correspond to the Hubble parameter data and the corresponding uncertainties obtained directly from the CC data. z_{CC} corresponds to the CC redshift points. We get simultaneous constraints on M_B and W_{k0} by minimizing the negative log-likelihood mentioned in Eq. (3.1). Since, W_{k0} and $\Omega_{k0}h^2$ are equivalent through Eq. (2.4), finally, we get simultaneous constraints on M_B and $\Omega_{k0}h^2$.

3.3 Combination of SN, CC and BAO data: constraints on M_B , $\Omega_{k0}h^2$, and r_d (comoving sound horizon at baryon drag epoch)

The BAO data have two kinds of measurements: one is in the line of sight direction and related to the quantity, D_H ; the second one is in the transverse direction and related to the quantity, D_M . D_H and D_M are given as

$$D_H = \frac{1}{r_d} \frac{c}{H}, \quad (3.2)$$

$$D_M = \frac{1}{r_d} \frac{d_L}{1+z}, \quad (3.3)$$

respectively, where r_d is the comoving sound horizon at baryon drag epoch [5]. We denote the BAO data which are related to D_H as BAO1 and we denote the other BAO data which are related to D_M as BAO2. So, BAO data can be considered as two types of data as BAO1 and BAO2 i.e. $\text{BAO} = \text{BAO1} + \text{BAO2}$.

Similar to the previous case, we reconstruct H at BAO redshift points (z_{BAO}) from the reconstructed m_{GPR} and m'_{GPR} (obtained from Sec. 3.1) via d_L and d'_L and the corresponding uncertainties. Note that the BAO1 and BAO2 redshift points are the same and we call these as BAO redshift points, z_{BAO} i.e. $z_{\text{BAO1}} = z_{\text{BAO2}} = z_{\text{BAO}}$. From this reconstructed Hubble parameter, we compute D_H and the corresponding uncertainties at BAO redshift points using Eq. (3.2). We denote these as D_H^{GPR} and ΔD_H^{GPR} respectively. We compare these with the D_H directly obtained from the BAO1 data and we denote this as D_H^{BAO1} . We denote the corresponding uncertainties as ΔD_H^{BAO1} . The corresponding log likelihood ($\log L_{\text{BAO1}}$) is defined as

$$\begin{aligned} \log L_{\text{BAO1}}(M_B, W_{k0}, r_d) = & -\frac{1}{2} \sum_{z_{\text{BAO}}} \frac{[D_H^{\text{GPR}}(z_{\text{BAO}}, M_B, W_{k0}, r_d) - D_H^{\text{BAO1}}]^2}{(\Delta D_H^{\text{tot}}(z_{\text{BAO}}, M_B, W_{k0}, r_d))^2} \\ & -\frac{1}{2} \sum_{z_{\text{BAO}}} \log \left[2\pi (\Delta D_H^{\text{tot}}(z_{\text{BAO}}, M_B, W_{k0}, r_d))^2 \right], \end{aligned} \quad (3.4)$$

where $(\Delta D_H^{\text{tot}})^2$ is the total variance in D_H given as

$$(\Delta D_H^{\text{tot}}(z_{\text{BAO}}, M_B, W_{k0}, r_d))^2 = (\Delta D_H^{\text{BAO1}})^2 + (\Delta D_H^{\text{GPR}}(z_{\text{BAO}}, M_B, W_{k0}, r_d))^2. \quad (3.5)$$

Next, using the reconstructed m_{GPR} (obtained from Sec. 3.1), we compute D_M (via d_L) at BAO redshift points using Eq. (3.3) and the corresponding uncertainties. We denote these as the D_M^{GPR} and ΔD_M^{GPR} respectively. We denote the D_M and ΔD_M directly obtained from

the BAO2 data as D_M^{BAO2} and ΔD_M^{BAO2} respectively. We compare these two by defining a corresponding log-likelihood ($\log L_{\text{BAO2}}$) given as

$$\begin{aligned} \log L_{\text{BAO2}}(M_B, r_d) = & -\frac{1}{2} \sum_{z_{\text{BAO}}} \frac{[D_M^{\text{GPR}}(z_{\text{BAO}}, M_B, r_d) - D_M^{\text{BAO2}}]^2}{(\Delta D_M^{\text{tot}}(z_{\text{BAO}}, M_B, r_d))^2} \\ & -\frac{1}{2} \sum_{z_{\text{BAO}}} \log \left[2\pi (\Delta D_M^{\text{tot}}(z_{\text{BAO}}, M_B, r_d))^2 \right], \end{aligned} \quad (3.6)$$

where $(\Delta D_M^{\text{tot}})^2$ is the total variance in D_M given as

$$(\Delta D_M^{\text{tot}}(z_{\text{BAO}}, M_B, r_d))^2 = (\Delta D_M^{\text{BAO2}})^2 + (\Delta D_M^{\text{GPR}}(z_{\text{BAO}}, M_B, r_d))^2. \quad (3.7)$$

Note that, in this step, the W_{k0} parameter is not involved. That is why, in the above two equations, the W_{k0} parameter is not present.

So, the total log-likelihood for the two kinds of BAO observations, $\log L_{\text{BAO}}$ is given as

$$\log L_{\text{BAO}}(M_B, W_{k0}, r_d) = \log L_{\text{BAO1}}(M_B, W_{k0}, r_d) + \log L_{\text{BAO2}}(M_B, r_d). \quad (3.8)$$

Here, one important fact to notice is that the r_d parameter is degenerate to both M_B and W_{k0} . This can be seen through Eqs. (2.14), (2.15), (2.16), (3.2), and (3.3). So, to break these degeneracies, we have to combine the CC data to the SN and BAO data. So, we get simultaneous constraints on M_B , W_{k0} , and r_d from combinations of SN, CC, and BAO data by maximizing the corresponding log-likelihood ($\log L_{\text{CC+BAO}}$) given as

$$\log L_{\text{CC+BAO}}(M_B, W_{k0}, r_d) = \log L_{\text{CC}}(M_B, W_{k0}) + \log L_{\text{BAO}}(M_B, W_{k0}, r_d). \quad (3.9)$$

Consequently we get simultaneous constraints on M_B , $\Omega_{k0}h^2$, and r_d . Note that, since r_d is degenerate to both M_B and $\Omega_{k0}h^2$ (through W_{k0}), addition of BAO data to SN+CC data makes the constraints on M_B and $\Omega_{k0}h^2$ tighter while simultaneously gives constraints on r_d .

3.4 Combination of SN, CC, BAO, and GRB data: bounds on gamma-ray bursts nuisance parameters

The Amati correlated gamma-ray bursts (GRB) data have simultaneous measurements in the observed peak energy, E_p^{obs} of GRB photons and bolometric fluence, S_{bolo} [6, 30, 58]. These quantities are related to the luminosity distance through Amati relations given by

$$E_{\text{iso}} = 4\pi d_L^2 S_{\text{bolo}} (1+z)^{-1}, \quad (3.10)$$

$$P = \log_{10} \left(\frac{E_{\text{iso}}}{\text{erg}} \right), \quad (3.11)$$

$$E_p^{\text{obs}} = \frac{E_p}{1+z}, \quad (3.12)$$

$$P = a + b \log_{10} \left(\frac{E_p^{\text{obs}}}{\text{keV}} \right), \quad (3.13)$$

where E_{iso} is the isotropic energy and E_p is the rest-frame peak energy of GRB photons; a and b are two nuisance parameters involved in the GRB observations.

From the reconstructed m_{GRB} and Δm_{GRB} (obtained from Sec. 3.1), we compute d_L and Δd_L at GRB redshift points using Eq. (2.15). Note that these values are functions of M_B parameter which can be seen from Eq. (2.15). Next, from the reconstructed d_L and Δd_L , we compute E_{iso} and ΔE_{iso} using Eq. (3.10). Note that, in this step, we use the S_{bolo} data from GRB observations. Next, from these E_{iso} and ΔE_{iso} , we compute P and ΔP using Eq. (3.11). We denote these as P_{GPR} and ΔP_{GPR} . Note that these are dependent on only M_B parameter.

From E_p^{obs} data from GRB observations, we compute E_p and ΔE_p using Eq. (3.12). From these E_p and ΔE_p , we compute P and ΔP using Eq. (3.13). Note that these are functions of a and b parameters which can be seen through Eq. (3.13). We denote this as P_{GRB} and ΔP_{GRB} respectively. Note that, in Eq. (3.13), P is linear in a and b , and only b is multiplied by an uncertainty propagating term but not in the case of a . So, in the uncertainty propagation through Eq. (3.13), the parameter a is not propagated in ΔP_{GRB} . So, ΔP_{GRB} is the function of only b parameter but P_{GRB} is the function of both a and b parameters.

The total variance in P is enhanced by an extra term given as σ_{ext}^2 , where σ_{ext} is a dispersion parameter. We now compare P_{GPR} with P_{GRB} by defining a log-likelihood ($\log L_{\text{GRB}}$) defined as

$$\begin{aligned} \log L_{\text{GRB}}(M_B, a, b, \sigma_{\text{ext}}) = & -\frac{1}{2} \sum_{z_{\text{GRB}}} \frac{[P_{\text{GPR}}(z_{\text{GRB}}, M_B) - P_{\text{GRB}}(a, b)]^2}{\Delta P_{\text{tot}}^2(z_{\text{GRB}}, M_B, b) + \sigma_{\text{ext}}^2} \\ & -\frac{1}{2} \sum_{z_{\text{GRB}}} \log [2\pi (\Delta P_{\text{tot}}^2(z_{\text{GRB}}, M_B, b) + \sigma_{\text{ext}}^2)], \end{aligned} \quad (3.14)$$

where ΔP_{tot}^2 is given as $\Delta P_{\text{tot}}^2(z_{\text{GRB}}, M_B, b) = \Delta P_{\text{GPR}}^2(z_{\text{GRB}}, M_B) + \Delta P_{\text{GRB}}^2(b)$.

One can check that, here, M_B and a parameters are degenerate. To break this degeneracy, we have to add the CC data, and the corresponding log-likelihood ($\log L_{\text{CC+GRB}}$) is given as

$$\log L_{\text{CC+GRB}}(M_B, W_{k0}, a, b, \sigma_{\text{ext}}) = \log L_{\text{CC}}(M_B, W_{k0}) + \log L_{\text{GRB}}(M_B, a, b, \sigma_{\text{ext}}). \quad (3.15)$$

We also combine BAO data for consistency checks. For this case, we get simultaneous constraints on M_B , W_{k0} , r_d , a , b , and σ_{ext} by maximizing the corresponding log-likelihood ($\log L_{\text{CC+BAO+GRB}}$) given as

$$\begin{aligned} \log L_{\text{CC+BAO+GRB}}(M_B, W_{k0}, r_d, a, b, \sigma_{\text{ext}}) = & \log L_{\text{CC+BAO}}(M_B, W_{k0}, r_d) \\ & + \log L_{\text{GRB}}(M_B, a, b, \sigma_{\text{ext}}). \end{aligned} \quad (3.16)$$

4 Results

The constraints on the nuisance parameters are dependent on the constraints on the W_{k0} parameter that is related to $\Omega_{k0}h^2$ through Eq. (2.4). We quote all the results through $\Omega_{k0}h^2$ parameter instead of W_{k0} .

In Figure 1, we have shown constraints on M_B , $\Omega_{k0}h^2$, and r_d parameters obtained from two different combinations of data. The dotted-blue and solid-black lines correspond to the constraints obtained from SN+CC and SN+CC+BAO combinations of data respectively. For

$\Omega_{k0}h^2$	0.028 ± 0.062	-0.005 ± 0.016
r_d	-	145.6 ± 3.5

Table 1. Constraints on M_B , $\Omega_{k0}h^2$, and r_d parameters obtained from SN+CC and SN+CC+BAO combinations of data.

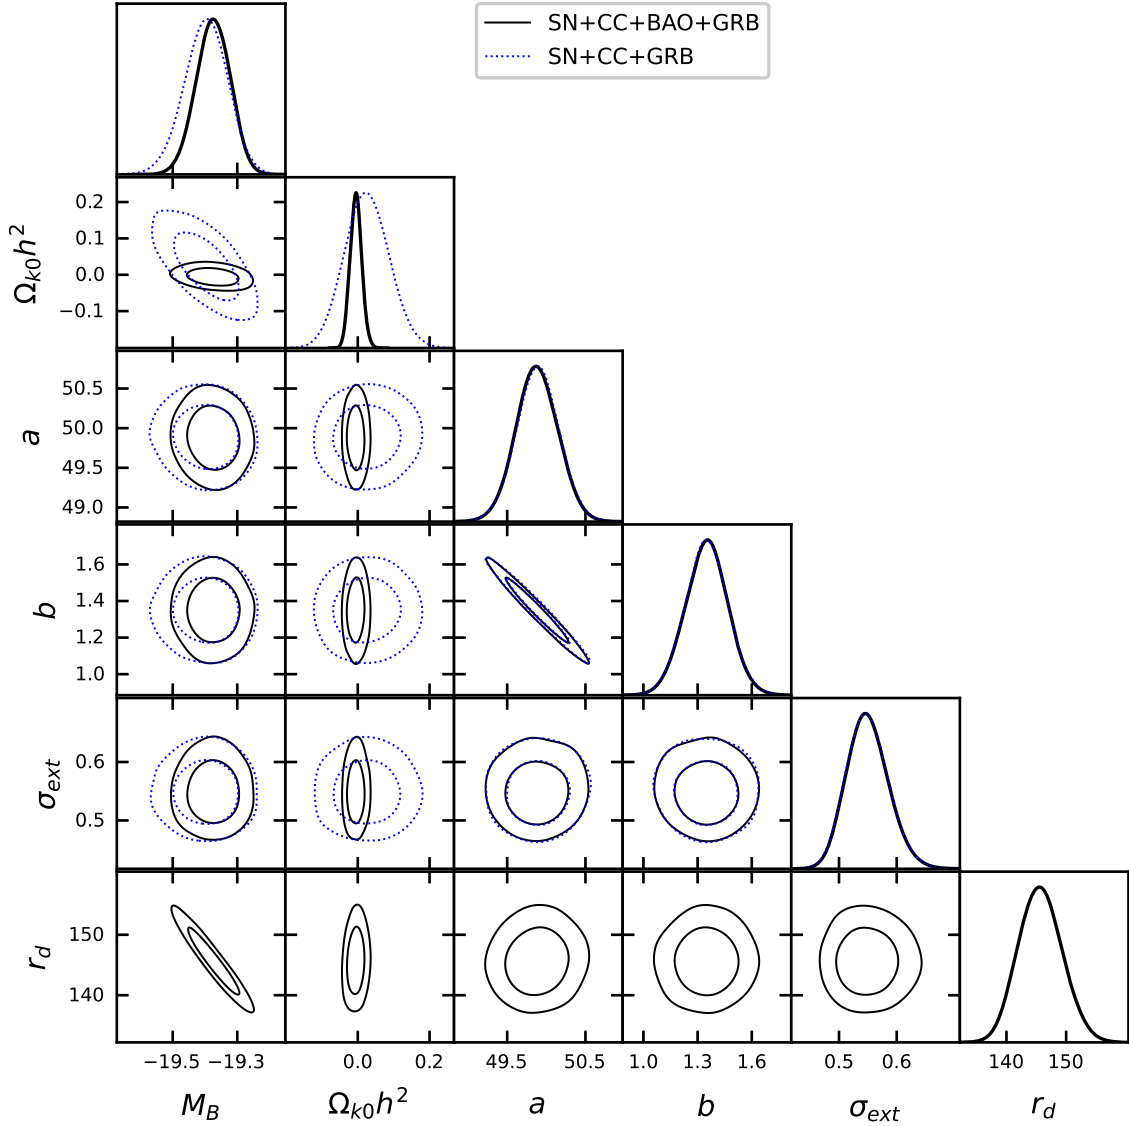

Figure 2. Constraints on M_B , $\Omega_{k0}h^2$, r_d , and GRB data-related nuisance parameters, a , b , and σ_{ext} obtained from SN+CC+GRB and SN+CC+BAO+GRB combinations of data. For a particular color or type, the inner and the outer contours correspond to the 1σ and 2σ confidence contours respectively. Dotted-blue and solid-black contours are obtained from SN+CC+GRB and SN+CC+BAO+GRB combinations of data respectively.

SN+CC, we obtain constraints only on M_B and $\Omega_{k0}h^2$ not on r_d . The addition of BAO data put constraints on r_d along with M_B and $\Omega_{k0}h^2$. For this case, constraints on M_B and $\Omega_{k0}h^2$ are comparatively tighter. The values of these constraints are mentioned in Table 1.

In Figure 2, we have shown the constraints on the GRB nuisance parameters, a , b , and σ_{ext} along with M_B , $\Omega_{k0}h^2$, and r_d parameters obtained from SN+CC+GRB and SN+CC+BAO+GRB combinations of data. For a particular color or type, the inner and the outer contours correspond to the 1σ and 2σ confidence contours respectively. Dotted-blue and solid-black contours are obtained from SN+CC+GRB and SN+CC+BAO+GRB combinations of data

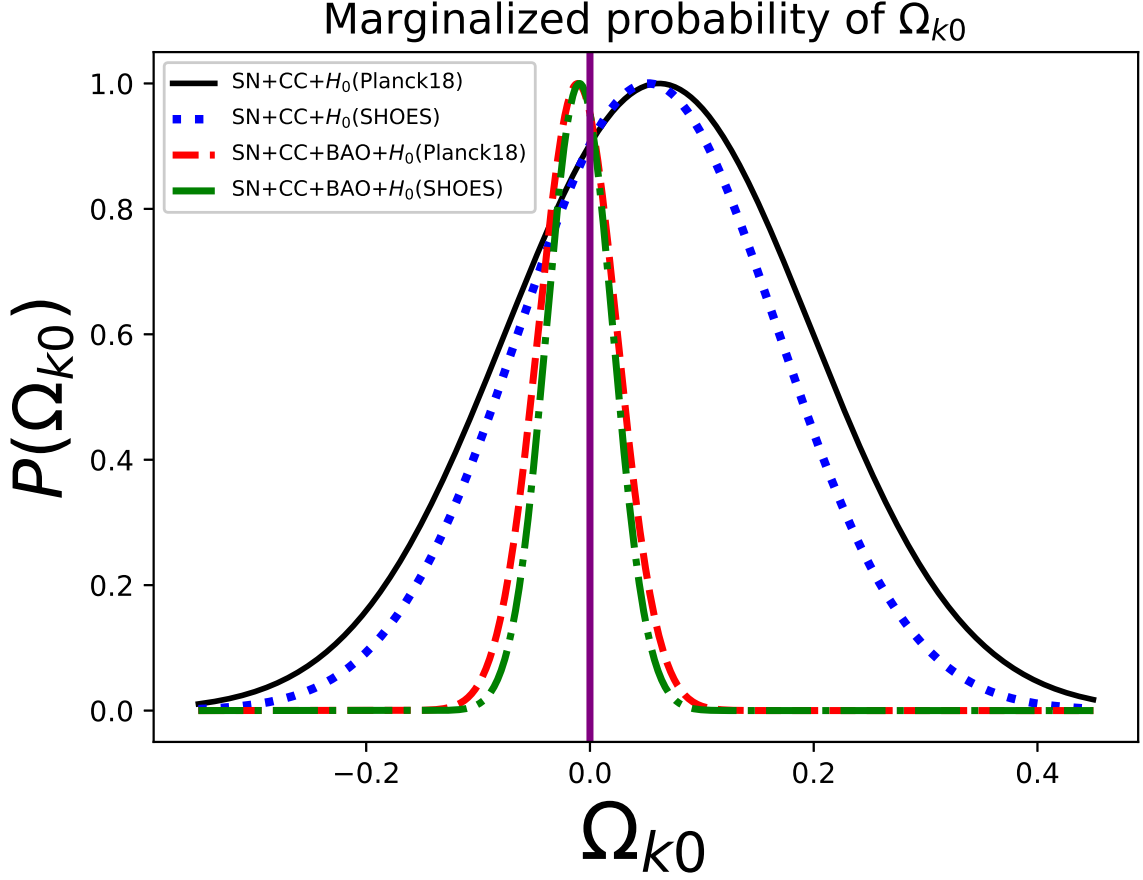

Figure 3. Marginalized probability distribution of Ω_{k0} corresponding to different combinations of data.

Parameters	SN+CC+GRB	SN+CC+BAO+GRB
M_B	-19.397 ± 0.067	-19.375 ± 0.053
$\Omega_{k0}h^2$	0.025 ± 0.062	-0.005 ± 0.016
r_d	-	$145.7^{+3.4}_{-3.8}$
a	49.89 ± 0.27	49.88 ± 0.27
b	1.35 ± 0.12	1.35 ± 0.12
σ_{ext}	$0.550^{+0.033}_{-0.039}$	$0.550^{+0.033}_{-0.038}$

Table 2. Constraints on M_B , $\Omega_{k0}h^2$, r_d , a , b , and σ_{ext} parameters obtained from SN+CC+GRB and SN+CC+BAO+GRB combinations of data.

respectively. Note that, the constraints on the M_B , $\Omega_{k0}h^2$, and r_d are similar as in Figure 1. This can be seen in Table 2 by the comparison in Table 1. This indicates that the constraints on M_B , $\Omega_{k0}h^2$, and r_d parameters are almost unaffected by the addition of the GRB data.

From all the figures and tables, we can see that the constraints on the GRB nuisance parameters are almost independent of the constraints on the M_B , $\Omega_{k0}h^2$, and r_d .

Another important fact to notice is that constraints on all the nuisance parameters are

Planck18	$H_0 = 67.4 \pm 0.5$	[3]
SHOES	$H_0 = 73.2 \pm 1.3$	[46]

Table 3. H_0 priors from Planck 18 mission and SHOES observations. The values are mentioned in $\text{KmS}^{-1}\text{Mpc}^{-1}$ unit.

Data combinations	$+H_0(\text{Planck18})$	$+H_0(\text{SHOES})$
SN+CC	0.062 ± 0.136	0.052 ± 0.116
SN+CC+BAO	-0.011 ± 0.035	-0.009 ± 0.030

Table 4. Constraints on Ω_{k0} parameter obtained from different combinations of data.

dependent on $\Omega_{k0}h^2$ (or equivalently on $\Omega_{k0}H_0^2$) but not individually on each of Ω_{k0} and H_0 . To get constraints on Ω_{k0} and H_0 parameters individually, one has to add data that directly provide observations either in H_0 or in the Ω_{k0} separately. That is why next we consider H_0 priors to get constraints on Ω_{k0} . For this purpose, we consider two kinds of priors on H_0 . One is from the results of the Planck 2018 mission [3] and another one is from the SHOES [46] observations. These are mentioned in Table 3.

From $\Omega_{k0}h^2$ and H_0 , we compute Ω_{k0} by using the equation given as

$$\Omega_{k0} = (\Omega_{k0}h^2) \left[\frac{100 \text{ Km S}^{-1}\text{Mpc}^{-1}}{H_0} \right]^2. \quad (4.1)$$

And we compute the corresponding uncertainties using the propagation of uncertainty. We have listed the constraints on Ω_{k0} for different cases in Table 4 and plotted the 1D marginalized probability distribution of Ω_{k0} in Figure 3, obtained from different combinations of data, mentioned in the figure. We have not shown the constraints from the GRB data, because the addition of these data does not affect the constraints on the $\Omega_{k0}h^2$ parameter and consequently on Ω_{k0} . We have already seen this fact from previous figures and tables. This is obvious because $\log L_{\text{GRB}}$ in Eq. (3.14) is independent of W_{k0} parameter.

We see that the mean values of Ω_{k0} are well inside the 1σ confidence region. So, there are no significant deviations from a flat Universe.

5 Conclusion

This analysis concludes that we can get constraints on cosmological nuisance parameters and the cosmic curvature density parameter corresponding to different observations by the different combinations of data in a minimal model dependent way using Gaussian process regression (GPR) analysis. This analysis has been done for important observations like SN, CC, BAO, GRB, and H_0 observations from Planck 2018 mission and SHOES. The constraints on the nuisance parameters, obtained in this analysis, can be used as the prior for the cosmological data analysis.

The results, obtained in this analysis, are not completely model independent, but model dependence is minimal. This is because there is model dependence through the kernel and the mean function in the GPR analysis and through data like BAO which consider a particular fiducial model. Hence the methodology, presented here, has minimal model dependence. The model dependence is not very significant though. In the future, the GPR analysis can be

replaced by more accurate, advanced, and modern reconstruction methods like deep learning and neural networks, but the methodology, presented here, would be very helpful to do that.

A Gaussian process regression analysis

Let us consider we have n number of data points from a kind of observation. X , Y , and ΔY are vectors of observational data points, the corresponding mean values of a quantity, and the standard deviation values of that quantity respectively. Gaussian process regression (GPR) analysis can predict the mean and standard deviation values of the same quantity at some different target points. Let us denote X_* , Y_* , and ΔY_* are vectors of target points, the corresponding mean values, and standard deviation values respectively with the help of a kernel covariance function and a mean function. Using GPR, we get the predicted values given as [45, 50, 51, 60]

$$Y_* = M_* + K(X_*, X) [K(X, X) + C]^{-1} (Y - M), \quad (\text{A.1})$$

$$\text{Cov}[Y_*, Y_*] = K(X_*, X_*) - K(X_*, X) [K(X, X) + C]^{-1} K(X, X_*), \quad (\text{A.2})$$

where 'Cov' stands for covariance, K is the kernel matrix according to a particular kernel covariance function, M and M_* are the mean vectors at data points and target points respectively corresponding to a particular mean function, and C is the noise covariance matrix of the data. If errors in data are uncorrelated then an element, C_{ij} of C matrix would be $C_{ij} = (\Delta Y_i)^2 \delta_{ij}$, with δ_{ij} being the usual Kronecker delta. If the errors in data are correlated then off-diagonal elements of C would be non-zero accordingly.

The details of the kernel covariance and mean functions are briefly discussed in the next section.

The kernel and mean functions have some parameters. We have to take their best-fit values for the mean prediction in Eqs. (A.1) and (A.2). To do so, we minimize the negative of log marginal likelihood (denoted by $\log P(Y|X)$) given as [50]

$$\begin{aligned} \log P(Y|X) = & -\frac{1}{2} (Y - M)^T [K(X, X) + C]^{-1} (Y - M) \\ & -\frac{1}{2} \log |K(X, X) + C| - \frac{n}{2} \log(2\pi), \end{aligned} \quad (\text{A.3})$$

where $|K(X, X) + C|$ is the determinant of the $K(X, X) + C$ matrix.

GPR can also predict the gradient of a quantity, for example, here, $y' = \frac{dy}{dx}$. By prime notation, we mean the derivative of a quantity w.r.t the argument, for example, here x , and in the main text, it is z . From GPR predictions, the mean vector and the covariance matrix corresponding to the first derivative are given as [50]

$$Y'_* = M'_* + [K'(X, X_*)]^T [K(X, X) + C]^{-1} (Y - M), \quad (\text{A.4})$$

$$\text{Cov}[Y'_*, Y'_*] = K''(X_*, X_*) - [K'(X, X_*)]^T [K(X, X) + C]^{-1} K'(X, X_*), \quad (\text{A.5})$$

where prime and double prime are the first and second derivatives of the corresponding function respectively; $k'(x, x_*)$ and $k''(x, x_*)$ are given as

Parameters	SE: Λ CDM	M5by2: Λ CDM	RQ: Λ CDM	SE: wCDM	SE: CPL
M_B	-19.375 ± 0.053	-19.374 ± 0.051	-19.374 ± 0.051	-19.374 ± 0.052	-19.373 ± 0.052
$\Omega_{k0}h^2$	-0.005 ± 0.016	-0.008 ± 0.016	-0.006 ± 0.016	-0.007 ± 0.016	-0.006 ± 0.017
r_d	$145.7^{+3.4}_{-3.8}$	145.5 ± 3.5	145.5 ± 3.5	145.6 ± 3.5	145.5 ± 3.5
a	49.88 ± 0.27	49.88 ± 0.27	49.89 ± 0.27	49.89 ± 0.27	49.88 ± 0.27
b	1.35 ± 0.12	1.35 ± 0.12	1.35 ± 0.12	1.34 ± 0.12	1.35 ± 0.12
σ_{ext}	$0.550^{+0.033}_{-0.038}$	$0.548^{+0.032}_{-0.039}$	$0.550^{+0.032}_{-0.039}$	$0.551^{+0.032}_{-0.040}$	$0.548^{+0.031}_{-0.039}$

Table 5. Constraints on M_B , $\Omega_{k0}h^2$, r_d , a , b , and σ_{ext} parameters obtained from SN+CC+BAO+GRB data for different kernels and means.

$$k'(x, x_*) = \frac{\partial k(x, x_*)}{\partial x_*}, \quad k''(x_*, x_*) = \frac{\partial^2 k(x_*, x_*)}{\partial x_* \partial x_*}, \quad (\text{A.6})$$

respectively. Here, by the notation k , we denote the matrix element of the main matrix K .

B Dependence of GPR predictions on kernels and mean functions

Some popular kernel covariance functions are listed below:

$$k(d) = \sigma_f^2 e^{-\frac{d^2}{2l^2}} \quad (\text{squared exponential}), \quad (\text{B.1})$$

$$k(d) = \sigma_f^2 \left(1 + \frac{\sqrt{5}d}{l} + \frac{5d^2}{3l^2} \right) e^{-\frac{\sqrt{5}d}{l}} \quad (\text{Matérn with order } 5/2), \quad (\text{B.2})$$

$$k(d) = \sigma_f^2 \left(1 + \frac{d^2}{2rl^2} \right)^{-r} \quad (\text{rational quadratic}), \quad (\text{B.3})$$

where σ_f , l , r are the corresponding kernel parameters which are called the hyperparameters; $d = |x_1 - x_2|$ and $k(x_1, x_2) = k(|x_1 - x_2|) = k(d)$. Among the above-listed kernels, the first one i.e. the squared exponential kernel is used in the main text. We denote this kernel as 'SE'. The second kernel is the Matérn kernel covariance function with order 5/2. We denote this kernel as 'M5by2'. The third one is the rational quadratic kernel covariance function. We denote this as 'RQ'.

In the main text, we have considered the Λ CDM model for the mean function for $m(z)$. Here we also consider the more general model, called Chevallier-Polarski-Linder (CPL) parametrization [15, 35], where the equation of state of the dark energy is given as

$$w = w_0 + w_a \frac{z}{1+z}, \quad (\text{B.4})$$

where w_0 and w_a are two model parameters. In the CPL model, the Hubble parameter is given as

$$\frac{H^2}{H_0^2} = \Omega_{m0}(1+z)^3 + \Omega_{k0}(1+z)^2 + (1 - \Omega_{m0} - \Omega_{k0})(1+z)^{3(1+w_0+w_a)} e^{-\frac{3w_a z}{(1+z)}}, \quad (\text{B.5})$$

where Ω_{m0} is the matter-energy density parameter. w CDM model is the subset of CPL model where $w_a = 0$ and Λ CDM model is the further subset where $w_a = 0$ and $w_0 = -1$.

Using Eq. (B.5), we can compute any quantity from Eq. (2.1) to Eq. (2.7) for Λ CDM, w CDM and CPL models accordingly.

To show how our results depend on different kernel and mean functions, in Table 5, we list constraints on the parameters for SN+CC+BAO+GRB combinations of data for different kernel and mean functions. We have not included other combinations of data, because only this combination of data is enough to show the fact that the dependence of the constraints on different kernels and mean functions is not significant.
