Abstract. Laser cooling and trapping of lanthanides has opened the possibility to carry out new experiments with ultracold dipolar gases, for example for quantum simulation of solid state physics. To identify new suitable candidates for laser-cooling, it is important to have a precise spectroscopic knowledge of the atom under consideration. Along this direction, we present here a detailed modeling of the energy levels of neutral neodymium (Nd), an element belonging to the left part of the lanthanide row, which has not yet been considered for laser-cooling. Using the semi-empirical method implemented in the Cowan suite of codes, we are in particular able to interpret more than 200 experimental levels of the NIST database belonging to both parities. The optimal set of atomic parameters obtained after the least-square fitting step can serve to calculate radiative transition probabilities in the future.

1. Introduction

In the field of ultracold atomic and molecular matter, quantum gases composed of particles with a strong intrinsic permanent dipole moment, called dipolar gases, have attracted great interest in the last few years because they can be controlled by external electric field or magnetic fields. Through long-range and anisotropic interactions between particles, dipolar gases enable the production and study of highly correlated quantum matter, which is critical for quantum information or for modeling many-body or condensed matter physics [1–3].

Among the different families of systems, open-shell atoms have a permanent magnetic dipole moment that is determined by their total electronic angular momentum. In the context of ultracold matter, important achievements were the first Bose-Einstein condensates of highly magnetic atoms obtained with chromium [4, 5]. Later, much attention began to be attracted to the lanthanides, a series of 15 elements with atomic numbers Z = 57-71, from lanthanum (La) through Lanthanides, along with lutetium (Lu). the chemically similar elements scandium and yttrium, are often collectively known as the rare earth elements. Lanthanide atoms open up new possibilities for interactions, not only because of their large ground state magnetic dipole moments, but also because of the large number of optical transitions with widely varying properties that provide a better controllability, or because of pairs of quasi-degenerate metastable levels, allowing the production of an electric and magnetic dipolar gases [6]. Finally, the lanthanides have the great advantage of having fermionic and/or bosonic stable isotopes.

These distinctive properties are primarily

due to a unique electronic structure: the socalled submerged f-shell configuration. Most lanthanides have a completely filled 6s shell and a partially filled inner 4f shell. Moreover, among the elements with the largest atomic numbers, many share a common set of properties and often have similar transitions at the same wavelengths [7, 8]. So far, laser cooling has been demonstrated for elements belonging to the right part of the lanthanide row, namely erbium [9–12], dysprosium [13–16], holmium [17], thulium [18, 19] and europium [20], as well as in erbium–dysprosium mixtures [21].

These achievements open the question of identifying new suitable species for laser cooling, especially in the left part of the lanthanide series. Among them, we notice that, cerium (Ce, Z= 58) has the ground configuration 4f 5d 6s², which makes this element a priori not convenient for such experiments. On the other hand, when we go to the middle of the series, we have radioactive promethium (Pm, Z = 61), after which the spectrum of the elements becomes more and more dense, starting with samarium (Sm, Z = 62), making these elements not favourable for possible laser cooling studies. Therefore, neodymium (Nd, Z = 60) and praseodymium (Pr, Z = 59) represent the most promising energy spectrum for the formation of a dipolar gas. Their lowest configurations are very close in energy, namely $4f^n 6s^2$, $4f^n 5d 6s$, $4f^{n-1} 5d 6s^2$ and $4f^{n-1} 5d^2 6s$, where n = 3 for Pr and n = 4 for Nd. The lowest levels of $4f^n 6s^2$ and $4f^{n-1} 5d 6s^2$ mainly have a spin equal to S = n/2, denoting that laser-cooling transitions may be chosen among these configurations. Meanwhile, the lowest levels of $4f^n 5d 6s$ and $4f^{n-1} 5d^2 6s$ configurations are mainly characterized by a spin S = n/2 + 1, which makes the decay by

Figure 1. Energy diagrams as functions of the electronic angular momentum J and sorted by electronic parity for neodymium (Nd, top panel) and dysprosium (Dy, bottom panel).

spontaneous emission toward levels of $4f^n 6s^2$ and $4f^{n-1} 5d 6s^2$ rather unlikely. The $4f^n 5d 6s$ and $4f^{n-1} 5d^2 6s$ configurations also have levels that are very close in energy, and that can be significantly mixed to induce an electric dipole moment [6]. Moreover Nd represents the great advantage of having bosonic and fermionic stable isotopes, while Pr has only one bosonic stable isotope.

In order to find possible laser-cooling transitions for neutral Nd, it is essential to carefully model the spectrum, *i.e.* energies and transition dipole moments (TDMs). In this work, as a first step, we carefully study the Nd energy levels. Particular attention is paid to accurately describing configuration-interaction (CI) mixing, to which TDMs are very sensitive, especially those that lead to weak transitions, which play an important

role in this design. Since Nd belongs to the left part of the lanthanide row, it presents a high density of levels in the range 8000-15000 cm⁻¹ in contrast with Dy (see figure 1). To calculate energies, we use the combination of *ab initio* and least-square fitting techniques implemented in the Cowan codes [22, 23]. We include the three lowest configurations of each parity which allows us to interpret more than 200 energy levels given in the NIST ASD database [24]. The main technical difficulty of this work comes from the least-squares fitting of close energy levels, because we need to determine to which experimental counterparts each computed level should converge.

The article is organized as follows: in section 2 we describe the general methodology of our spectroscopic calculation. Then section 3 is devoted to the calculation of neutral Nd. In that section we also present the results of the calculations divided in several steps and we conclude the work in section 4.

2. Methodology

The calculations of the neutral Nd spectrum are performed with the semi-empirical technique provided by Robert Cowan's atomic-structure suite of codes, for which we used both the McGuinness [25] and the Kramida [23] versions, and whose theoretical background is presented in [22]. In the present section, we briefly review the principles of those calculations.

As a first step, ab initio single-electron radial wave functions $P_{n\ell}$ for all the subshells $n\ell$ of the considered configurations are computed with the relativistic Hartree-Fock (HFR) method. The principal output, for each configuration, consists of energy parameters, such as center-of-gravity configuration energies $E_{\rm av}$, direct F^k and exchange G^k electrostatic integrals, or spin-orbit integrals $\zeta_{n\ell}$, that are the

building blocks of the atomic Hamiltonian and are required to calculated the energy levels. For each couple of configurations, the wave functions P_{nl} serve also to calculate the CI parameters R^k .

In a second step, the program sets up energy matrices for each possible value of total angular momentum J, diagonalizes each matrix to get eigenvalues and eigenvectors. It is possible to calculate Landé q-factors, as well as electric-dipole (E1), electric quadrupole (E2) and magnetic-dipole (M1) radiation spectra with wavelengths, oscillator strengths, radiative transition probabilities and radiative lifetimes. It is important to emphasize that the basis functions used by the codes are the numerical functions obtained after the HFR calculation for each configuration, which are then combined appropriately to describe the atom in the desired angular momentum coupling scheme, i.e., LS, jj or others.

In LS or Russell-Saunders coupling conditions the electrostatic interactions between electrons are much stronger than the interaction between the spin of an electron and its own orbital motion. In this case, an atomic level is in particular characterized by its total orbital and its total spin quantum numbers, L and S. With increasing Z, the spin-orbit interactions become increasingly more important. When these interactions become much stronger than the Coulombic terms, the coupling conditions approach pure jj coupling case. In the present study, atomic levels are usually well represented in intermediate coupling, i.e. their eigenvectors are sums of basis states written in LS coupling.

When higher accuracy is desired, in a third step, radial energy parameters are treated as adjustable parameters of a leastsquare fitting calculation. This is done in order to find the best possible agreement between the

Figure 2. Experimental (blue), newly interpreted (red) and newly predicted (only theoretical) (black, short) energy levels of even parity (top) and odd parity (bottom) configurations of neutral Nd as functions of the electronic angular momentum J. Plots are limited to energy values of 25000 cm⁻¹.

Hamiltonian eigenvalues and the experimental energies. As experimental energies we use the data published in the NIST database [24]. The accuracy of the fit is measured by means of the standard deviation:

$$s = \left[\frac{\sum_{i=1}^{N_{\text{lev}}} (E_{\text{th},i} - E_{\text{exp},i})^2}{N_{\text{lev}} - N_{\text{par}}} \right]^{\frac{1}{2}}, \tag{1}$$

where $E_{\exp,i}$ are the observed energy values and $E_{\text{th},i}$ are the computed eigenvalues, N_{lev} is the number of levels being fitted and N_{par} is the number of adjustable parameters (or parameter groups) involved in the fit [22].

In an attempt to improve the quality of the fit, a variety of "effective-operator" parameters, called α , β and γ , also known as the effective electrostatic parameters or

Trees parameters, and "illegal-k" F^k , G^k have been introduced, representing corrections to both the electrostatic and the magnetic single-configuration effects [22]. "Illegal-k" means that these are the values of k for which $k + \ell + \ell'$ is odd, where ℓ and ℓ' are the orbital angular momenta of the electrons coupled by the effective operator; for example $(\ell, \ell')=(3, 2)$ for (4f, 5d) electrons. effective parameters, unlike other parameters, can not be calculated ab initio, but are there to compensate the absence of electronic configurations not included in the model. Due to the lack of HFR estimates, the initial values of the effective parameters are obtained from comparisons with similar spectra.

To make some comparisons between different elements and ionization stages, one often defines the scaling factor (SF) $f_X = X_{\rm fit}/X_{\rm HFR}$ between the fitted and the HFR value of a given parameter X. During the fitting procedure, it is sometimes convenient to be able to link several parameters together in such a way that their SFs remain identical throughout the calculation; such groups of constrained parameters are characterized by the same r_n value in tables 4 - 6. The word "fixed" means that the corresponding parameters are not adjusted.

3. Results for Nd

This section, dedicated to our results for Nd, is divided as follows. In subsection 3.1 we present the different steps of our least-square fitting calculation, discussing especially the configurations included, the number of fitting parameter groups, and the resulting standard deviations. In the next subsections, we describe in more details our results, where: (i) we include in the fit levels of the NIST database that are interpreted, see

Figure 3. Differences between calculated and experimental Landé g-factors for energy levels with an experimentally known g-factor. The picture on the bottom is an enlarged version to show the differences in detail. The largest difference at 11129 cm^{-1} (top panel) is out of the y-scale on the bottom panel. Energy levels are in cm^{-1} .

subsection 3.2; and (ii) we include levels that are not interpreted, see subsection 3.3.

3.1. Description of calculations

The calculations were performed with three configurations in each parity, namely:

- $4f^4 6s^2$, $4f^4 5d 6s$, $4f^3 5d 6s 6p$ for the even parity;
- $4f^4 6s 6p$, $4f^3 5d 6s^2$, $4f^3 5d^2 6s$ for the odd parity.

For both parities, we use values from the NIST database as reference energy levels [24]. The primary source of data on neutral Nd levels in the NIST database is Martin *et al.* [26].

B-d2s	7	16633	16747	1.059	1.265	21%	$^{7}\mathrm{K}$	$^7\mathrm{H}$

Since it belongs to the left part of the lanthanide row of the Periodic Table of the Elements, Nd possesses a dense spectrum, which makes it difficult to identify the levels. In order to overcome this issue, we have divided the calculation into steps. As a first step, for even parity, the configurations 4f⁴6s² and 4f⁴5d 6s were considered together, and the calculations for the configuration 4f³ 5d 6s 6p were carried out separately. For the first group when we have included 42 experimental levels and the fitting is done with 11 groups of parameters, the standard deviation is 91 cm^{-1} . For the configuration 4f³ 5d 6s 6p the calculations were done with 10 groups of parameters. When 14 interpreted experimental levels are included the standard deviation is 101 cm^{-1} .

After the calculation, the optimal values of the energy parameters were determined. In the next step, these two groups were combined together, and the optimal parameters of the individual calculations were taken as an initial set for the combined calculation. In this step 54 interpreted experimental levels are included for three even parity configurations and the fitting is done with 12 groups of free parameters. The standard deviation for this combined calculation is 89 cm⁻¹. The latter results are discussed in more details in subsection 3.2.

We followed a similar method for odd parity configurations. We have treated separately the configurations $4f^3 \, 5d \, 6s^2$ and $4f^3 \, 5d^2 \, 6s$ on one hand, and $4f^4 \, 6s \, 6p$ on the other hand. For the first group of odd parity configurations the calculation is done with 11 parameter groups and 79 experimental levels are included. After the final calculation the standard deviation is 94 cm⁻¹. For configuration $4f^4 \, 6s \, 6p$ we have 19 experimental levels included and 10 parameter groups. For this configuration standard deviation is $160 \, \text{cm}^{-1}$. When these two separate analyzes

have been completed, we treated these three configurations together. The final least square fitting is done with 15 parameter groups and there are 96 levels included. Standard deviation in this case is 111 cm⁻¹. Again, the latter results are discussed in more details in subsection 3.2.

In what follows we will use the following abbreviations for even parity configurations: $4f^4 6s^2 = A-6s2$, $4f^4 5d 6s = A-ds$ and $4f^3 5d 6s 6p = B-d6sp$ and for odd parity configurations: $4f^4 6s 6p = A-6sp$, $4f^3 5d 6s^2 = B-ds2$ and $4f^3 5d^2 6s = B-d2s$.

3.2. NIST interpreted levels

In the NIST database, some of the Nd levels are well interpreted: detailed information are given, such as Landé g-factors, dominant configurations, terms, etc. To distinguish these levels from other levels present in the NIST database, we refer to them as "NIST

interpreted" levels. This subsection is devoted to the calculation when only the interpreted experimental levels are included in the fitting process.

As stated before the dense spectrum of neutral neodymium makes it difficult to identify the levels. This is especially true for levels of J=4, 5 and 6. For most levels, the matching between theory and the NIST database is quite good. However, we noticed differences which can be divided into three groups:

Case 1: when the configurations are the same, but there are differences in the leading terms (see table 1).

Case 2: when there is a good match in energy levels, but the configurations are different (see table 2).

Case 3: when the configurations are different, but in the second or third component of the level eigenvector, the configuration

Table 3. Differences between NIST database and theoretical results for energies, Landé-g factors and dominant LS terms, with the percentage of the theoretical one. Case 3: when the configurations are different, but among the other components of the level eigenvectors, there is one whose configuration or term make identification possible (see the last three columns). All energy levels are in cm⁻¹.

and/or the term is the same as in the experimental leading term, which makes the identification possible (see table 3).

Except the first level of table 1, those three tables only contain levels of odd parity, mostly with intermediate angular momenta J=4 to 6, for which the energy spectrum is the densest. Their leading term have a low percentage (mostly below 50 %), which means that the leading term coming out of calculations can be sensitive to the radial parameters. The corresponding optimal radial parameters and their SFs are given in the supplementary material.

3.3. Newly interpreted levels

After successfully performing the calculation for six Nd configurations with NIST-interpreted levels and finding the optimal parameters for each configuration, we proceeded to include in the fit levels that are present in the database but are not interpreted. We were

able to identify 25 levels for even-parity configurations and over 200 levels for odd-parity configurations (see figure 2). The inclusion of these new interpreted levels produced the following results: for even parity, with 83 levels included and 12 parameter groups, the standard deviation is 90 cm⁻¹, and for even parity, with 298 levels included and 15 parameter groups, the standard deviation drops to 74 cm⁻¹.

Figure 2 shows the energies of even and odd configurations as functions of the angular momentum J. Note that unlike figure 1, figure 2 has one panel for each parity. The blue lines show the experimental energy of interpreted levels present in the NIST database, red lines correspond to the experimental energies of levels that are present in the database but have not been interpreted in detail. Finally, black short lines correspond to newly predicted levels, indicating that their energies are purely theoretical. We see that

the latter are numerous and that they are located among experimental levels. In the even parity, there are no experimental levels between approximately 16000 and 20000 cm⁻¹, corresponding respectively to the highest interpreted levels of the $4f^4$ 5d 6s configuration and the lowest ones of the $4f^3$ 5d 6s 6p configuration. In the odd parity, the density of levels is even larger. For extreme values of J, the predicted levels are significantly more present than experimental ones. This trend is not visible for intermediate values J=4-7 where more experimental levels were observed spectroscopically.

When identifying the levels and trying to find the corresponding counter-experimental levels to the theoretical ones calculated by us for the least-square fit, we noticed some differences in the Landé g-factors for some levels. Figure 3 shows that for most levels, the difference in Landé g-factors is limited to the region [-0.1:0.1]. However, there are levels for which the absolute value of the difference exceeds 0.4. There are three such the Landé g-factor of level J =3 of configuration A-6s2, with an energy value of 11129 cm⁻¹, differs from its counterexperimental level by 1.237. The J=5 level of the A-ds configuration with an energy value of 21899 cm^{-1} has a Landé g-factor that differs from the experimental one by 0.790. And, finally, the Landé g-factor of the level J=6of the A-ds configuration with an energy value of 11134 cm⁻¹ diverges from the experimental one by -0.451.

When the optimal set of parameters and the best (smallest) standard deviation are found, it is interesting to calculate the scaling factors (SF) for all parameters and groups of parameters that participated in the calculations, including CI ones. Table 4 shows the optimal parameters $(X_{\rm fit})$ for even parity

configurations, as well as their constraints and scaling factors (f_X) if the parameter had an initial HFR value. Table 5 presents the same information for odd parity configurations, and table 6 for the CI parameters of even and odd parity configuration pairs.

Table 4–6 also presents the constraints defining groups of fitting parameters: the parameters having the same r_n value belong to the same group. Because our fit was made in several steps, in which the constraints have not been the same, the parameters with the same r_n coefficients do not necessarily have the same scaling factors. Among the latter, we note especially large values for G^k parameters of the 4f⁴ 6s 6p configuration and small values for CI parameters for even configuration pairs implying 4f³ 5d 6s 6p. We can compare our fitted parameters to Ref. [27] which is dedicated to even-parity configurations $4f^4 6s^2 + 4f^4 5d 6s$. The agreement between theoretical and experimental levels is very good, but we note surprisingly small values of $F^k(4f4f)$ parameters of the 4f⁴ 5d 6s configuration.

4. Conclusion

In this article, we have given a theoretical interpretation of the spectrum of neutral neodymium, which is an essential component for new experiments with ultracold dipolar gases. We did the calculations for three even configurations: $4f^4 6s^2$, $4f^4 5d 6s$, $4f^3 5d 6s 6p$, and three odd configurations: $4f^4 6s 6p$, $4f^3 5d 6s^2$ and $4f^3 5d^2 6s$. For this purpose we used Cowan's suite of codes.

Although Nd is a difficult element for such calculations, due to its very dense spectrum, we have been able to carry out the calculations by introducing a method in which we divide the calculation of each parity into two parts. The challenging part of this

calculation was the least squares fit, because we needed to find experimental analogs for each theoretical level to which they should converge. We were able to interpret more than 200 levels for odd parity configurations and 25 levels for even parity configurations, for which there were no detailed information in the NIST ASD database. In the course of calculations, we noticed discrepancies with the NIST database values, for example, in Landé g-factors. After comparison we showed that for all levels except for three, the absolute value

of the difference between the theoretical and experimental Landé g values does not exceed 0.4.

The logical continuation and perspective of this work for the future will be the calculation of the transition dipole moments (TDMs) and Einstein coefficients, which are necessary to characterize the efficiency of laser cooling and trapping of atoms. For better accuracy, we plan to fit the Einstein coefficients using the FitAik package [28], for which we will use the optimal set of parameters that we have

Table 6. Fitted configuration interaction (CI) parameters, their scaling factors ($f_X = X_{\text{fit}} / X_{\text{HFR}}$) and constraints for even and odd configurations of neutral Nd. All parameters are in cm⁻¹.

Improving the spectroscopic knowledge of neutral Neodymium: Supplementary material

Gohar Hovhannesyan and Maxence Lepers

Laboratoire Interdisciplinaire Carnot de Bourgogne, UMR 6303 CNRS Univ. Bourgogne Franche-Comté, 9 Avenue Alain Savary, BP 47 870, F-21078 DIJON Cedex FRANCE

This supplementary material is designed to accompany an article in the Journal of Physics B: Atomic, Molecular and Optical Physics. In what follows, we will use the following abbreviations for even parity configurations: $4f^4 6s^2 = A-6s2$, $4f^4 5d 6s = A-ds$ and $4f^3 5d 6s 6p = B-d6sp$ and for odd parity configurations: $4f^4 6s 6p = A-6sp$, $4f^3 5d 6s^2 = B-ds2$ and $4f^3 5d^2 6s = B-d2s$.

1 Fitted energy parameters

In this section, we present tables with fitted parameter values (X_{fit}) for configurations of Nd after the last calculation and their scaling factors (f_X) (if the parameter had an initial HFR value), when only NIST interpreted levels are included in the fitting process (see Subsection 3.2 of the main text).

Table 1: Parameters, constraints, fitted parameters and their scaling factors ($f_X = X_{\text{fit}} / X_{\text{HFR}}$) for even configurations of neutral Nd. All parameters are in cm⁻¹.
