

# Longitudinal Sentiment Analyses for Radicalization Research

## Intertemporal Dynamics on Social Media Platforms and their Implications

a Discussion Paper by Dennis Klinkhammer

**Abstract** *Sentiment analysis is a sub-discipline in the field of natural language processing and computational linguistics and can be used for automated or semi-automated analyses of qualitative data. The primary context of application is to recognize an expressed attitude as positive or negative as it can be contained in qualitative data, such as comments on social media platforms. However, a cross-sectional perspective regarding sentiments within social media comments has proven to be error prone when it comes to the detection of radicalization, extremism and hate speech. Since these phenomena are processes over time, there seems to be an increasing demand for longitudinal perspectives in the context of radicalization research. This discussion paper demonstrates how longitudinal sentiment analyses can depict intertemporal dynamics on social media platforms, what challenges are inherent and how further research could benefit from a longitudinal perspective. Furthermore and since tools for sentiment analyses shall simplify and accelerate the analytical process regarding qualitative data at acceptable inter-rater reliability, their applicability in the context of radicalization research will be examined regarding the Tweets collected on January 6th 2021, the day of the storming of the U.S. Capitol in Washington. Therefore, a total of 49,350 Tweets will be analyzed evenly distributed within three different sequences: before, during and after the U.S. Capitol in Washington was stormed. These sequences highlight the intertemporal dynamics within comments on social media platforms as well as the possible benefits of a longitudinal perspective when using conditional means and conditional variances. Limitations regarding the identification of supporters of such events and associated hate speech as well as common application errors will be demonstrated as well. As a result, only under certain conditions a longitudinal sentiment analysis can increase the accuracy of evidence based predictions in the context of radicalization research.*

**Keywords** Sentiment Analysis, Natural Language Processing, Social Media, Radicalization Research

### (I) Introduction

Sentiment analyses can be used to capture the sentiment in qualitative data, such as comments on social media platforms. Within comments on social media platforms the polarity can be classified word by word as positive or negative and in some cases as neutral via basic sentiment analysis. In addition, different types of emotional states can be classified via advanced sentiment analysis by using the NRC Word-Emotion Association Lexicon, the first word-emotion lexicon with eight basic emotional states (Mohammad 2020). Despite positive and negative sentiments, it is possible to classify anger, fear, anticipation, trust, surprise, sadness, joy, and disgust as well.

Furthermore, sentiment analyses have a sufficient inter-rater-reliability with less time requirements. The inter-rater-reliability is a degree of agreement among independent observers who rate, code, or assess the same phenomenon within qualitative data. While scientist usually achieve an inter-rater-reliability up to 80%, sentiment analyses can achieve up to 70%. This appears to be an acceptable value, because even if different types of sentiment analyses would agree up to 100%, research indicates that scientists would still disagree by 20% (Ogneva 2010). Therefore, sentiment analyses can be found in a broad application context. However, the question regarding their accuracy in the context of radicalization research has not yet been adequately answered, but sentiment analyses are nevertheless increasingly used regarding related phenomena on social media platforms (Torregrosa et al. 2022).

Especially social media platforms like Twitter offer several users a low-threshold opportunity to exchange opinions and experiences. For example, these opinions and experiences can affect various areas of society, such as political and economical ones. Research indicates that, for example, comments on social media platforms can be used to capture social issues like radicalization and extremism (Tanoli et al. 2022), sexuality (Wood et al. 2017), side effects of medication and drugs (Korkontzelos et al. 2016) as well as for the reflection of the offline political landscape (Tumasjan

et al. 2010). A well known use-case is the political campaign of former U.S. president Barack Obama, who used sentiment analysis back in 2012. There are many possible use-cases, but also numerous challenges in the application of sentiment analyses. Accordingly, research in this area continues (Klinkhammer 2022; Hamborg & Donnay 2021).

## (II) Theoretical Background

Social media platforms like Twitter have demonstrated a continuous increase of active users over the most recent years (Pereira-Kohatsu et al. 2019). An average of 500 million Tweets per day combined with a low threshold regarding the participation leads to a high diversity of opinions (Koehler 2015). As a result, Twitter is not to be interpreted as one singular social network, but as several social sub-networks, who enable users to exchange information with each other.

Some of these sub-networks are so-called echo chambers (Bright 2017). Echo chambers can arise through an accumulation of thematically related Tweets, replies, likes and followers. Since Twitter as social media platform allows its users to switch quickly and uncomplicated from one social sub-network into another (Prior 2005), it is to be assumed that echo chamber are most likely to arise and unfold their dynamics. As a result, users usually participate within echo chambers, which correspond with their own opinion and the so called echo arises. Within an echo chamber the own opinion can be confirmed and this confirmation bias can lead to distortions regarding the perception of social phenomena outside a social media platform like Twitter (Cinelli et al. 2021; Jacobs & Spierings 2018).

It has already been confirmed that these confirmation biases within echo chambers with a political agenda can lead to a gradual accumulation from radical to extreme to anti-constitutional opinions (O'Hara & Stevens 2015). According to Neumann (2013), extremism is a context-specific term and must be compared and adapted to the accepted socio-political realities of the observed society. Extremism emerges from the process of radicalization and can be divided into cognitive and violent extremism (Neumann et al. 2018): It can also be stated that extremism is characterized by a willingness to act in order to endanger life, freedom and rights of others.

Furthermore, these echo chambers enable users to perform a continuing defamation of dissenters and in some cases these defamation strategies follow the aim of political influence (Glaser & Pfeiffer 2017). This negative communication is called hate speech and

aims at the exclusion of single persons or groups of persons, because of their ethnicity, sexual orientation, gender identity, disability, religion or political views (Pereira-Kohatsu et al. 2019; Warner & Hirschberg 2012). According to Kay (2011) and Sunstein (2006), extremist networks show a low tolerance towards individuals and groups who think differently and are generally less cosmopolitan.

As a result of these echo chambers, hate speech as well as radicalizing elements show an increasing number on social media platforms (Reichelmann et al. 2020; Barberá et al. 2015). Therefore, Twitter is often accused of being a platform for polarizing, racist, antisemitic or anti-constitutional content (Awan 2017; Gerstenfeld et al. 2003). This content is usually also freely accessible to children and young people (Machackova et al. 2020). It could now be hypothesized that certain messages will get more attention, even if only a small minority of activists uses the echo chambers accordingly.

However, such social media elements could also be used to investigate communications patterns inside social networks and social sub-networks, in order to focus the role of individual users and what influence the content of their comments and actions might have on the underlying structures of a social network (Klinkhammer 2020). Therefore, social media platforms could also become a sensor of the real world and provide important information for criminological investigations and predictions (Scanlon & Gerber 2015; Sui et al. 2014). Corresponding research papers have been published recently (Hamachers et al. 2020) and five studies represent the scientific efforts regarding the identification of hate speech and extremism on Twitter (Charitidis et al. 2020; Mandl et al. 2019; Wiegand et al. 2018; Bretschneider & Peters 2017; Ross et al. 2017).

Some of these research papers refer to mathematical and statistical methods in order to identify hate speech as well as radicalizing elements. Regression models and classification models are most commonly used in machine learning based approaches and a few approaches are based on deep learning via logistic regression models as basis for simple neural networks (Schmidt & Wiegand 2017), whereas more sophisticated approaches make use of convolutional neural networks as well as sentiment analyses (Hamachers et al. 2020).

While methodologically it is feasible to count the number of hate speech and radicalizing elements and, for example, to study the impact of anti-hate laws regarding social media platforms by using

semi-automated and merely descriptive approaches (Wienigk & Klinkhammer 2021), the process of automated identification without human supervision has proven to be error-prone. For example, mean values and variance values as used as reference values in many of these approaches only lead to a correct identification in the short term (Klinkhammer 2020). However, the same approaches can lead to false positive or false negative results when conducted again at a later point in time. The decisive factor could be the intertemporal dynamics on social media platforms, which also could impact approaches based upon sentiment analyses (Grogan 2020). Accordingly, in respect to the changing size and topics of echo chambers over time and considering that radicalization is a process, a longitudinal perspective seems recommended (Greipl et al. 2022). As an intermediate result, two hypotheses can be derived for this discussion paper:

- (1) Patterns of communication on social media platforms can be subject to intertemporal dynamics.
- (2) Phenomena in the context of radicalization research can be superimposed by intertemporal dynamics.

Therefore, it seems necessary to consider these hypotheses, not only to perform a longitudinal sentiment analyses, but also in order to implement the outcomes of sentiment analyses as independent variables for evidence based predictions in the context of radicalization research.

### (III) Software Requirements

This discussion paper bases upon previously published working papers and tutorials on arXiv: *Analysing Social Media Network Data with R: Semi-Automated Screening of Users, Comments and Communication Patterns* (Klinkhammer 2020) and *Sentiment Analysis with R: Natural Language Processing for Semi-Automated Assessments of Qualitative Data* (Klinkhammer 2022). Both are based on R, an object based programming language. Therefore, datasets, variables, cases, values as well as functions can be applied as a combination of objects. This longitudinal approach for sentiment analyses requires six additional packages in order to expand the range of basic R functions, which are listed here in order to make the requirements and the process of data pre-processing and the subsequent analysis more transparent:

- (1) Since the analysis of comments on social media platforms requires a focus on every single element that is to be analysed, it is necessary to break down the underlying data structure into manage-

able little pieces. A package that is specifically designed to do so is called *dplyr*. It can split, apply and combine qualitative data for further analytical steps (Wickham 2022).

- (2) The second package is called *stringr*. Since qualitative data, like social media comments, is represented by character variables in R, a package that can process and - if necessary - manipulate individual characters within the strings of a character variable is required (Wickham 2019); A string is marked either by single quote signs or double quote signs.
- (3) Another necessary package is called *textdata*. It contains several words as references and sentiment libraries, such as the NRC Word-Emotion Association Lexicon (Mohammad 2020), as well as the Bing Sentiment Lexicon (Hu & Liu 2004).
- (4) Sentiment analysis is a text mining technique and the package *tidytext* is required in order to convert conventional qualitative data into tidy formats, such as single words without punctuation or spaces (De Queiroz et al. 2022). This allows scientists to focus on paragraphs or otherwise separated content word by word. As a result, the tidy text format lists and counts all words individually and assigns them a number according to the original Tweet.
- (5) The package *tidytext* provides a connection between most commonly used packages like *dplyr* and *ggplot2* by using their basic formulas and commands. The latter is responsible for the detailed visualisation of sentiments and other types of results, based on “The Grammar of Graphics” (Wickham et al. 2022). In particular, defining the details of a visualisation enables scientists to create informative as well as attractive plots.
- (6) Finally, the package *gridExtra* enables scientists to arrange multiple visualizations at once and to create dashboards for an intuitive display of relevant information (Auguie & Antonov 2017).

The previously mentioned working papers and tutorials provide a step by step guide through the process of data pre-processing as well as the analysis. Furthermore, the process of collecting data regarding social media networks and comments is demonstrated as well.

### (IV) Dataset and Data Pre-Processing

Data pre-processing is used to check datasets for irrelevant and redundant information present or noisy and

unreliable data. In a first step, 49.350 Tweets from January 6th 2021, the day the U.S. Capitol in Washington was stormed, have been transformed into a tibble. Tibbles are plain and simple datasets that can be processed by R. Furthermore, sentiment analyses require a tidy data set. In a tidy data set, each word within a Tweet is separated without losing connection to related words in the same Tweet. As a result, the tidy dataset can be described as a listing of all words within different Tweets. This allows the sentiment analysis to be performed word by word for each Tweet. Since non-essential words, such as *and* or *is*, may be included in this list, they need to be eliminated. In addition, custom words and duplicates can also be excluded from this object.

In a final step of data pre-processing, the dataset (49.350 Tweets) will be splitted into three evenly distributed sequences: Before (16.450 Tweets), during (16.450 Tweets) and after (16.450 Tweets) the storming of the U.S. Capitol in Washington. This subdivision is necessary because each point in time is marked by different contextual conditions which might have impact on the underlying dynamics of Tweets and thus for intertemporal sentiment analyses. For example, if there is a strict social norm about a topic at a given point in time, one might expect smaller variance than when there are weak norms about a topic. However, social norms can vary over time and in relation to acute events. Or one might observe that people who highly identify with a group have a smaller variance than those who are weakly identified with that group. Again, it must be taken into account, that the identification with groups might be subject to temporal fluctuations as well.

## (V) Methodological Approach

In order to highlight the dynamics regarding the appearance of sentiments and emotional states over time, a smoothed slope will be used. A smoothed slope does not represent actual values, e.g. mean values, but expected values based upon statistical modelling, e.g. conditional mean values. The conditional expectation can be either a random variable, noted as  $E[X|Y]$ , or a function, noted as  $E[X|Y = y]$ , where  $Y$  respectively  $Y = y$  represent the conditions. If a random variable can take on only a finite number of values, the conditions are that the variable can only take on a subset of those values which the slope of the function would depict accordingly. One of the advantages of expected values is their robustness to statistical outliers. Readers interested in the history of statistics will recognize parallels to the underlying work of Pierre-Simon Laplace, which was formalized

by Andrey Kolmogorov using the Radon-Nikodym theorem (Feller 1991).

Applying conditional expectations for longitudinal sentiment analyses is necessary, because the slope of a function based on actual values could be erratic due to sporadic occurring values. Nevertheless, only few longitudinal sentiment analyses consider conditional values (Jacobs & Spierings 2018), although this method was suitable to depict the dynamics of Tweets regarding politicians from populist parties. Considering the large amount of Tweets (here: 49.350) that are to be analyzed, sporadic occurring values are to be expected and will be compensated by applying conditional expectations. Conditional expectations will be calculated for each sequence of Tweets (here: 16.450) to establish intertemporal contextuality. It is to be assumed that applying more small-stepped sequences could increase the accuracy of the analysis further. The accuracy refers to the identification of individual data points that could be relevant in the context of radicalization research, e.g. radical comments regarding the storming of the U.S. Capitol in Washington. The analysis will highlight that conditional means and conditional variances are more suitable for that task than mean values and variance values.

In the actual analysis, not only the number of used sentiments over time is to be analyzed, but also their summative score. The first analytical step focuses the conditional mean values and conditional variance values regarding the number of used sentiments over time, for which the NRC Word-Emotion Association Lexicon is a suitable basis (Mohammad 2020). The NRC Word-Emotion Association Lexicon differentiates between positive and negative sentiments as well as eight emotional states: Anger, fear, anticipation, trust, surprise, sadness, joy, and disgust. Since a Tweet can consist of zero up to several sentiments, the expected values must be greater than or equal to zero within each sequence of Tweets. Another way of analysing the intertemporal use of sentiments and emotional states is based upon summative scores. A sentiment score results from the sum of positive ( $1$ ) and negative ( $-1$ ) values in respect to the underlying sentiment. Since the NRC Word-Emotion Association Lexicon from the first analytical step differentiates between positive and negative sentiments as well as eight emotional states, a validating lexicon can be added that differentiates only between positive and negative sentiments: The Bing Sentiment Lexicon (Hu & Liu 2004). For each Tweet with sentiments the score of these sentiments is assigned as sum of all positive ( $1$ ) and negative ( $-1$ ) sentiments and the conditional mean values and conditional variance val-

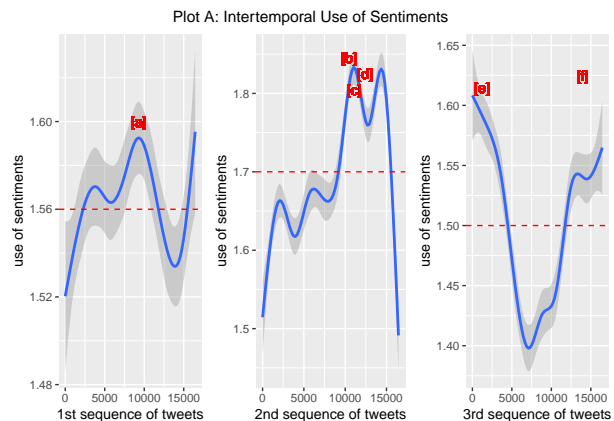

ues will be plotted as smoothed slope again. Thus, the number of used sentiments over time is to be analyzed via smoothed slopes and based upon the NRC Word-Emotion Lexicon as well as their summative scores based upon the Bing Sentiment Lexicon, each applied on all three sequences of the dataset in order to frame the intertemporal dynamics. The possibility of a specific identification of individual comments on social media platforms will be demonstrated by comparing the values of means and variances within each sequence with their expected values of the smoothed slope.

## (VI) Intertemporal Use of Sentiments

Focusing the intertemporal use of sentiments is supposed to reveal the intertemporal dynamics within Tweets. Each sequence will compare the mean values (red line) against the conditional mean values (blue slope). As can be seen, the intertemporal dynamics of each sequence would not be represented by one mean value for each sequence, whereas conditional means vary clearly below and above average. Furthermore, two important points for such analyzes are revealed: Intertemporal dynamics, as can be seen by focusing the below and above average fluctuations, tend to be small-stepped. For example, the mean values between the three sequences vary from 1.56 to 1.70 and finally 1.50. In the present data, the second sequence stands for the storming of the U.S. Capitol in Washington. Such an event is reflected in the intertemporal dynamics by an increase in the use of sentiments. The conditional means fluctuate a little bit more and run below and above the mean values, covering a below average use of sentiments as well as an above average use of sentiments. Corresponding analyzes must therefore be very sensitive in order to cover these fluctuations. Based on these sequences, it can now be examined which topic is depicted on Twitter with which intertemporal use of sentiments. Finally, individual Tweets and their positioning along the smoothed slope can be identified in order to specify the patterns of communication.

The first sequence is determined by two general topics: The necessity of measurements regarding the COVID-19 pandemic as well as the elections won by the Democratic Party in the federal state of Georgia. The lowest values of the slope indicate COVID-19 as dominant topic, whereas the highest values represent the point in time the results of the elections in Georgia and their confirmation were publicly announced. It becomes clear that the ongoing COVID-19 pandemic as topic is characterized by a lower use of sentiments on Twitter than the elections in Georgia. An example for

that specific event and the associated intertemporal dynamics is a Tweet that can be located at the local maximum of the slope ([a] Tweet 8.022): *“jon ossoff will stand for all of georgia in the fight for health-care jobs justice and our nation will be all the better for having him congratulations”*. However, when it comes to the use of sentiments, differences between democratic and republican voters can hardly be identified within the first sequence. Pro-democratic as well as pro-republican voters vary regarding the use of sentiments only within the confidence interval of each sequence (grey area). Furthermore, the course of the slope, as well as the amplitude, seem also to be influenced by other topics, as will be illustrated in the second and third sequence.

As expected, the use of sentiments increases within the second sequence and during the storming of the U.S. Capitol in Washington. As a result, the amplitude increases and leads to two local maxima right after each other. An intensive use of sentiments can be monitored, either to support or to oppose this event. As a result, when it comes to evaluating the use of sentiments from a numerical point of view, supporters and opponents seem hardly to differ regarding their patterns of communication. The following supportive Tweet is representative for these developments ([b] Tweet 12.105): *“we the people love you mr president we admire your courage and determination to listen to us and defend our rights thank you president trump for defending the constitution respecting us and fighting for us you are our president all 50 states are red”*. Another Tweet represents the opponents ([c] Tweet 12.183): *“this isnt a peaceful protest this is an attack on our democracy and domestic terrorism to try to stop certifying elections this should be treated as a coup led by a president that will not be peacefully removed from power”*. The majority of Tweets speaks out against the storming of the U.S. Capitol in Washington and the use of sentiments increases even more if people

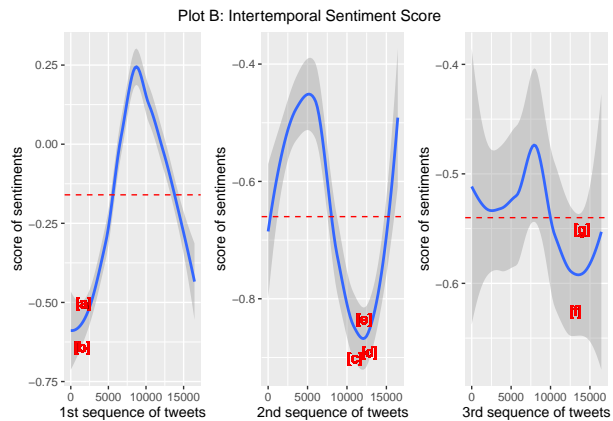

are directly affected by the events ([d] Tweet 12.326): *“i just had to evacuate my office because of a pipe bomb reported outside supporters of the president are trying to force their way into the capitol and i can hear what sounds like multiple gunshots”*. Again, all Tweets from supporters and opponents seem to vary within the confidence interval of the sequence.

The third sequence is characterized by many soothing and thus less emotionally charged Tweets. As a result, the intertemporal use of sentiments descends to the lowest values of the slope. Instead of emotional outbursts, argumentative Tweets appear on both sides. At the beginning of the third sequence some supporters of the storming of the U.S. Capitol in Washington compose emotionally charged Tweets, but it is important to note that they do not affect the course of the slope ([e] Tweet 778): *“the corrupt democrats and educational system efficiently spread their antiamerican cancer republicans stood around like deer in the headlights you are the only one who fought it total destruction of our democracy is ahead unless you continue fighting”*. Instead, the course of the slope is distorted by other topics, such as sexual content ([f] Tweet 13.961): *“seems my sub is ready for a good dicking if i get 100 retweets maybe ill upload my video of how i fucked his ass fuck interracial bdsm slave master”*. The fact that such content has very different patterns of communication than socio-political topics seems to shape a corresponding intertemporal dynamic, which is illustrated by the amplitude. As a result, individual Tweets as well as radical or extreme actors can be overshadowed on Twitter and a case sensitive inspection seems required. The intertemporal sentiment score can further clarify this.

## (VII) Intertemporal Sentiment Score

The same three sequences will be analyzed regarding the intertemporal sentiment score. This is not about how many sentiments are used, but whether they have a positive or negative connotation when it comes to their sum within a Tweet. As a result, the first sequence shows that the COVID-19 pandemic has more negative connotations than the outcome of the elections in the federal state of Georgia. With a view to the first part of the analysis, this means that fewer Tweets contain sentiments on the subject of COVID-19, but their intertemporal score is quite negative. Overall, the mean values within each sequence are negative, whereas the first sequence contains the weakest negative mean value, because of the outcome of the elections in Georgia. Again, the mean values do not cover the dynamics of the sequences, as the amplitude of conditional means suggests.

For example, supporters and opponents of a strict COVID-19 policy slightly use negative sentiments, as can be demonstrated for the supporters ([a] Tweet 1.717): *“when do all the right wing accounts and pundits paid by right wing billionaires apologize for underplaying the covid virus”*. This can be shown for the opponents as well ([b] Tweet 1.616): *“the new lockdown is primarily about giving the police leeway to be more draconian in enforcing it expect many more examples of wanton authoritarianism and brutality to follow”*. A moderate, but nevertheless slightly negative use of language can be detected by focusing the sentiment score. With regard to the outcome of the elections in Georgia, not only more sentiments can be detected within Tweets, but these are also significantly more positive overall, as could be shown in the previous step of the analysis. The low confidence interval over the course of the slope within the first sequence seems remarkable. This could mean that the patterns of communication of supporters and opponents are similar regarding these topics.

The second sequence confirms that the storming of the U.S. Capitol in Washington goes along with the local minimum of the slope regarding the intertemporal sentiment score. Accordingly, the amplitude is strongest in this sequence. The dominant emotional state at the local minimum of this sequence is fear, as can be demonstrated with two examples of opponents of the storming of the U.S. Capitol in Washington ([c] Tweet 12.500): *“i am in the capitol i am safe and my team and i are sheltering in place the president of the united states has incited a riot that has now stormed the capitol there are rioters roaming the halls of the capitol i saw them with my own eyes our country deserves better”* as well as ([d] Tweet 12.770) *“i am safe we are sheltering in place make no mistake president trump and his enablers are directly responsible for this violence”*. Accordingly, the lowest values of the slope are not to be detected after the storming

of the U.S. Capitol in Washington, but almost simultaneously. Again, the intertemporal sentiment score shows a parallel between opponents and supporters when it comes to the intensity of shown sentiments and the underlying emotional states as well as their variance around the slope. For example, supporters also refer to fear and trust as emotional state and use it within their Tweets at a comparable rate ([e] Tweet 12.689): *“no matter what happens today stay strong do not waiver do not walk in fear no matter what it looks like hold the line of faith trump is our president”*. However, there is no difference between the Tweets of the so-called Trumpists and other supporters of the event. Their patterns of communication vary only in accordance with the course of the slope.

One of the most significant dynamics is revealed in the third sequence. The confidence interval around the slope seems to increase significantly. This does not primarily indicate that supporters and opponents after the storming of the U.S. Capitol in Washington tend to have more differences regarding their intertemporal sentiment score, but can rather be interpreted as a signal for more emerging topics within the Tweets. As illustrated in the previous step of the analysis, the intertemporal use of sentiments decreases in this sequence. Therefore, the amplitude has decreased as well compared to the previous sequence. This is another indication that sensitivity is required for corresponding analyses. On the one hand, Twitter users seem to make use of fewer sentiments, on the other hand, they seem to differ more clearly regarding the strength of the sentiments expressed. This can be interpreted as a slight after-effect in respect to the current events. Furthermore, the length of the Tweets decrease and the topics return to the topics of the first sequence, e.g. the necessity of measurements regarding the COVID-19 pandemic in combination with the storming of the U.S. Capitol in Washington ([f] Tweet 13.987): *“not a mask to be seen at the trump sore loser rally”*. The contents of the Tweets also seem to be devoted more to a substantive debate ([g] Tweet 14.069): *“if masks are so great why do the mask mandates show growth in the graphs after implementation”*.

As a result, and in accordance with the first part of the analysis, events deviating from the current events with more sentiments and emotional states can lead to a significant distortion of the slope. This makes it harder to spot promoters of events like the storming of the U.S. Capitol in Washington. Likewise, it seems harder to differentiate between supporters and opponents by relying solely on quantitative indicators.

## (VIII) Summary

The analysis has shown that differences between supporters and opponents of relevant social affairs, like the storming of the U.S. Capitol in Washington, can be similar in their patterns of communication. In fact, they can even be so similar that it seems almost impossible to differentiate them solely based upon quantitative characteristics. This similarity was determined via the number of sentiments and emotional states used over time, but also via their associated summative score. As a result, the values of individual Tweets vary most likely within the conditional mean values and conditional variance values, even if their content supports such events. Therefore, all Tweets from supporters and opponents vary within the confidence interval of each sequence. This is due to the fact that the intertemporal dynamics are affected by social affairs and corresponding Tweets vice versa. The assumption that extremist Tweets or hate speech can be identified by above-average quantitative values would therefore be wrong. Furthermore it would be wrong to use mean values and variance values without considering the intertemporal dynamics framed by the context. This could result in false-positive identifications in the context of radicalization research.

Furthermore, the analysis demonstrated that intertemporal dynamics influence the course as well as the amplitude of the slope. This influence is not exclusively due to social affairs or similar events. Topics with different patterns of communication, like sexual content, can significantly influence the intertemporal dynamics as well. Especially the permeability of social media platforms like Twitter and the interaction between different echo chambers could not only affect the course of the slope globally (Cinelli et al. 2021), but also the intertemporal dynamics partially within the echo chambers. Thereby, relevant phenomena for the context of radicalization research can be overshadowed.

This confirms the two hypotheses that intertemporal dynamics can be traced and obscure relevant phenomena in the context of radicalization research. As a result, longitudinal sentiment analyses seem less suitable for the targeted identification of individual Tweets, but more suitable for depicting a development over time in the sum of all Tweets. This is in accordance with the findings of Grogan (2020) as well as the suggestion made by Greipl et al. (2022) to conduct longitudinal analyses in radicalization research. The developments can be mapped almost in real time, which offers the possibility for qualitative inspections of Tweets, which seems necessary. Ac-

cordingly, the importance of qualitative perspectives was appropriately emphasized in the anthology of Hamachers et al. (2020). Finally, the question arises, whether the similarities found between the supporters and opponents of the storming of the U.S. Capitol in Washington are not a result of the predefined structures of social media platforms. As a social media platform, Twitter specifies the same input format for all its users, whereby their patterns of communication can be influenced as well.

## (IX) Recommendations

Taking into account the permeability of echo chambers on social media platforms and their intertemporal dynamics, a longitudinal approach seems necessary in order to depict process-based phenomena in the context of radicalization research. With regard to sentiment analysis and in accordance with current research, it can be stated that this methodological approach seems not suitable for a precise identification of these phenomena outside their echo chambers, either in a cross-sectional nor in a longitudinal perspective. However, sentiment analyses seem rather suitable for depicting the intertemporal dynamics on social media platforms in general. By doing so, the use of several sentiment analysis dictionaries in order to validate the findings has shown to be a beneficial factor.

It could also be shown that phenomena relevant for the context of radicalization research do not necessarily have the strongest influence on the intertemporal dynamics, but other phenomena could rather superimpose them. Therefore, it would be negligent to identify radicalization, extremism and hate speech solely on the basis of above-average quantitative values. The distribution of these phenomena seems rather to depend on the fact that they are within the range of conditional mean values and conditional variance values. One could also say that these users seem to have mastered the rules of social media platforms. As a result, in this example, the Tweets from Trumpists, Republicans and Democrats are quite similar regarding the storming of the U.S. Capitol in Washington. If a social event elicits increased activity from one side, it appears to do the same for the other side. Accordingly, the highs and lows of these intertemporal dynamics should be a reminder for a deeper insight via qualitative research and human expertise.
