Twisted double bilayer graphene is a compensated semi-metal near the charge neutrality point with the presence of small electron and hole pockets in its band structure. We show that strong Coulomb attraction between the electrons and holes can lead to the formation of indirect excitons. Condensation of these excitons at low temperature creates an excitonic metal with charge density wave order for an appropriate range of interaction strength. This has interesting implications for low-temperature transport in the system as a function of carrier density and temperature. The reorganization of the single particle excitations and their density of states in the excitonic metal can lead to peaks in resistivity as a function of carrier density, recently seen in experiments at low temperatures. The fluctuations of the Landau damped order parameter in the quantum critical metal lead to non-Fermi liquid behaviour, which can explain the sublinear  $T^{2/3}$  dependence of the resistance near the charge neutrality point.

## I. INTRODUCTION

When sheets of two-dimensional materials are stacked on top of each other, and their crystal axes are twisted (rotated) by a small angle, the electronic structure of these heterostructures become extremely sensitive to the angle of twist between them<sup>1–10</sup>. This has led to the idea of twistronics<sup>6,11</sup>, where the twist angle will be used as an experimental knob to change the electronic properties of these systems. The tunability of electronic structure with twist angles has been successfully studied in a controlled fashion in several systems, including multiple layers of graphene<sup>11–16</sup> and Bernal stacked bilayer graphene<sup>17–19</sup>, graphene-Boron Nitride sandwiches<sup>20</sup>, and heterostructures made of dichalcogenides<sup>21,22</sup>. A common feature of these systems is the presence of (multiple) magic twist angles<sup>1,7</sup>, where the bandwidth of the system is a minimum and the fate of the system is determined by strong electronic interactions. In graphene-based systems, such magic angles occur around  $1–1.6^\circ$ <sup>14,23,24</sup>, leading to large incommensurate moiré unit cells  $\sim 8–15$  nm.

In twisted bilayer graphene (tBLG), where two sheets of graphene are twisted with respect to each other, the electronic interactions lead to a plethora of symmetry broken phases as a function of the electron density at the magic angle, from correlated insulators<sup>11,23,25</sup> to orbital ferromagnets<sup>26</sup> to superconductors<sup>12,13,23,27,28</sup>. In twisted trilayer graphene (tTLG), where three sheets of graphene are twisted with respect to each other, the electronic correlations again lead to a superconducting state over a range of carrier densities<sup>14,15,29,30</sup>. In comparison, their close cousin, the twisted double bilayer graphene (tDBLG), where two sheets of Bernal stacked bilayer graphene is rotated with respect to each other, had shown simple metallic behaviour as a function of filling in early experiments<sup>17,19</sup>. While there is evidence of correlated behaviour in presence of perpendicular electric<sup>17,18,24,31</sup> or magnetic fields<sup>17,31</sup>, the phenomenology of plain vanilla tDBLG seemed to be explained by a non-

interacting picture<sup>9,10,17,19</sup>.

The metallic behaviour of tDBLG even near the charge neutrality point (CNP) with no external doping is readily explained by the fact that the flat valence and conduction bands in tDBLG overlap with each other in energy. This leads to the formation of small electron and hole pockets in this regime<sup>9,10,32</sup>. tDBLG at CNP is thus a compensated semi-metal. The presence of these electron and hole pockets near CNP in tDBLG has now been demonstrated unambiguously through recent magnetotransport measurements<sup>33</sup>. This brings us to an interesting question: Do the strong electronic interactions have any qualitative effect on the small electron and hole pockets near CNP, or do they behave like almost non-interacting systems? In this paper, we show that indirect excitons are formed due to the attraction between the electron and hole pockets, and condensation of these excitons can lead to the formation of a CDW state near CNP at low temperatures. The system remains metallic on either side of the transition for a range of parameters. The phase transition in the background of itinerant electrons is driven by Landau damped fluctuations of the excitonic order. The scattering of electrons by these fluctuations lead to non-Fermi liquid behaviour in these systems<sup>34–42</sup>. Thus interactions have profound effects on the small electron and hole pockets in the system.

The formation of excitonic condensate leads to a reorganization of the electronic structure into multiple “mini-bands” with their respective Fermi seas. This leads to anomalous peaks in the inverse density of states at Fermi level as a function of carrier density, which mimics the peaks in resistance as a function of carrier density seen in recent experiments<sup>33</sup>. Within a mean field theory, the simultaneous presence of the anomalous peaks as well as a Fermi sea to account for metallic behaviour strongly constrains the interaction parameters. We find that the allowed parameter ranges are reasonable for tDBLG.

Another surprising result from these experiments<sup>33</sup> is that close to CNP, the measured resistance exhibits a

unique sublinear temperature dependence ( $R \sim T^{2/3}$ ) in the temperature range 0 – 10 K. Above this temperature range, the resistance increases linearly with temperature. Far away from the CNP, the resistance reverts to a standard superlinear temperature dependence ( $R \sim T^2$ ) seen in usual metals. The sublinear temperature dependence of resistivity is rarely seen in metals and cannot be explained by standard scattering mechanisms (disorder, electron-electron or electron-phonon) within a Fermi liquid theory. On the other hand, in a quantum critical metal on the verge of forming excitonic condensates, the quantum fluctuations of the order parameter will be Landau damped by the low energy Fermions present in the system. We show that the scattering of charge carriers in the small Fermi pockets from such overdamped critical fluctuations gives rise to a non-Fermi liquid with a  $T^{2/3}$  dependence of resistance at low temperatures. At higher temperatures, we reach an equivalent of a “Bloch Gruneisen” temperature for these fluctuations and the resistivity shows linear temperature dependence beyond that scale. The question of a breakdown of Fermi liquid theory in a metal due to quantum fluctuations near a critical point is a matter of great theoretical interest, and has been studied using sophisticated formalisms<sup>34,37–42</sup>. Here we propose that the presence of small Fermi surfaces in these systems undergoing phase transitions make sure that the non-Fermi liquid behaviour shows up in low temperature transport as a non-analytic temperature dependence of the resistivity. Thus we propose that the magic angle tDBLG is not a garden-variety metal; rather there is strong experimental evidence for an underlying non-Fermi liquid state formed due to interactions in a compensated semi-metal.

In this paper, we review the formation of electron and hole pockets in tDBLG in Sec. II. Sec. III provides the details of the mean field theory of the excitonic condensate near CNP. In Sec. IV, we show how the electronic reorganization due to exciton formation leads to peaks in the inverse density of states and compare it to experiments. In Sec. V, we discuss how the Landau damping near a critical point leads to a non-Fermi liquid behaviour. We also discuss the connection of this underlying non-Fermi liquid state to the sublinear temperature dependence in resistivity. Finally in Sec. VI, we conclude with a summary of our results.

## II. ELECTRON AND HOLE POCKETS IN TDBLG

The low energy electronic states of tDBLG at magic angle at and around the CNP consist of both electron and hole pockets. This is in contrast with other members of the twisted graphene family (tBLG or tTLG) which forms a Dirac node at CNP and shows either electron or hole like states when doped away from the CNP<sup>1,3,10,32,43,44</sup>. As a result, tDBLG shows metallic behaviour near CNP, while the other moiré graphene

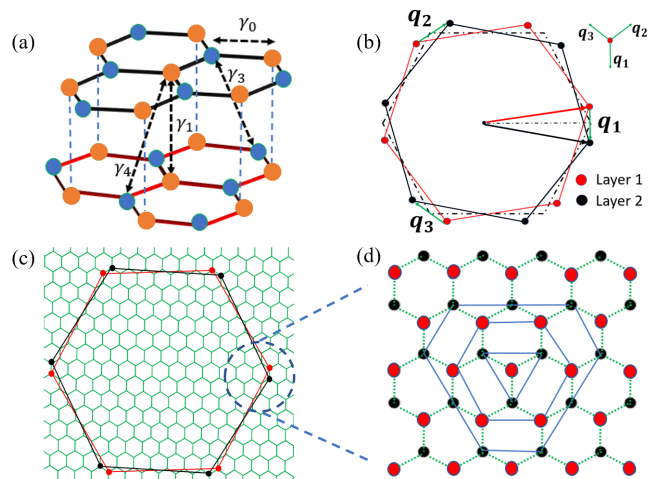

FIG. 1: (a) Schematic of Bernal stacked bilayer graphene and relevant intra ( $\gamma_0$ ) and inter( $\gamma_{1(3)(4)}$ )-layer tunnelings. (b) Brillouin zone of two bilayer-graphene sheets rotated w.r.t each other by a small twist angle. Three transfer momenta ( $q_{1(2)(3)}$ ) between the Dirac points of each layer are marked. (c) and (d) show the smaller moiré Brillouin zone created by the twist. The zoomed-in image shows the construction of consecutive shells and the momentum cut-off used in the continuum model.

systems show weakly insulating ( $R \sim 10 - 50 \text{ k}\Omega$ ) behaviour<sup>11,13–15,19,24,29,45</sup>.

Since tDBLG is made of two layers of bilayer graphene (BLG) with a twist between them, it is useful to start with the band structure of BLG. A schematic of a Bernal (A-B) stacked BLG is shown in Fig. 1(a). The carbon atoms in each layer form a honeycomb lattice and are coupled by a nearest neighbour in-plane hopping  $\gamma_0$  where,  $\frac{\sqrt{3}}{2}\gamma_0 = \hbar v_0/a \sim 2.1354 \text{ eV}$ <sup>32</sup>, while the out of plane hopping is primarily between atoms which sit on top of each other (in the so-called dimer sites) with a scale  $\gamma_1 = 400 \text{ meV}$ . A simplified model of BLG with only  $\gamma_0$  and  $\gamma_1$  produces a Dirac point where two quadratic bands touch each other, with a Berry monopole of charge 2 located at the Dirac point. However, if one considers additional interlayer hoppings between the non-dimerized sites (the trigonal warping  $\gamma_3 = 320 \text{ meV}$ ), or between dimerized and non-dimerized sites ( $\gamma_4 = 44 \text{ meV}$ ), this simple picture changes at low energies. The single band touching point splits into a central Dirac point and three satellite Dirac points, where linearly dispersing bands touch each other<sup>46</sup>. The central and the satellite Dirac points carry Berry monopoles of opposite charges. The formation of the satellite Dirac points and associated Lifshitz transitions in BLG have been probed both theoretically and experimentally<sup>47,48</sup>. We also include an on-site potential of dimerized sites with respect to non-dimerized sites,  $\delta' = 50 \text{ meV}$ <sup>32</sup>.

We consider the  $AB - AB$  stacked tDBLG. In this case,

the graphene Brillouin zone is tiled by the moiré Brillouin zone (mBZ), with a reciprocal lattice vector of size  $k_M = k_D \sin \theta / 2$ , where  $k_D$  is the reciprocal lattice vector of the BLG Brillouin zone and  $\theta$  is the twist angle, as shown in Fig. 1(b). The two twisted layers are tunnel-coupled with tunneling between the same sublattices  $u_{AA} = u_{BB} = 79.7$  meV and the tunneling between different sublattices  $u_{AB} = 97.5$  meV. For these set of parameters, used in a wide range of earlier papers<sup>10,24,32</sup>, the magic angle is  $1.2^\circ$ , which matches with experimental estimates of magic angle for tDBLG<sup>33</sup>. The inter-BLG tunnelings couple momentum states in one mBZ to those in nearby zones; as shown in Ref. 1 and Fig. 1(c-d). One can limit the number of Brillouin zones used to calculate the band dispersion of the moiré system at low twist angles<sup>1</sup>. We use the 5 nearest shells which lead to a 184 dimensional continuum Hamiltonian to obtain the low energy band dispersion of tDBLG within an accuracy of 1%.

The low energy band structure of tDBLG near the magic angle consists of a valence and a conduction band with a bandwidth  $\sim 20$  meV. In Fig. 2(a), we plot the dispersion of the conduction and valence bands along the principal directions of the mBZ ( $K_M - \Gamma_M - M_M - K'_M$ ). We clearly see that the bands overlap in energy along the  $\Gamma_M - M_M$  line (shown by the shaded region in Fig. 2(a)); hence at the charge neutrality point, one would expect a compensated metal with electron and hole pockets. We would like to note that particle-hole symmetric band structures, obtained from a simplified description of BLG with only  $\gamma_0$  and  $\gamma_1$ , do not show this band overlap<sup>9,10</sup>. The presence of trigonal warping  $\gamma_3$  is crucial in obtaining this overlap. In Fig. 2(b), we show a 3d plot of the dispersion of the valence and the conduction band, which clearly shows that the bands do not cross each other; rather they touch each other at two anisotropic Dirac points along the  $\Gamma - M$  line at slightly different energies, leading to the band overlap. The valence and conduction band dispersions are plotted as color plots in the full Brillouin zone in Fig 2(d) and (e). The thick lines mark the Fermi surfaces (curves) of the electron (conduction band) and hole (valence band) pockets at the CNP. We clearly see that there are three electron and three hole pockets related by  $C_3$  symmetry. The pockets are centered around the points where the bands touch each other. We note that we have plotted the moire bands around one valley of the original BLG dispersion. The band touchings and electron-hole pockets of the other valley can be obtained by applying a rotation of  $\pi$  to this figure.

As we move away from the CNP on the electron doped side, the size of the electron pocket increases, while the hole pocket shrinks. At an electron density  $n/n_s \sim 0.13$ , the hole pocket shrinks to a point and beyond this density, the system only has three electron pockets. Here  $n_s \approx 3.3 \times 10^{12} \text{ cm}^{-2}$  is the density where the conduction band is fully filled (including spin and valley degeneracies). On the other hand, with hole doping, the hole

pocket grows and the electron pocket shrinks, till it disappears at  $n/n_s \sim -0.2$ . Fig 2(f) plots the Fermi surfaces for the electron and hole pockets on either side of CNP at densities  $n/n_s = -0.17$  and  $n/n_s = 0.12$  to show the evolution described above. Note that the centers of the pockets do not change with density and the wave-vectors joining the centers of the nearest electron and hole pockets,  $\mathbf{Q}_1$ ,  $\mathbf{Q}_2$ , and  $\mathbf{Q}_3$  are clearly shown in Fig 2(f). While there are interesting evolution of the Fermi surface at higher densities, in this paper, we will focus on densities between  $n/n_s = -0.2$  and  $n/n_s = 0.13$ , where both electron and hole pockets are present.

The finite density of states at the Fermi level coming from these electron and hole pockets lead to metallic behaviour in tDBLG<sup>17-19,24,45</sup> in absence of perpendicular electric field. We note that the waxing and waning of the electron and hole pockets compensate each other to keep the total density of states at the Fermi level finite and independent of the carrier density near CNP, as shown in Fig 2(c). Recently the strong magnetic field dependence of the low temperature resistance and thermopower in these systems<sup>33</sup> have provided concrete evidence of the existence of these electron and hole pockets in tDBLG.

### III. EXCITON CONDENSATES NEAR CNP

An important question in systems with low electronic density is: what is the fate of the system when the strong electronic interactions are taken into account? While earlier experiments in tDBLG<sup>17-19,24,45</sup> showed a fairly standard metallic behaviour in absence of perpendicular electric fields (correlated states were found at finite electric fields), a recent experiment<sup>33</sup> at very low temperatures ( $T < 2K$ ) has shown a double peak structure in the resistance as a function of carrier density near CNP where both electron and hole pockets are present. These double peak structures cannot be explained by a non-interacting theory, since electrons and holes contribute additively to the electrical response, and the total density of states near CNP is almost independent of doping as seen in Fig 2(c). These are the first concrete experimental signatures that electronic correlations play an important role in tDBLG near the CNP.

In systems with electron and hole states at the Fermi level, the Coulomb attraction between the oppositely charged electrons and holes often leads to the formation of charge neutral electron-hole pairs called excitons. Formation of exciton states are commonly seen in semiconductor systems<sup>49,50</sup>, as well as Van der Waals heterostructures<sup>51,52</sup>. Coherent condensation of these particle-hole pairs, leading to superfluidity of charge neutral objects, have been predicted and demonstrated in bilayer quantum Hall systems<sup>53-56</sup> as well as bilayer graphene<sup>57</sup>. The electron-hole pockets in tDBLG, which are separated by a small momentum  $|\mathbf{Q}_i| \sim 0.01 \text{ \AA}^{-1}$ , are ideal candidates for the formation of excitonic condensates with finite momentum (indirect excitons). We

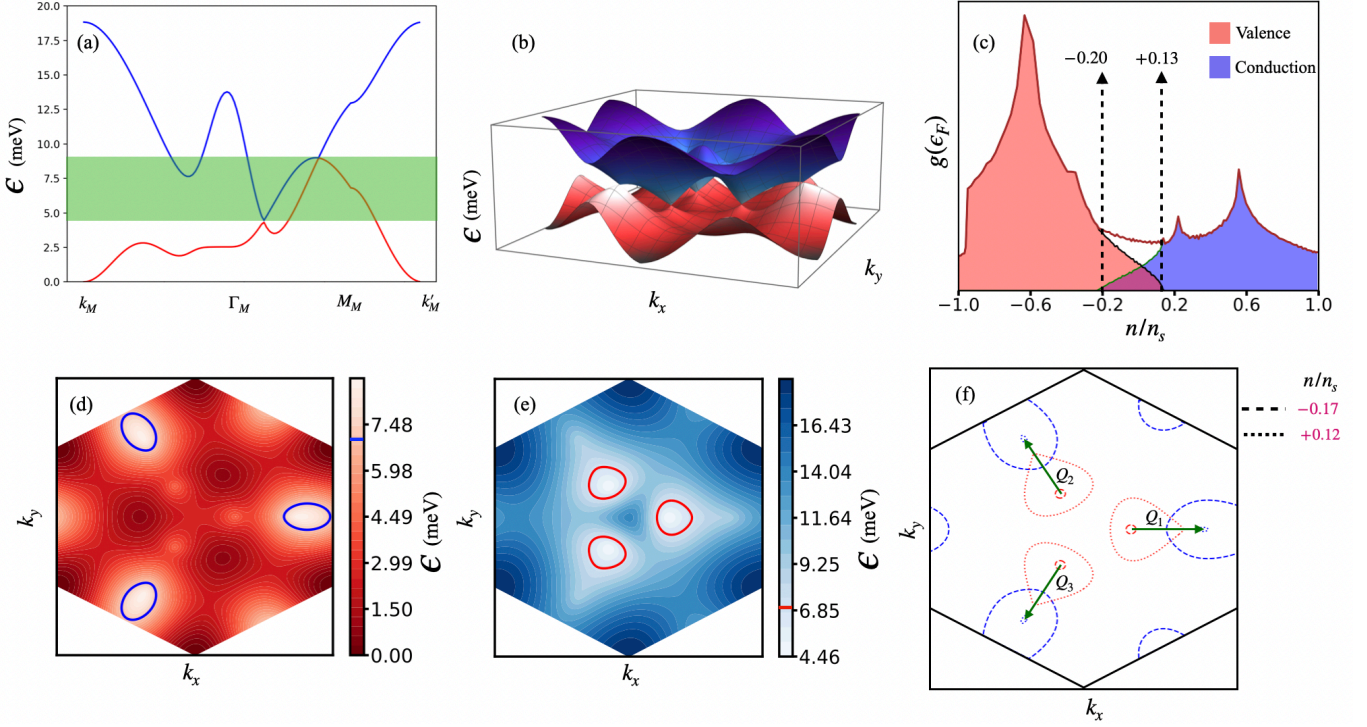

FIG. 2: (a) Non-interacting band dispersion of tDBLG along high symmetry directions in the moire Brillouin zone. The valence (red) and conduction (blue) bands are plotted. The shaded region denotes the energies where the bands overlap. (b) A 3-d depiction of the energy dispersion in the mBZ to show the six satellite Dirac points around the  $\Gamma_M$  point. (c) Valence (red) and conduction (blue) bands' density of states at the Fermi level are plotted with the normalised carrier density. The bands overlap between carrier densities (marked)  $\approx -0.20$  and  $+0.13$ . (d) and (e) Contour plots of the valence (red) and conduction (blue) bands respectively with Fermi surfaces at CNP marked separately. The blue pocket in (d) and the red pocket in (e) denote the hole and electron pocket respectively. (f) The electron (red) and hole (blue) pockets at two different carrier densities around the CNP are shown to point out that one of the pockets shrinks and another one inflates as one moves away from CNP. The  $Q_{1(2)(3)}$  vectors connect the e-h pocket centers and are related by  $C_3$  symmetry.

will now explore this possibility within mean field theory.

We consider the two-band Hamiltonian

$$H = \sum_{\mathbf{k}\eta} (\epsilon_{\mathbf{k}}^c - \mu) C_{\mathbf{k},\eta}^{c\dagger} C_{\mathbf{k},\eta}^c + (\epsilon_{\mathbf{k}}^v - \mu) C_{\mathbf{k},\eta}^{v\dagger} C_{\mathbf{k},\eta}^v + \frac{1}{\Omega} \sum_{\mathbf{k},\mathbf{k}',\mathbf{q},\eta,\eta'} V(\mathbf{q}) C_{\mathbf{k}+\mathbf{q},\eta}^{v\dagger} C_{\mathbf{k},\eta}^v C_{\mathbf{k}'-\mathbf{q},\eta'}^{c\dagger} C_{\mathbf{k}',\eta'}^c \quad (1)$$

where  $C^{c(v)}$  denotes the electron annihilation operator in the conduction (valence) band,  $\eta$  is a composite spin and valley index and  $\epsilon_{\mathbf{k}}^{c(v)}$  is the conduction and valence band dispersions shown in the previous section. Here  $V(\mathbf{q})$  is the screened Coulomb interaction between the conduction and valence band electrons. We note that we have neglected interaction between electrons in the same band, since our primary focus is on understanding the formation of interband excitons. We have also assumed that the large momentum connecting the two valleys of BLG  $\sim 1\text{\AA}^{-1}$  makes it unfavourable for Coulomb interaction to scatter electrons from one valley to the other. Note

that although excitons are often understood as pairing of electrons and holes, where the hole can be obtained by a particle-hole transformation on the valence band, i.e.  $C^v \rightarrow h^{v\dagger}$ , we prefer to work with electron coordinates in both bands. The size of the small Fermi pockets as well as the momentum separating the center of the electron and hole pockets are  $\sim 0.01\text{\AA}^{-1}$ . We assume that  $V(\mathbf{q})$  does not change rapidly over this scale and can be approximated by a constant value  $V_0$  for our calculation. For our calculations, we will use  $u_0 = 10.9\text{ meV}$  where  $u_0 = V_0/\Omega$ . We will later try to constrain its value both from theoretical and experimental estimates.

From Fig. 2(f), we see that there are three electron and hole pockets in the mBZ, and three wave-vectors  $\mathbf{Q}_{1(2)(3)}$  connecting them. We will consider a mean-field description of finite momentum interband excitonic condensate, which has an equal amplitude at each of the momenta  $\mathbf{Q}_i$ , i.e.  $\frac{V_0}{\Omega} \sum_{\mathbf{k}} \langle C_{\mathbf{k},\eta}^{c\dagger} C_{\mathbf{k}+\mathbf{Q}_i,\eta}^v \rangle = \Delta$  (See Fig. 3(a) for a schematic of finite momentum exciton). We note that formation of finite momentum excitonic

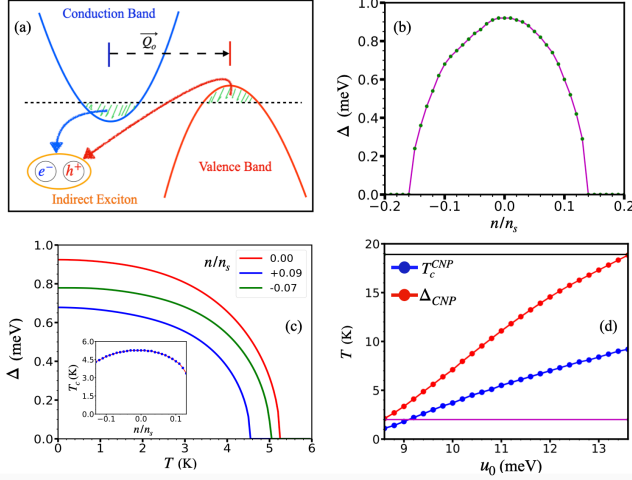

FIG. 3: (a) Schematic showing the formation of indirect excitons from the two bands. (b) Mean field order parameter ( $\Delta$ ) is plotted with carrier density.  $\Delta$  has a peak at CNP and goes down on either side of CNP. (c) The temperature dependence of  $\Delta$  is shown for three values of  $n/n_s = 0.00, 0.09, -0.07$ . In the inset, we have plotted the variation of  $T_c$  with density around CNP.  $T_c$  is weakly dependent on  $n/n_s$  with a peak at CNP. (d)  $\Delta$  (in the units of temperature) (red) and mean field  $T_c$  (blue) are plotted as a function of the interaction strength  $u_0$ . The pink line is the experimentally observed  $T_c$ . The black line indicates  $\Delta_c$ , where the system forms an excitonic insulator rather than a metal for  $\Delta > \Delta_c$ .

condensates in this system is equivalent to the appearance of a charge density wave (CDW) order in the system. Since  $\sum_i \mathbf{Q}_i = 0$ , our ansatz of equal condensates for all momenta ensure that there is no underlying valley current in the ground state of the system. It also ensures that the  $C_3$  symmetry of each valley remains unbroken in the system. Note that  $\mathbf{Q}_i \rightarrow -\mathbf{Q}_i$ , if the valley is flipped, and the net current summed over valleys would have been zero even for an ansatz with unequal condensates. With this ansatz, using the basis  $(C_{\mathbf{k}}^c, C_{\mathbf{k}+\mathbf{Q}_1}^v, C_{\mathbf{k}'}^c, C_{\mathbf{k}'+\mathbf{Q}_2}^v, C_{\mathbf{k}''}^c, C_{\mathbf{k}''+\mathbf{Q}_3}^v)$ , we obtain the  $6 \times 6$  mean field Hamiltonian,

$$\mathcal{H} = \begin{bmatrix} d_{\mathbf{Q}_1}(\mathbf{k}) & 0 & 0 \\ 0 & d_{\mathbf{Q}_2}(\mathbf{k}') & 0 \\ 0 & 0 & d_{\mathbf{Q}_3}(\mathbf{k}'') \end{bmatrix} \quad (2)$$

where

$$d_{\mathbf{Q}_i}(k) = \begin{bmatrix} \frac{\epsilon_{\mathbf{k}}^c}{3} - \mu & \Delta \\ \Delta & \frac{\epsilon_{\mathbf{k}+\mathbf{Q}_i}^v}{3} - \mu \end{bmatrix}. \quad (3)$$

Here  $\mathbf{k}'$  and  $\mathbf{k}''$  vectors are generated by rotating the  $\mathbf{k}$  vector by  $2\pi/3$  and  $4\pi/3$  respectively. The quasiparticle

excitation spectrum of the mean field theory is

$$E_{\mathbf{Q}_i}^{\pm}(\mathbf{k}) = \frac{\epsilon_{\mathbf{k}}^c + \epsilon_{\mathbf{k}+\mathbf{Q}_i}^v}{6} - \mu \pm \sqrt{\frac{(\epsilon_{\mathbf{k}}^c - \epsilon_{\mathbf{k}+\mathbf{Q}_i}^v)^2}{36} + \Delta^2} \quad (4)$$

The self-consistency equations, which determine the order parameter  $\Delta$  and the chemical potential  $\mu$ , are given by

$$1 = \frac{V_0}{2\Omega} \sum_{\mathbf{k}, \mathbf{Q}_i} \frac{-1}{E_{\mathbf{k}}} [f(E_{\mathbf{Q}_i}^+(\mathbf{k})) - f(E_{\mathbf{Q}_i}^-(\mathbf{k}))];$$

$$n = \frac{1}{3} \sum_{\mathbf{k}, \mathbf{Q}_i} [f(E_{\mathbf{Q}_i}^+(\mathbf{k})) + f(E_{\mathbf{Q}_i}^-(\mathbf{k}))] \quad (5)$$

where  $f$  is the Fermi function. In Fig. 3(b) we plot the self-consistent  $\Delta$  at  $T = 0$  as a function of the carrier density  $n/n_s$  for a system with  $u_0 = 10.9$  meV. The order parameter shows a maxima around the CNP ( $\sim 0.9$  meV) and decreases on either side of CNP, finally vanishing through a sharp jump at the boundaries where the electron-hole pockets cease to exist simultaneously. The electron and hole pockets are matched in size (albeit shifted in momentum) at the CNP. As we move away, the electron(hole) pocket grows while the hole (electron) pocket shrinks. This mismatch of the Fermi pockets leads to a weakening of the order parameter at finite carrier densities. The temperature dependence of the order parameter at three different densities are shown in Fig. 3(c). From the vanishing of the order parameter, one can obtain the mean-field  $T_c$  of the system, which is plotted in Fig. 3(c) inset as a function of carrier density. We see that  $T_c$  is very weakly dependent on carrier density and hovers around 5 K for our chosen set of parameters. Our estimate is in the same ballpark as the experimentally obtained  $T_c \sim 2$  K<sup>33</sup>, where the resistance peaks disappear. We would like to note that this mean-field estimate is an upper bound for the real  $T_c$ , which will be further degraded by fluctuations and disorder. In Fig. 3(d), we have shown the  $u_0$  dependence of  $\Delta(T = 0)$  and  $T_c$  at CNP. The magenta horizontal line is the experimentally observed  $T_c \sim 2$  K<sup>33</sup>. The black horizontal line corresponds to the maximum value of  $\Delta(T = 0)$  for which the system remains metallic (see discussion in Sec. IV for details). These two lines thus provide lower and upper bounds on  $u_0$  (9.1 meV and 13.6 meV respectively) to be used in the calculation. We have used  $u_0 = 10.9$  meV in the middle of this range.

#### IV. EXCITON CONDENSATES AND ELECTRONIC STRUCTURE

The occurrence of excitonic condensates in materials<sup>49–51,58</sup> often lead to the underlying Fermi surface being gapped out, leading to an excitonic insulator. This is inevitably the case when the condensate is formed with 0 net momentum, as is the case in quantum Hall bilayers and bilayer graphene<sup>53–57</sup>. However, the shift between

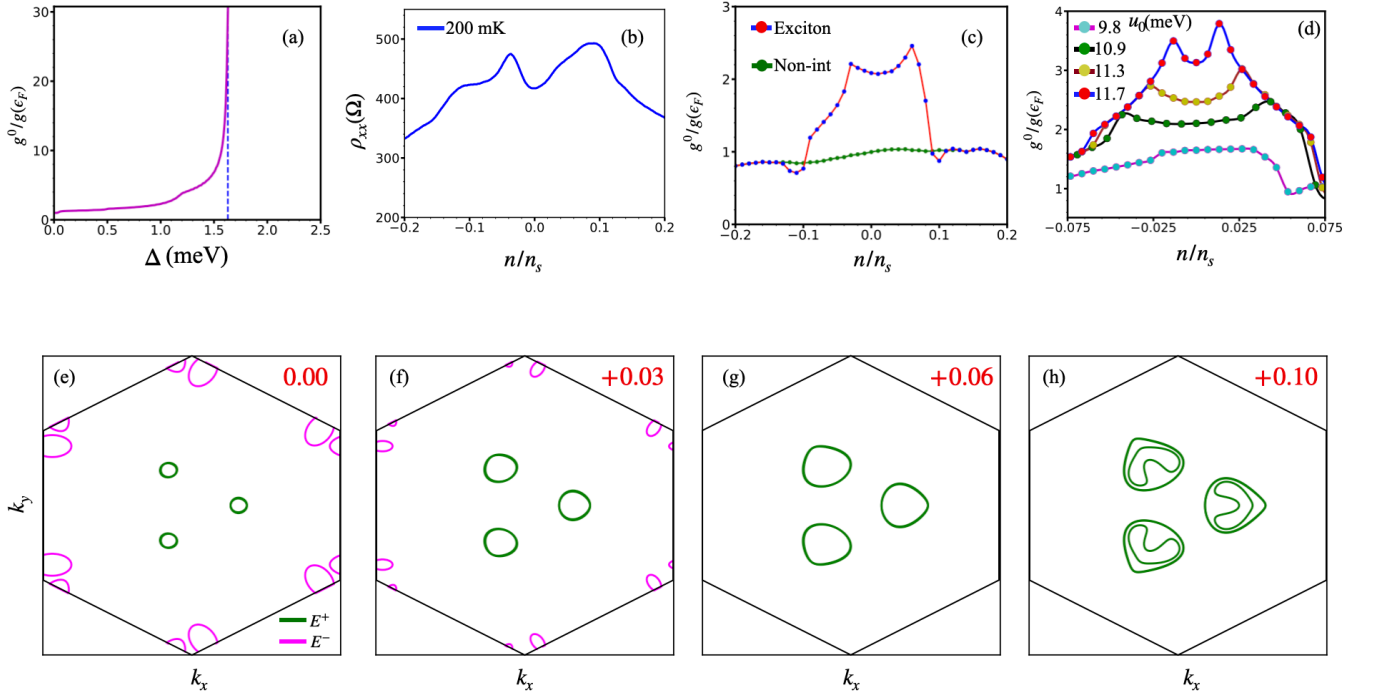

FIG. 4: (a) Inverse DOS at the Fermi energy for the excitonic metal is plotted with  $\Delta$ . For  $\Delta > \Delta_c \sim 1.6$  meV (marked by the blue dotted line), the system shows insulating behaviour with zero density of states at the Fermi level. (b) Experimentally obtained longitudinal resistivity of tDBLG as a function of carrier density at 200 mK exhibiting the double peak structure. (c) Inverse DOS at Fermi level for the excitonic metal (red) and the non-interacting state (brown) as a function of carrier density. The excitonic condensate leads to two peaks in the inverse DOS similar to the experimental data in (b), whereas the non-interacting DOS at Fermi level is almost independent of density in this regime. (d) Inverse DOS at the Fermi level of the excitonic metal for different interaction strengths are plotted as a function of carrier density. The fact that the two peak structure disappears at low interaction strength, while the system is insulating at large interaction strength allows a small range of the interaction parameter which is compatible with the existing experimental data. We will use  $u_0 = 10.9$  meV for our calculations unless otherwise stated. (e-h) shows the evolution of the Fermi surfaces of the two exciton bands ( $E^{+(-)}$ ) (green(pink)) in the mBZ with changing densities. For  $0 < n/n_s < +0.06$  the green contours increase while the pink contours shrink. This leads to an increase in the resistivity. At  $n/n_s = 0.10$ , the Fermi level enters a higher miniband of the excitonic state. The additional density of states leads to a decrease in the resistivity, thus giving rise to the peak as a function of density. A similar story plays out on the other side of CNP, leading to the double-peak structure in resistivity.

the center of the electron and hole pockets in tDBLG near CNP naturally leads to excitonic condensates with finite momenta. This leads to the possibility of having either metallic or insulating behaviour depending on the magnitude of the excitonic order in the system and the resulting quasiparticle spectrum  $E_{\mathbf{Q}_i}^{\pm}$ . Note that the original 2-band system is mapped to a 6 band system in the presence of excitonic order.

A simple measure of metallicity of the system is the density of states at the Fermi level,  $g(\epsilon_F) = \sum_{\pm, i, \mathbf{k}} \delta(E_{\mathbf{Q}_i}^{\pm}(\mathbf{k}) - \epsilon_F)$ . For metals we expect  $g(\epsilon_F)$  to be finite, while it should go to 0 for insulators. We now consider how  $g(\epsilon_F)$  behaves with carrier density for different values of  $\Delta$ . These  $\Delta$  values are not obtained from a self-consistent solution of the gap equation; rather our intention is to vary  $\Delta$  and understand the range of values

for which we can recover the metallic behaviour seen in the experiments. For each  $\Delta$ , we solve the number equation to obtain the Fermi level for the excitonic quasiparticles. In Fig. 4(a), we plot  $g^0/g(\epsilon_F)$  as a function of the order parameter  $\Delta$  at CNP. Here  $g^0$  is the density of states at the Fermi level of the non-interacting system at CNP. For  $\Delta > 1.63$  meV the system is insulating in nature and below that it's a metal. Since the experimental data<sup>33</sup> clearly shows metallic behaviour at low temperatures for all densities near CNP, this provides an upper bound for the possible values of  $\Delta$ . Within the mean field theory, this in turn provides an upper bound on the interaction strength  $u_0$ . For  $\Delta_{CNP} < 1.63$  meV, we obtain  $u_0 < 13.6$  meV. In this work, we use a value of  $u_0 = 10.9$  meV which is consistent with earlier work<sup>59</sup>.

In recent experiments, resistance of tDBLG at low tem-

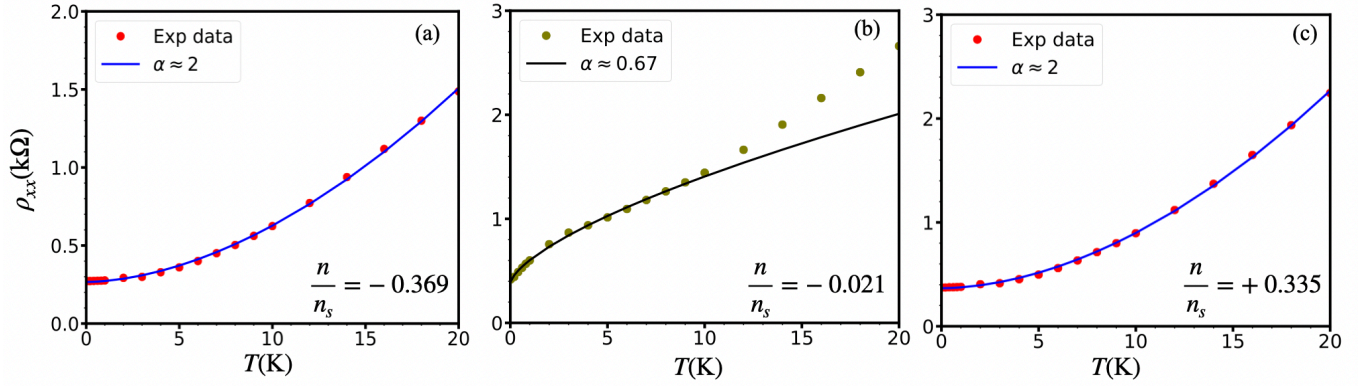

FIG. 5: (a)-(c) shows the experimental data for the temperature dependence of longitudinal resistivity near and away from CNP. Note that the non-interacting Fermi temperature  $T_F \sim 23K$ . In (a) and (c) a fit to the data of the form  $R_0 + A T^\alpha$  gives  $\alpha \sim 2$ , showing Fermi liquid scaling. The data near CNP in (b) clearly shows sublinear behaviour of the resistivity below 10K and an almost linear behaviour above it. Here the data up to 10K is fitted to  $R_0 + A T^\alpha$ , yielding  $\alpha = 0.67$ . This sublinear temperature dependence is a manifestation of an underlying non-Fermi liquid in the system.

peratures have shown a distinct two-peak structure as a function of carrier density near CNP. This is seen in the region where electron and hole pockets are simultaneously present. A representative experimental data is shown in Fig. 4(b). We will use the inverse of the density of states at the Fermi level as a proxy for the resistivity of the system. This assumes that Fermi velocity is not sharply anisotropic in the density range considered, which is valid for tDBLG near CNP with its small electron and hole pockets. In Fig. 4(c), we plot  $g^{-1}(\epsilon_F)$  as a function of carrier density for a system with indirect excitonic condensate ( $u_0 = 10.9$  meV). We clearly see the presence of two peaks, as seen in the experiments. For comparison, we have also plotted  $g^{-1}(\epsilon_F)$  for the non-interacting system, which does not show any structure in the relevant density range. This shows that the presence of excitonic condensate can explain the double peak structure seen in experiments. In Fig. 4(d) we plot  $g^{-1}(\epsilon_F)$  with carrier density for different interaction strengths and see that the two-peak feature is lost for  $u_0 < 10$  meV. This is close to the lower bound obtained from experimental  $T_c$  discussed in the earlier section.

In order to theoretically understand the origin of the two peaks, we look at the dispersion of the 6 bands in presence of the excitonic condensate (detail band dispersion of all 6 bands are plotted in Appendix. B). In Fig. 4(e-h), we plot the Fermi surfaces of the quasiparticles (with spectrum  $E_{\mathbf{Q}_i}^\pm(\mathbf{k})$ ) in the mBZ for four different carrier densities,  $n/n_s = 0, 0.03, 0.06, 0.10$ . At CNP (Fig. 4(e)), we find that both  $E^+$  and  $E^-$  bands pass through the Fermi level, and hence give rise to their respective Fermi surfaces (shown by green and pink lines respectively). This leads to the finite density of states at Fermi energy and hence to metallic behaviour in the system. As we move away from the CNP on the electron doped side, the Fermi surfaces corresponding to  $E^-$  re-

duces, while that of  $E^+$  bands increases in size (Fig. 4(e)-(h)). This leads to a reduction in the density of states at the Fermi level and hence to an increase in resistivity till the  $E^-$  Fermi surface vanishes at  $n/n_s = 0.06$  (Fig. 4(g)), which corresponds to the peak in the inverse density of states. Beyond this point, we see additional Fermi surfaces as the chemical potential enter one of the bands which was gapped at CNP. This leads to a large increase in the density of states at the Fermi level and consequently a sharp decrease in the resistivity, explaining the peak seen in the resistivity for  $n > 0$ . A similar argument, with the roles of  $E^+$  and  $E^-$  reversed, explains the peak for  $n < 0$ . We would like to note that the transport features are expected to be more smeared than single particle features due to the presence of inhomogeneities in the system. This is consistent with the experiments, which see relatively smoother features compared to the theoretical estimates.

## V. TEMPERATURE DEPENDENCE OF RESISTIVITY AND NON-FERMI LIQUID BEHAVIOUR

An intriguing signature of strong electronic correlations is seen in recent experiments<sup>33</sup> on the temperature dependence of resistance of tDBLG near the charge neutrality point. The resistance shows a sublinear ( $R = R_0 + A T^\alpha$  with  $\alpha \approx 2/3$ ) behaviour up to  $T \sim 10$  K, and an almost linear behaviour above that temperature (Fig. 5(b)). In contrast, the temperature dependence of resistance at larger electron (hole) densities, ( $n/n_s = +0.335$ ) and ( $n/n_s = -0.369$ ), are superlinear and can be fitted to the standard quadratic Fermi liquid scaling,  $R = R_0 + A T^\alpha$  with  $\alpha \approx 2$ , expected for a 2d system with small Fermi pockets, both from electron-

electron and electron-phonon scattering. This is shown in Fig 5(a) and (c).

This novel sublinear behaviour cannot be explained within a Fermi liquid paradigm of perturbative effects of electronic interactions around a free Fermi gas. Electron-electron interactions lead to a  $\sim T^2$  dependence of the resistivity. In 2 dimensions, the density of states of longitudinal phonons  $\rho(\omega) \sim \omega$ . This leads to  $\sim T^4$  dependence of resistivity when small angle scattering dominates at low temperatures and  $\sim T^2$  behaviour of resistivity when scattering at all angles contributes. For compensated semi-metals like tDBLG, with small Fermi surfaces, one would expect the resistivity  $\sim T^2$ . At higher temperatures (beyond the Bloch Gruneissen temperature), the scattering from classical phonons would lead to a linear  $T$  dependence of resistivity<sup>60</sup>. None of these mechanisms can explain a sublinear temperature dependence of resistivity, as is seen in the experiments.

In this section, we will show that a tDBLG system near CNP, which is at the precipice of a quantum criticality towards the formation of an excitonic condensate, will show a sublinear  $T^{2/3}$  temperature dependence of resistance. At criticality, the low energy gapless fluctuations of the excitonic (CDW) order parameter would be strongly Landau damped due to the presence of the electronic states of the metal around the Fermi surfaces. The scattering between electrons and the Landau damped fluctuations lead to a non-analytic low energy decay rate for the single particle electronic excitations, resulting in non-Fermi liq-

uid behaviour. For compensated semimetals like tDBLG, with small Fermi surfaces, the transport scattering rate and the quasiparticle scattering rate has the same energy dependence. This non-analytic frequency dependence of the scattering rate leads to the sublinear temperature dependence of resistivity in this system. We note that this mechanism is an alternate to theories of Planckian metal<sup>61</sup>, which predicts linear temperature dependence of resistivity all the way down to  $T = 0$ .

The fluctuations of the order parameter,  $\phi(q, \omega)$  are governed by an action,

$$S_{fl} = \int d^2q \int d\omega \phi^*(q, \omega) \Pi_{inter}^{-1}(q, \omega) \phi(-q, -\omega) \quad (6)$$

where  $\Pi_{inter}$  is the (interacting) inter-band polarizability of the system. When driven to the critical point,  $\Pi_{inter}^{-1}(Q, 0) = 0$ ; i.e. the gap vanishes (this can be seen within a simple RPA like theory), and generically we would have

$$\Pi_{inter}^{-1} \sim \left[ \omega^2 - c^2 \bar{q}^2 - i\gamma \frac{|\omega|}{|\bar{q}|} \right] \quad (7)$$

where  $\bar{q} = q - Q$ ,  $c$  and  $\gamma$  are constants denoting the speed of the fluctuation waves and the scale of damping. The singular  $\frac{|\omega|}{|\bar{q}|}$  damping is a consequence of the presence of low energy fermions, and derives from the imaginary part of the non-interacting inter-band polarizability.

---

The non-interacting interband polarizability of the system is given by

$$\Pi_{inter}^0(q, \omega) = \sum_k \frac{f[\epsilon_c(k)] - f[\epsilon_v(k+q)]}{\omega + i\eta + \epsilon_c(k) - \epsilon_v(k+q)} |\langle \psi_c(k) | \psi_v(k+q) \rangle|^2 + c \leftrightarrow v \quad (8)$$

where  $f$  is the Fermi function and  $|\psi_{c(v)}(k)\rangle$  is the Bloch wavefunction of the corresponding band in the mBZ. To see the Landau damping, in Fig. 6(a), we plot the imaginary part of  $\Pi_{inter}^0$  as a function of  $\omega$  for several values of  $q$  along the  $[1, 0]$  direction. Note that  $Q_1 \sim [0.016, 0]A^{-1}$  is along  $[1, 0]$  direction, so we will be crossing the exciton wave-vector in the process. At low  $\omega$ , the plots are linear and we extract a slope from this linear part of the graph. The slope is plotted as a function of  $q$  in Fig. 6(b). The slope diverges at  $q = Q_1$ , showing the singular nature of the Landau damping. We have checked by taking momentum cuts along other directions passing through  $Q_1$ , that the divergence of the slope happens whenever we approach  $Q_1$  along any direction, i.e. there is no difference in the scaling between directions along and perpendicular to the exciton/CDW wave-vector (see Appendix. A for details).

We can understand this further by constructing a simple model for the valence and conduction band. The electron pocket of the conduction band is modeled by a Dirac dispersion centered around  $k = 0$ , i.e.  $\epsilon_c(k) = v_F|k|$ , while the hole pocket in the valence band is modeled by an inverted Dirac dispersion centered around  $Q$ , i.e.  $\epsilon_v(k) = \epsilon_0 - v_F|k - Q|$  in Fig. 6(c). Here  $\epsilon_0$  is the energy difference between the Dirac points. At CNP, the chemical potential sits at  $\mu = \epsilon_0/2$  giving a Fermi wave vector  $k_F = \mu/v_F$  for electrons and holes. Usually, the orthogonality of the band wavefunctions as

$q \rightarrow 0$  plays an important role in determining the low  $\omega, q$  behaviour of  $\Pi_{inter}^0$  in graphene. However, here we are interested in  $\Pi_{inter}^0$  near  $q = Q$  where orthogonality considerations do not play a role. The band overlaps do not change the scaling of various terms (although they can change the value of the coefficients like  $\gamma$  etc.). Hence we ignore band overlaps in our calculation of  $\Pi_{inter}^0$ . In this case, the polarization function can be calculated exactly and the detailed formulae are given in Appendix A. Near  $Q$ , the imaginary part of  $\Pi_{inter}^0$  has the following form:

$$\begin{aligned}
-\Im \Pi_{inter}^0(q, \omega) &\sim \frac{k_F^3}{4\pi\mu^2} \left| \frac{\epsilon}{\bar{q}} \right|; (\omega < v_F \bar{q} \text{ when } \bar{q} < k_F) \text{ or, } (\omega < \epsilon_0 - v_F \bar{q} \text{ when } \bar{q} > k_F) \\
&\sim \frac{k_F^2}{8\mu} \quad ; \quad \epsilon_0 - v_F \bar{q} > \omega > v_F \bar{q}
\end{aligned} \tag{9}$$

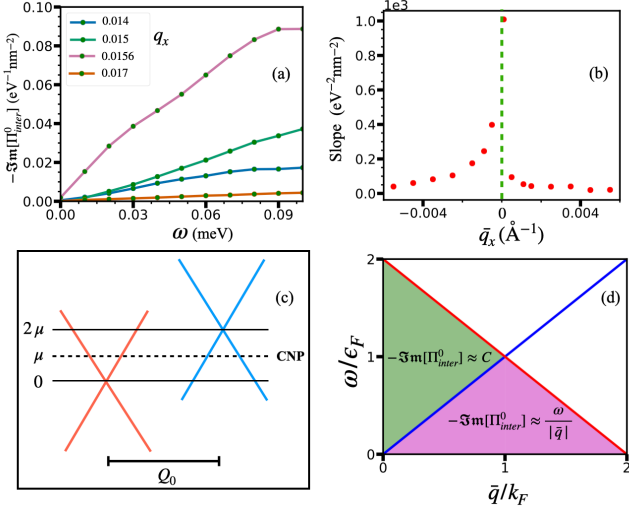

FIG. 6: (a) Imaginary part of the interband polarizability function is plotted with frequency for different  $q_x$  values. Note that the direction of the  $\vec{q}$  variation has been taken along the  $[1, 0]$  direction, and around  $Q_1 \approx (0.016, 0)$ , which is the connecting wavevector between one of the e-h pockets. The low frequency behaviour is linear with the slope showing a huge increase near  $Q_1$ . (b) The slope at different  $q_x$  from (a) is plotted here to show the divergence at  $\vec{q} = Q_1$  (or,  $\bar{q} = 0$ ). (c) A simple theoretical model of the electron and hole pockets for calculating the inter-band polarizability of the system is shown here. The conduction (blue) and valence (red) Dirac bands are separated by  $Q_0$  momentum inverted with respect to each other. The Dirac points are separated in energy by  $\epsilon_0$ . At CNP, the chemical potential  $\mu = \epsilon_0/2$ . (d) Schematic showing the regions in  $\bar{q} - \omega$  plane where the imaginary part of the polarizability of the simple model shows (i) singular Landau damping  $\Im m(\Pi_{inter}^0) \approx \frac{\omega}{|\bar{q}|}$  and (ii) a constant damping rate. The non-Fermi liquid behaviour resulting from the Landau damping leads to the  $T^{2/3}$  dependence of the resistivity.

Thus both the numerical calculation on the full model and the analytic calculation with the simple model shows the presence of the singular Landau damping around  $q \sim Q$ . The Landau damped fluctuations have an energy momentum relation  $\omega \sim \bar{q}^3$ , leading to a density of states  $\rho(\omega) \sim \omega^{-1/3}$ . The scattering of electrons by these

fluctuations lead to a single particle scattering rate

$$\Gamma_{qp} \propto \int_0^\omega d\omega' \rho(\omega') \sim \omega^{2/3}, \text{ at } T = 0 \tag{10}$$

$$\propto \int_0^{\omega_c} d\omega \rho(\omega) \coth\left(\frac{\omega}{2T}\right) \sim T^{2/3}, \text{ at } T \neq 0 \tag{11}$$

where  $\omega_c$  is a cutoff below which the long wave-length description mentioned above holds with the condition  $\omega_c \gg T$ . The damping rate  $\omega^{2/3}$  is larger than the energy of excitations leading to non-Fermi liquid behaviour. Since the Fermi pockets in tDBLG near CNP are small, scattering at all angles contribute to transport and hence the transport scattering rate  $\Gamma_{tr} \sim \Gamma_{qp} \sim T^{2/3}$ . This is the origin of the  $T^{2/3}$  dependence of resistance in the system. Thus the sublinear temperature dependence is a reflection of an underlying non-Fermi liquid state in a quantum critical metal.

Starting with the work of Hertz and Millis,<sup>35,36</sup> non-Fermi liquid behaviour of itinerant quantum critical systems have been studied in the context of high temperature superconductivity<sup>39,40,62</sup>, for the antiferromagnetic metal<sup>38,63,64</sup> and for the nematic transition in metals<sup>34,65</sup> using sophisticated renormalization group techniques. The general conclusion is that the imaginary part of the electron self energy  $\sim \omega^{2/3}$  when the order parameter is at 0 wave vector<sup>34</sup> (as in nematic transition), while we get a  $\sim \omega^{1/2}$  dependence for a finite  $Q$  wave-vector order like spin density waves<sup>42</sup>. We note that in our case the finite wave-vector relates the center of the electron pocket to the center of the hole pocket, so the electron and hole Fermi surfaces lie on top of each other when shifted by this wave vector. Thus, although the CDW is formed at finite wave vector, our itinerant quantum criticality is similar to the nematic case with effective  $q = 0$  and we recover the  $\sim \omega^{2/3}$  scaling.

In the experiments, it is seen that the resistivity shows a linear temperature dependence above  $T = 10K$ . We note that the Fermi temperature corresponding to the e-h pockets is  $T_F \sim 20 - 25K$  and one would expect quantum behaviours to vanish beyond this temperature. For a 2-dimensional system with small Fermi surfaces, a more relevant scale would be the effective ‘‘Bloch Gruneissen’’ temperature of these critical fluctuations, i.e. their energy for  $\bar{q} \sim 2k_F$ . While this requires interaction renormalized estimates of  $\gamma$  and  $c$ , which are beyond the scope of this paper, one would expect this temperature to be lower than  $T_F$ . If we assume that beyond  $T = 10K$ , these fluctuations are classical, we can obtain the linear

temperature dependence of resistivity in this regime.

As we move away from the CNP on either side, the mismatch between the electron and hole Fermi surfaces increases, and the Landau damping would be shifted to finite  $\bar{q} > \Delta k_F$ , where  $\Delta k_F$  is the mismatch of the Fermi wave vectors of the electron and hole pockets. In this case, the low temperature behaviour of resistivity would deviate from the  $T^{2/3}$  scaling. Assuming the  $|\omega/\bar{q}|$  scaling of the Landau damping is cut-off on the scale of  $\Delta k_F$ , i.e. it scales as  $|\omega/\Delta k_F|$ , one would get a linear  $T$  dependence of the resistivity. However, this exponent would be strongly influenced by disorder and Fermi surface anisotropies. In general, one would expect the exponent to increase as one goes away from CNP. Once the simultaneous presence of electron and hole pockets vanish at larger doping, one gets back the standard  $T^2$  scaling of the Fermi liquid theory.

## VI. CONCLUSION

Strong electronic interactions determine the plethora of symmetry broken phases in magic angle tBLG and tTLG. In contrast, tDBLG is usually thought of as a plain vanilla metal in the absence of electric/magnetic fields. The metallicity of magic angle tDBLG near CNP comes from the overlap of flat conduction and valence bands which creates small electron and hole pockets at the Fermi surface.

In this paper, we have considered the possible effects of Coulomb interaction on these small e-h pockets in the compensated semi-metal near CNP. We show that the interactions lead to the formation of indirect excitons (i.e. particle-hole pairs with finite momenta). The condensation of such pairs lead to the formation of CDW states. We show that for a reasonable range of interaction pa-

rameters, this ordered state has reorganised Fermi pockets and hence metallic behaviour is expected. However, the density of electronic states is strongly renormalised in the process. The inverse density of states at Fermi level shows peaks at finite doping on either side of CNP. This can explain the peaks in the resistance as a function of density seen in recent low temperature experiments<sup>33</sup>. We further show that the Landau damped critical fluctuations of the excitonic order can give rise to non-Fermi liquid behaviour of the electrons with a scattering rate,  $\Gamma \sim T^{2/3}$ . For systems like tDBLG, with small Fermi pockets, this can give rise to sub-linear  $T^{2/3}$  resistance seen in recent experiments<sup>33</sup>.

Our theoretical predictions thus strongly indicate that effect of excitonic/CDW order and its fluctuations have already been observed through the non-Fermi liquid temperature dependence of resistivity. A hallmark of CDW insulators is the current produced by sliding mode when the order is depinned by finite energy probes (non-linear/AC conductivity). However, in a metallic system like tDBLG, these contributions would be masked by the usual single particle contributions. We believe the fluctuations of the finite particle-hole condensate should give additional contributions to current noise but we leave this calculation for a future manuscript.

## VII. ACKNOWLEDGEMENT

R.S. would like to thank Mohit Randeria for useful discussions. UG and RS acknowledge computational facilities at the Department of Theoretical Physics, TIFR Mumbai. R.S. acknowledges support of the Department of Atomic Energy, Government of India, under Project Identification No. RTI 4002. UG would like to thank Md. Mursalin Islam for useful discussions related to computational part of the project.

## APPENDIX

### A. INTERBAND POLARIZABILITY AND LANDAU DAMPING

We are interested in the low energy dispersion of valence and conduction bands in tDBLG, especially the modes which constitute the electron and hole pockets near the CNP. For these modes, the energy dispersion can be approximated as two Dirac cones separated in momentum and energy as shown in Fig. 6(c). We use the hole band of the Dirac cone inverted around higher Dirac point and the electron band around lower Dirac point as,

$$\begin{aligned}\epsilon_{\mathbf{k}}^c &= v_F |\mathbf{k}| \\ \epsilon_{\mathbf{k}}^v &= 2\mu - v_F |\mathbf{k} - \mathbf{Q}_0|\end{aligned}\quad (12)$$

Here,  $\epsilon_k^{c(v)}$  is the energy dispersion of conduction(valence) band,  $\mu$  is the chemical potential at CNP,  $v_F$  denotes the Fermi velocity of the effective Dirac points and the momentum separation wavevector between two Dirac cones is given by  $\mathbf{Q}_0$ . Also one can note that exciton order parameter  $\Delta(\mathbf{q}) \sim \sum_{\mathbf{k}} \langle C_{\mathbf{k}}^{c\dagger} C_{\mathbf{k}+\mathbf{q}}^v \rangle$ , so its fluctuations,  $\chi_{\Delta\Delta}(q, t - t') = i\theta(t - t') \sum_{\mathbf{k}\mathbf{k}'} \langle [C_{\mathbf{k}}^{c\dagger}(t) C_{\mathbf{k}+\mathbf{q}}^v(t), C_{\mathbf{k}'}^{v\dagger}(t') C_{\mathbf{k}'-\mathbf{q}}^c(t')] \rangle$  are related to the non-interacting interband polarizability,

$$\Pi_{cv}^0(\mathbf{q}, \omega) = \sum_{\mathbf{k} \in \text{mBZ}} \frac{f(\epsilon_{\mathbf{k}}^c - \mu) - f(\epsilon_{\mathbf{k}+\mathbf{q}}^v - \mu)}{\omega + \epsilon_{\mathbf{k}}^c - \epsilon_{\mathbf{k}+\mathbf{q}}^v} |\langle \psi_{\mathbf{k}}^c | \psi_{\mathbf{k}+\mathbf{q}}^v \rangle|^2 \quad (13)$$

Where the total polarizability  $\Pi_{inter}^0 = \Pi_{cv}^0 + \Pi_{vc}^0$ . Usually the orthogonality of the band wavefunctions as  $q \rightarrow 0$  plays an important role in determining the low  $\omega, q$  behaviour of  $\Pi_{inter}^0$  in Graphene. However, here we are interested in  $\Pi_{inter}^0$  near  $q = Q$  where orthogonality considerations do not play a role. The band overlaps do not change the scaling of various terms. Hence we can drop the term  $|\langle \psi_{\mathbf{k}}^c | \psi_{\mathbf{k}+\mathbf{q}}^v \rangle|^2$  from Eq. 13 and write it as,

$$\Pi_{cv}^0(\mathbf{q}, \omega) \sim \int \frac{d^2\mathbf{k}}{4\pi^2} \frac{f(\epsilon_{\mathbf{k}}^c - \mu)}{\omega + \epsilon_{\mathbf{k}-\bar{\mathbf{q}}}^c + \epsilon_{\mathbf{k}}^c - 2\mu} - \int \frac{d^2\mathbf{k}}{4\pi^2} \frac{1 - f(\epsilon_{\mathbf{k}}^c - \mu)}{\omega + \epsilon_{\mathbf{k}}^c + \epsilon_{\mathbf{k}+\bar{\mathbf{q}}}^c - 2\mu} \quad (14)$$

where  $\bar{\mathbf{q}} = \mathbf{q} - \mathbf{Q}_0$ . Now using dimensionless parameters,  $X = k/k_F$ ,  $Y = \bar{q}/k_F$ , and  $Z = \omega/\mu$ , the Eq. 14 can be rewritten as,

$$\begin{aligned}\Pi_{cv}^0(\mathbf{q}, \omega) \sim & -\frac{k_F^2}{4\pi^2\mu} \left[ -\int_0^1 X dX \int d\phi \frac{1}{Z - 2 + X + \sqrt{X^2 + Y^2 - 2XY \cos \phi}} \right. \\ & \left. + \int_1^\Lambda X dX \int d\phi \frac{1}{Z - 2 + X + \sqrt{X^2 + Y^2 + 2XY \cos \phi}} \right]\end{aligned}$$

Here  $\phi$  is the azimuthal angle between  $\mathbf{k}$  and  $\bar{\mathbf{q}}$ . Here  $\Lambda$  is an ultraviolet cut-off. We note that the Landau damping we calculate is a low energy property, which is independent of  $\Lambda$ . We are interested in the imaginary part of the polarizability,  $\Pi'' \equiv \Im[\Pi_{cv}^0]$ , which then becomes,

$$\begin{aligned}\Pi'' \sim & -\frac{k_F^2}{4\pi\mu} \left[ \int_0^1 X dX \int_{-1}^{+1} \frac{du}{\sqrt{1-u^2}} \delta[Z - 2 + X + \sqrt{X^2 + Y^2 - 2XYu}] \right. \\ & \left. - \int_1^\Lambda X dX \int_{-1}^{+1} \frac{du}{\sqrt{1-u^2}} \delta[Z - 2 + X + \sqrt{X^2 + Y^2 + 2XYu}] \right]\end{aligned}$$

Here  $u = \cos \phi$ . This azimuthal integral can be done analytically to get,

$$\Pi'' \sim -\frac{k_F^2}{4\pi\mu} \left[ \int_0^1 - \int_1^\Lambda \right] X dX \frac{\theta[4X^2Y^2 - (X^2 + Y^2 - (2 - Z - X)^2)^2]}{\sqrt{4X^2Y^2 - (X^2 + Y^2 - (2 - Z - X)^2)^2}}$$

which can also be written as,

$$\Pi'' \sim -\frac{k_F^2}{4\pi\mu} \left[ \int_0^1 - \int_1^\Lambda \right] X dX \frac{\theta[\{(2 - Z)^2 - Y^2\}(X^+ - X)(X - X^-)]}{\sqrt{4\{(2 - Z)^2 - Y^2\}(X^+ - X)(X - X^-)}} \quad (15)$$

where,  $X^\pm = ((2 - Z) \pm Y)/2$ . We will work with  $Y, Z > 0$  and  $Y, Z \ll 1$  so that,  $Z < 2$  and,  $Y < 2 - Z$ . In this case,  $X^+ > X^- > 0$ . Now depending on the value of  $Y, Z$  we can have different regions in the phase space where the integrals take qualitatively different forms,

**Case-(i):**

$0 < Z < 1$  and  $0 < Y < Z$ ,

or,  $1 < Z < 2$  and  $0 < Y < 2 - Z$ ,

$$\begin{aligned} -\Pi'' &\sim \frac{k_F^2 (2 - Z)}{16\mu \sqrt{(2 - Z)^2 - Y^2}} \\ &\approx \frac{k_F^2}{16\mu}; \quad (Y \ll 2 - Z) \end{aligned} \quad (16)$$

**Case-(ii):**

$0 < Z < 1$  and  $Z < Y < 2 - Z$ ,

$$\begin{aligned} -\Pi'' &\sim \frac{k_F^2}{8\pi\mu \sqrt{(2 - Z)^2 - Y^2}} \left[ (2 - Z) \sin^{-1}\left(\frac{Z}{Y}\right) - \sqrt{Y^2 - Z^2} \right] \\ &\approx \frac{k_F^2}{8\pi\mu} \frac{Z}{Y}; \quad (Y \rightarrow 0, Z/Y \rightarrow 0) \\ &\sim \frac{k_F^3}{8\pi\mu^2} \frac{|\omega|}{|\bar{q}|} \end{aligned} \quad (17)$$

Therefore we analytically show the Landau damping factor  $(\frac{|\omega|}{|\bar{q}|})$  arising from imaginary part of the interband polarizability function assuming two simple Dirac bands separated from each other in energy and momentum space. One can easily see that  $\Pi_{vc}^0$  will give the same contribution. Collecting all these,

$$-\Im \Pi_{inter}^0(q, \omega) \sim \frac{k_F^2}{8\mu}; \quad Y < Z < 2 - Y \text{ for } Y < 1 \quad (18)$$

$$\sim \frac{k_F^3}{4\pi\mu^2} \frac{|\omega|}{|\bar{q}|}; \quad (Z < Y \text{ for } Y < 1) \text{ or, } (Z < 2 - Y \text{ for } Y > 1) \quad (19)$$

FIG. 7: In (a), we have shown a schematic of the three  $C_3$  symmetric critical points in the momentum space. Around the  $Q_1$  point, we have taken the  $q$ -cuts of  $\frac{d\Pi''}{d\omega}|_{\omega \rightarrow 0}$  along the directions drawn and plotted them in (b). Notice that  $q$  has been scaled to  $\bar{q} = q - Q_1$ . The slope along all three directions  $[1,0]$ (Blue),  $[1,1]$ (Red) and  $[0,1]$ (Green) show divergence at the critical point and a very small anisotropy on top of the isotropic background. One thing to note is for this figure (b) we have used a different set of parameters (momentum grid  $350 \times 350$  and broadening  $\eta = 0.05 \text{ meV}$ ) than for Fig. 6(b) where we used (momentum grid  $800 \times 800$  and broadening  $\eta = 0.02 \text{ meV}$ ). That is the reason the divergence scale of the slopes are a different for these two figures which is expected.

As shown in the main text, the numerical evaluation of  $\Pi''$  using the actual tDBLG dispersion and wavefunctions also give rise to similar singular damping. In the main text, we looked at  $\frac{d\Pi''(q,\omega)}{d\omega}|_{\omega \rightarrow 0}$  as a function of  $q$ . Here in Fig. 7 (b), we additionally plot the slope  $\frac{d\Pi''}{d\omega}|_{\omega \rightarrow 0}$  along a cut in  $q$  which passes through  $Q_0$  and moves along  $[0,1]$ ( $90^\circ$ ) and  $[1,1]$ ( $45^\circ$ ) directions (the directions are schematically shown in Fig. 7(a)). We see that the slope diverges at  $Q_0$  irrespective of the direction in which it is approached. Thus the Landau damping has only small anisotropies riding on an isotropic background, even though the Fermi velocities at the Dirac points are anisotropic. This isotropy is important for scaling arguments used to explain  $T^{2/3}$  resistivity.

## B. BAND RENORMALIZATION DUE TO EXCITON FORMATION

In the main text, we had shown that the presence of excitonic order leads to formation of 6 minibands out of the original tDBLG dispersion. Here, we present the detailed dispersion of these 6 bands and how they change with density around CNP in Fig. 8-10. In Fig. 8, we plot the dispersion of the 6 bands (3 conduction bands in top row and 3 valence bands in bottom row) at CNP as a color plot. The electron and hole Fermi surfaces are shown as solid lines. Note that the dispersion of the bands are not  $C_3$  symmetric for individual  $Q_i$ 's. The e-h pocket that is coupled by the excitonic order is gapped out. Fig. 9 plots the same dispersion at  $n/n_s = 0.06$ . One can see that the electron pockets have grown while the hole pockets have shrunk to zero. Finally, the Fig. 10 plots the dispersion at  $n/n_s = 0.10$ . The hole pockets from the valence band have vanished and electron pockets are still present. But additional electron pockets appear in the conduction band. The extra density of states from these new pockets lead to a suppression of resistivity giving rise to the two-peak structure in the resistivity vs density data<sup>33</sup>.

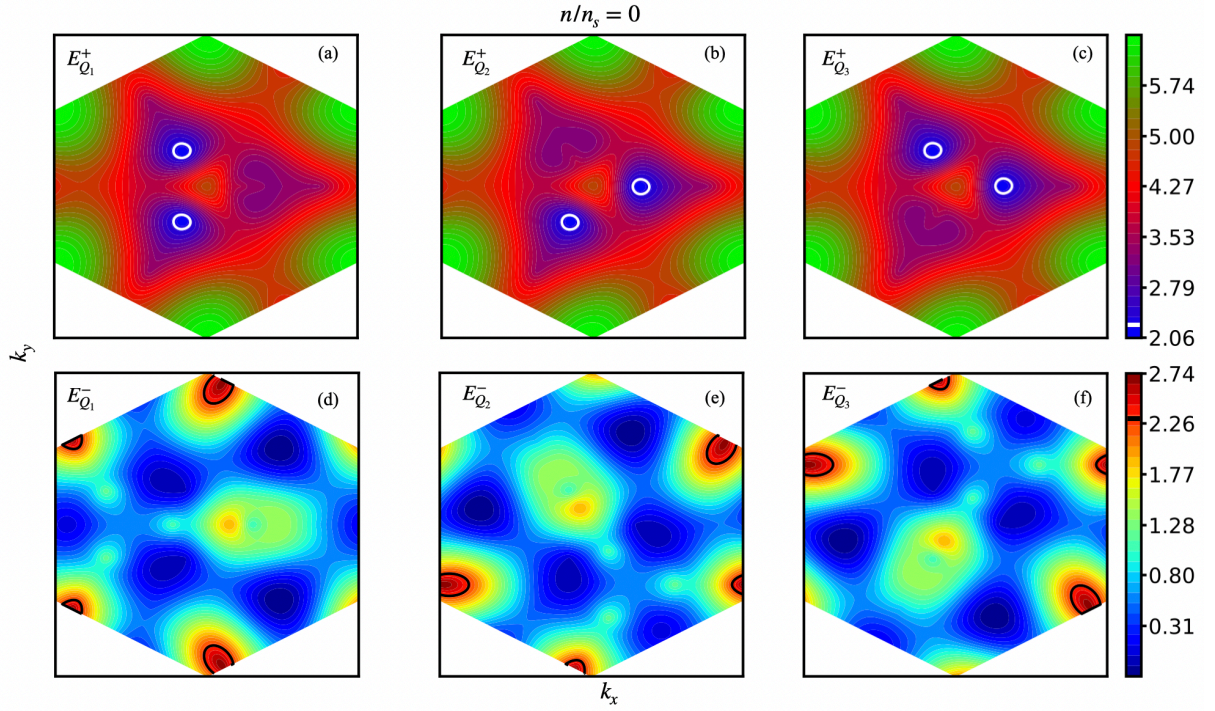

FIG. 8: In (a)-(c) we show color plots of the renormalized conduction bands due to the presence of excitonic order parameters for the three e-h pocket connecting wave-vectors  $Q_{1(2)(3)}$  respectively at CNP. We plot the renormalized valence bands at CNP in (d)-(f). The solid lines represent the Fermi surface at CNP. Here both the electron and hole pockets contribute to the resistivity of the system.

FIG. 9: Similar to Fig. 8 here we have plotted the exciton bands for density  $n/n_s = 0.06$ . One can notice that the hole pockets have vanished which explains the suppression of density of states which leads to increase in the resistivity.

FIG. 10: Similar to Fig. 8 here we have plotted the exciton bands for density  $n/n_s = 0.10$ . Here one can notice that extra electron pockets have emerged from higher bands which causes the increment of density of states that leads to decrease in the resistivity. The Fig. 8-10 thus explains the double-peak feature seen in the recent experiments<sup>33</sup>
