Abstract

The whole Al-Li phase diagram is predicted from first principles calculations and statistical mechanics including the effect of configurational and vibrational entropy. The formation enthalpy of different configurations at different temperatures was accurately predicted by means of cluster expansions that were fitted from first principles calculations. The vibrational entropic contribution of each configuration was determined from the bond length vs. bond stiffness relationships for each type of bond and the Gibbs free energy of the different phases was obtained as a function of temperature from Monte Carlo simulations. The predicted phase diagram was in excellent agreement with the currently accepted experimental one in terms of the stable (AlLi, Al₂Li₃, AlLi₂, Al₄Li₉) and metastable (Al₃Li) phases, of the phase boundaries between them and of the maximum stability temperature of line compounds. In addition, it provided accurate information about the gap between Al₃Li and AlLi solvus lines. Finally, the influence of the vibrational entropy on the correct prediction of the phase diagram is discussed. Overall, the methodology shows that accurate phase diagrams of alloys of technological interest can be predicted from first principles calculations. Keywords: Al-Li alloys; prediction of phase diagrams; lattice vibration; first principles calculations; cluster expansion.

Computational Materials Science. Accepted for publication October 2022

1. Introduction

Equilibrium phase diagrams are at the core of current strategies to design new materials with particular microstructures or to optimize existing ones through integrated computational material engineering [1]. The phase diagram provides the information about the stable phases for a given composition at a given temperature and pressure, and is one of the keystones to establish the processing-properties-structure paradigm of materials science [2].

So far, the determination of phase diagrams has been achieved through the CALPHAD (CALculation of PHAse Diagrams) methodology [3]. This strategy begins by collecting experimental information on phase equilibria and thermochemical properties of a given system, and uses appropriate mathematical models with adjustable parameters to obtain the Gibbs free energy of the different phases. This information is used to determine the stable phases as a function of composition, temperature and pressure. Notwithstanding the huge success of the CALPHAD methodology, the the predicted phase diagrams are not always as precise as required [4,5]. In particular, the limitations imposed by kinetics and metastability to experimentally determine thermodynamics and thermochemical parameters as well as the inherent approximations of the CALPHAD methodology hinder the accuracy.

Another approach to determine the phase diagram is through the combination of first principles calculations and statistical mechanics [6]. First principles calculations based on density functional theory (DFT) can be used to obtain the mixing enthalpies of different atomic configurations (possible arrangements of chemical species on a crystal lattice) at 0 K. The configurations on the convex hull in the enthalpy-composition space are ground state phases at 0 K but other configurations above the convex hull may appear at higher temperatures due to thermal fluctuations [7]. The thermodynamic properties of each phase at high temperature depends on all possible microstates but it is not feasible to determine the energies of all possible microstates by first principles calculation [8]. This limitation can be overcome by the construction of cluster expansion (CE) Hamiltonians [9,10]. The CE expresses the energy of a given

configuration as a linear combination of atomic clusters multiplied by the corresponding cluster interaction coefficients, that are fitted from the mixing enthalpies obtained by DFT for a (sufficiently) large number of configurations. Thus, the mixing enthalpies of many different microstates can be accurately and efficiently predicted using the CE formalism and the free energies of different configurations (including the entropic contribution due to the configurational disorder) can be obtained as a function of temperature from Monte Carlo simulations using the principles of statistical mechanics. This information enables the parameter-free prediction of the phase diagram [11,12].

One limitation of this strategy to determine the phase diagrams is that requires previous knowledge of the crystal lattices which leads to phases in the convex hull because it is not possible to fit CE Hamiltonians for an unlimited number of lattices. This information is normally obtained from previous experimental data. In addition, the accurate prediction of the phase diagram also demands to account for the contribution of vibrational disorder - on top of the configurational one - to the free energy [13,14]. Even though the vibrational entropy contribution is normally much smaller than the configurational one, it cannot be ignored in many cases to make accurate predictions of the stable phases as a function of temperature, the phase boundaries or the solubility [15-18]. A typical example is the stability of θ and θ' phases in the Al-Cu phase diagram. Both phases have the same stoichiometry (Al₂Cu) but different lattices. θ' is in the convex hull and remains the stable phase up to 550K, but becomes metastable (and θ becomes the stable phase) at higher temperature due to the contribution of the vibrational disorder to the free energy [9], and the solvus line of θ' also changes accordingly.

The standard strategy to account for the vibrational entropy contribution to the free energy is based in the quasi-harmonic approximation [19]. Within this framework, the thermal properties of solid materials are traced back to those of a system of noninteracting phonons whose frequencies are, however, allowed to depend on volume or on other thermodynamic constraints. Thus, phonon calculations have to be carried out to determine the force constant matrix of each atom, which reflects the energy response from lattice vibration at each temperature [19]. Unfortunately, phonon calculations are very expensive computationally [20,21], and it is not possible to conduct phonon calculations for all possible microstates. This effort can be, however, dramatically reduced in systems with simple lattices because the force constant matrix can be transferred among different configurations and the stretching and bending stiffness of the different bonds can be accurately approximated through a bond length *vs.* bond stiffness relationship (thereafter denominated L-S relationship) in the force constant matrix [22-26]. Thus, the L-S relationship is determined for several configurations by comparison with full phonon calculations, and it is used to predict the force constant matrix of atoms in other configurations with the same lattice structure with minimum computational effort. This methodology has been successfully used to calculate the vibrational entropy contribution to the free energy of different intermetallic compounds [22-24] but - to the authors' knowledge - it has never been used to predict the whole phase diagram including several phases.

In this investigation, the Al-Li phase diagram is predicted by first principles calculations and statistical mechanics principles including the effect of vibrational entropy. To this end, the L-S relationships of nearest-neighbor bonds in the Al-Li system were obtained from several ordered configurations, and the accuracy of this approach to calculate the phonon density of states was proven by comparison with the full phonon calculations. Then, the formation enthalpies of many configurations were determined using first principles calculations and the vibrational free energy of each configuration was included using the L-S relationship. Temperature-dependent CEs were fitted taking into account the formation enthalpy and vibrational free energy of each configuration, and they were used to predict the free energies of the different phases. The whole Al-Li phase diagram was predicted from this information and compared with the currently established phase diagram [27,28]. In addition, the effect of vibrational entropy was assessed by comparison with our previous predictions of the Al-Li phase diagram without this contribution [29].

2. Methodology

2.1. Bond length vs. bond stiffness relationship

In Al-Li system, the stable phases share an either fcc-based or bcc-based ordered structure. Thus, Al (space group $Fm\overline{3}m$) and Al₃Li (space group $Pm\overline{3}m$) are ordered structures on the fcc lattice, while the AlLi (space group $Fd\overline{3}m$), Al₂Li₃ (space group $R\bar{3}m$), AlLi₂ (space group *Cmcm*), Al₄Li₉ (space group C2/m) and Li (space group $Im\bar{3}m$) are ordered structures on the bcc lattice. The L-S relationship is related to the lattice symmetry [30] and only face-centered cubic (fcc) and body-centered cubic (bcc) lattices need to be considered because all phases in the Al-Li system are either fcc or bcc. Four ordered configurations were used to determine the L-S relationship for the fcc lattice and only three for the bcc lattice. The structures of the selected configurations were fully relaxed at P=0 using first principles calculations with Quantum Espresso [31]. The electron exchange-correlation was described using the generalized gradient approximation with the Perdew-Burke-Ernzerhof exchange-correlation functional and ultrasoft pseudo potentials [32]. The cut-off energy for the plane waves was 114 Ry. The Monkhorst-Pack scheme [33] was used for k-point sampling with a density of 40 points/Å⁻¹. They were compressed and expanded up to 10% in volume to create cells with different bond lengths. For each volume, a supercell of 12×12×12 unit cells was used and a displacement of 0.2 Å was applied for each symmetrically different atom in the unit cell.

The force constant matrix, $\Psi_{i\alpha,j\beta}$ (where *i* and *j* stands for the atoms and α and β for the Cartesian directions) can be calculated from the forces on atom *j*, $F_{j\beta}$ due to the $u_{i\alpha}$ displacement of atom *i* in direction α from full phonon calculations based on supercells according to [34],

$$\Psi_{i\alpha,j\beta} = \frac{\partial F_{j\beta}}{\partial u_{i\alpha}} = \frac{\partial^2 E}{\partial u_{i\alpha} \partial u_{j\beta}} \tag{1}$$

where *E* is the energy of the perturbed supercell. $\Psi_{i\alpha,j\beta}$ between symmetrically different pairs of atoms *i* and *j* can be expressed as $\Psi(i, j)$, and is usually simplified as

a diagonal matrix with only two independent stiffness terms, namely the stretching stiffness (s) and the bending stiffness (b) [35, 36], according to

$$\Psi(i,j) = \begin{pmatrix} b & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & s \end{pmatrix}$$
(2)

A L-S relationship for each type of bonding interaction (either Al-Al, Li- Li or Al-Li) was fitted from the values *b* and *s* obtained for each lattice deformed in tension and compression up to 10%.

2.2. Vibrational free energy

Following the quasi-harmonic approximation, the vibrational free energy of a configuration is determined by Born-von Karman model according to [37]

$$F_{vib}(V,T) = E(V) - TS_{vib}(V,T)$$
(3)

where E(V) is the volume-dependent energy of the configuration, *T* the absolute temperature and $S_{vib}(V,T)$ the vibrational entropy. E(V) and $S_{vib}(V,T)$ at a given volume can be expressed as [38, 39]

$$E(V) = \int \hbar \omega \, n(\omega) \left[\frac{1}{2} + \frac{\vartheta}{1+\vartheta} \right] d\omega \tag{4}$$

$$S_{vib}(V,T) = -k_B \int \frac{n(\omega)}{1-\vartheta} [\vartheta \log(\vartheta) + (1-\vartheta)\log(\vartheta)] \, d\omega$$
(5)

where \hbar is the reduced Planck's constant, k_B the Boltzmann constant, $\vartheta = e^{-\hbar\omega/k_BT}$ and $n(\omega)$ represents the phonon density of states (DOS), which is defined as the total number of modes with frequencies between ω and $\omega + d\omega$ per unit volume. For each configuration, the phonon DOS is determined from the dynamical matrix $D_{i,j}(q)$ which is obtained by means of the Fourier transform of $\Psi(i, j)$ at wavevector q from which the eigenfrequencies ω are computed. After all eigenfrequencies are computed, the phonon DOS is calculated [9].

The $\Psi(i, j)$ matrix can be obtained either from the full phonon calculation (as indicated in section 2.1) or through the L-S relationship as long as the equilibrium bond lengths are available. To this end, 154 different configurations in the fcc lattice and 489

configurations in the bcc lattice were generated. They were fully relaxed at P=0 using Quantum Espresso with the same parameters used for the ordered configurations above. The lattice distortion of each configuration after relaxation was determined to assess whether the lattice symmetry changed. Following the criteria reported in the literature [40,41], only configurations whose distortion was below 10% were considered to keep the original lattice symmetry and used to fit the CE for each lattice [29]. In fact, 18 configurations of the fcc system and 297 configurations of the bcc system changed the original lattice during relaxation and they were no longer considered. The equilibrium bond lengths were obtained for each stable configuration and the $\Psi(i, j)$ matrices in each configuration were predicted through the L-S relationship. This information was used to determine $F_{vib}(V, T)$ for each configuration through eqs. (3) to (5).

2.3. Temperature dependent cluster expansion

The temperature-dependent mixing enthalpy H^{mix} of a configuration with composition $Al_{1-x}Li_x$ - including the vibrational entropy contribution - can be expressed as [42]

$$H_{Al_{1-x}Li_{x}}^{mix}(T) = F_{vib}^{Al_{1-x}Li_{x}}(T) - (1-x)F_{vib,s}^{Al}(T) - xF_{vib,s}^{Li}(T)$$
(6)

where $F_{vib,s}^{Al}(T)$ and $F_{vib,s}^{Li}(T)$ stand for the vibrational free energy of pure Al and Li in the corresponding lattice at temperature *T*. It should be noted that the mixing enthalpy given by eq. (6) will be used to fit the CE but it does not correspond to the actual formation enthalpy, H^f , that is expressed as

$$H^{f}_{Al_{1-x}Li_{x}}(T) = F^{Al_{1-x}Li_{x}}_{vib}(T) - (1-x)F^{Al}_{vib}(T) - xF^{Li}_{vib}(T)$$
(7)

where $F_{vib}^{Al}(T)$ and $F_{vib}^{Li}(T)$ stand for vibrational free energy of pure Al and Li in their equilibrium structure, namely fcc Al and bcc Li.

The temperature-dependent CE formalisms for the fcc and bcc lattices can be fitted from the temperature-dependent mixing enthalpies of the configurations in fcc and bcc lattices, respectively. They are expressed as [43, 44]

$$H^{mix}(\vec{\sigma},T) = \sum_{\alpha} m_{\alpha} J_{\alpha}(T) \langle \varphi(\vec{\sigma}) \rangle_{\alpha}$$
(8)

where the summation index stands for all distinct clusters α under symmetry operation. m_{α} stands for the multiplicity of clusters α and $J_{\alpha}(T)$ is the effective cluster interaction (ECI) coefficient of each cluster at temperature T. $\langle \varphi(\vec{\sigma}) \rangle_{\alpha}$ is the cluster function of α defined as a product of orthogonal point functions, and $\vec{\sigma}$ is vector that indicates which type of atom sits on lattice site *i*, i.e. $\sigma_i = -1$ when the lattice site *i* is occupied by an Al atom and $\sigma_i = +1$ when the lattice site *i* is occupied by a Li atom. The number of clusters and the ECI coefficients for both fcc and bcc lattices were fitted using the ATAT package [45]. It should be noted that the mixing enthalpies provided by the CE formalism can used to predict actual formation enthalpy of any configuration including the vibrational entropy contribution.

2.4. Phase diagram construction

The grand canonical free energy \emptyset is defined as [46]

$$\beta \phi(\beta, \Delta \mu) = -\ln Z \tag{9}$$

where $\beta = \frac{1}{k_B T}$ is the reciprocal of temperature, $\Delta \mu$ represents the difference in chemical potential between the Al and Li and the partition function *Z* is calculated as [47]

$$Z = \sum_{i} exp \left(-\beta N \left(H_{i}^{f} - \Delta \mu x \right) \right)$$
⁽¹⁰⁾

where N is the number of atoms in the crystal lattice, H_i^f formation enthalpy of each possible microstate *i* and *x* the atomic fraction of Li in the configuration.

From eqs. (9) and (10), the grand potential \emptyset for each phase can be written as

$$d(\beta \phi) = N(\langle H^f \rangle - \Delta \mu x) d\beta - N\beta x \, d(\Delta \mu) \tag{11}$$

where $\langle H^f \rangle$ stands for the average formation enthalpy per atom. The partition function Z was evaluated by means of semi-grand canonical MC simulations for different values

of *T* and $\Delta \mu$ according to eq. (10) and then \emptyset can be calculated through thermodynamic integration. For a given $\Delta \mu$, \emptyset is given as [48]

$$\emptyset(\beta_1, \Delta \mu) = \emptyset(\beta_0, \Delta \mu) + \frac{N}{\beta} \int_{\beta_0}^{\beta_1} (H^f - \Delta \mu x) \, d\beta \tag{12}$$

and as

$$\emptyset(\beta, \Delta\mu_1) = \emptyset(\beta, \Delta\mu_0) - N \int_{\Delta\mu_0}^{\Delta\mu_1} x \, d\Delta\mu$$
 (13)

for a given β , where β_0 , $\Delta \mu_0$ and β_1 and $\Delta \mu_1$ stand for the range of temperatures and chemical potentials explored in the MC simulations.

In the case of solid-state transformations at atmospheric pressure, the difference between Gibbs and Helmholtz free energies can be neglected and the Gibbs free energy G is expressed as [47]

$$G = \emptyset - \Delta \mu x \tag{14}$$

The semi-grand canonical MC simulations [49] of fcc and bcc Al-Li systems were carried out using ATAT package in periodic supercells of dimensions $20 \times 20 \times 20$ primitive unit cells. The temperature range varied from 10 K to 1000 K with a temperature increment of 10 K for each chemical potential. At each temperature, MC simulations were carried out from the ground state phases with increasing and decreasing $\Delta\mu$ with an increment of 0.005 eV/atom in the chemical potential. For each value of *T* and $\Delta\mu$, a MC simulation included 2000 passes for equilibrium, followed by 5000 passes for calculating the thermodynamic averages. For two adjacent phases with the same lattice structure, the two-phase equilibrium region in the phase diagram can be determined by the intersection of \emptyset obtained from increasing and decreasing $\Delta\mu$. For two adjacent phases with different lattice structures, the two-phase equilibrium region in the phase diagram can be determined by the common tangent of their Gibbs free energies curves at a given temperature.

3. Results

3.1. Bond length vs. bond stiffness relationship

There are three types of chemical bonds between different atomic species in Al-Li alloys, namely Al-Al, Li-Li and Al-Li bonds. Their L-S relationships in the fcc lattice were obtained from the ordered Al, Al₃Li, AlLi and Li compounds, whose structures are shown in Fig. 1. The first-nearest neighbor bonds in fcc Al and fcc Li (Figs. 1(a) and (d)) are Al-Al and Li-Li and their equilibrium bond lengths are 2.837 Å and 3.05 Å, respectively. The first-nearest neighbor bonds in fcc Al₃Li (Fig. 1(b)) are Al-Al and Al-Li with the same equilibrium bond length of 2.828 Å. Finally, the first-nearest neighbor bonds in fcc Al₄Li (2.820 Å) and Al-Li (2.839 Å). They were also used to fit the L-S relationships to ensure that they are transferable.

Fig. 1. Crystal structures of ordered Al-Li configurations with fcc lattice. (a) Al; (b) Al₃Li; (c) AlLi; (d) Li. The first nearest-neighbor bonds are indicated with red lines.

The force constant matrix of the three types of bonds in the ordered fcc Al-Li configurations with different volumes were determined from full phonon calculations and the corresponding L-S relationships. The stretching and bending stiffnesses of each bond are depicted in Fig. 2. The stretching stiffness decreases dramatically with bond length in the three bonds, while the bending stiffness increases slightly. The stretching and bending stiffness terms for the three types of bonds (Al-AL, Al-Li and Li-Li) are

very close, regardless of the ordered configuration, and this result indicates that the force constant matrix is transferable for different configurations with the same lattice. The L-S relationships of stretching and bending stiffness for each type of bond were fitted by quadratic polynomials using the least-squares method and they are plotted as solid lines in Fig. 2. They can be used to predict the force constant matrix of configurations with many atoms arranged in a fcc lattice.

Fig. 2. Bond stiffness *vs.* bond length relationships fitted from ordered fcc Al-Li configurations. The symbols stand for the results obtained from full phonon calculations according to eq. (1). The solid lines are the fitted polynomials. (a) Al-Al bond; (b) Li-Li bond; (c) Al-Li bond. *s* stands for the stretching stiffness and *b* for the bending stiffness.

The Al, AlLi and Li ordered configurations, whose structures are displayed in Fig. 3, were used to determine the L-S relationships in the bcc lattice. The first-nearest neighbor bonds in bcc Al and Li are Al-Al and Li-Li (Figs. 3(a) and (c)) and their equilibrium bond lengths are 2.778 Å and 2.968 Å, respectively. The first-nearest neighbor bonds in bcc AlLi (Fig. 1(b)) are Al-Al, Al-Li and Li-Li with the same equilibrium bond length of 2.736 Å in all cases.

Fig. 3. Crystal structure of ordered Al-Li configurations with bcc lattice. (a) Al; (b) AlLi; (c) Li. The first nearest-neighbor bonds are indicated with red lines.

The force constant matrix of the three types of bonds in the ordered bcc Al-Li configurations with different volumes were determined from full phonon calculations. The corresponding L-S relationships are depicted in Fig. 4. The stretching and bending stiffnesses in the three bonds follow the same trends found previously in the fcc ordered configurations (Fig. 2). The L-S relationships of stretching and bending stiffness for each type of bond were fitted into quadratic polynomials using the least-squares method and they are plotted as solid lines in Fig. 4. They were used to predict the force constant matrix of configurations with the bcc lattice.

Fig. 4. Bond stiffness *vs.* bond length relationships fitted from ordered bcc Al-Li configurations. The symbols stand for the results obtained from full phonon calculations according to eq. (1). The solid lines are the fitted polynomials. (a) Al-Al bond; (b) Li-Li bond; (c) Al-Li bond. *s* stands for the stretching stiffness and *b* for the bending stiffness.

3.2. Vibrational free energy

The accuracy of the L-S relationship to obtain the phonon DOS and the vibrational entropy contribution to the Gibbs free energy can be assessed by comparison with the results obtained from full phonon calculations for the most relevant phases in the Al-Li system. The vibrational free energies, F_{vib} , of Al, Al₃Li, AlLi, Al₂Li₃, Al₄Li₉ and Li calculated using both approaches are plotted as a function of temperature in Figs. 5(a) to 5(f), and the corresponding phonon DOS are inserted in each figure. The red curves stand for the results obtained from full phonon calculations while the black curves indicate the vibrational free energy and phonon DOS predicted with the L-S relationships. The phonon DOS predicted with the L-S relationships are consistent with those obtained from full phonon calculations for all the different intermetallic compounds with fcc and bcc lattices. As a result, the vibrational entropic contribution -

that is obtained by the integration of the phonon DOS through eq. (5) - obtained with the L-S relationships is very close to the actual one determined from the full phonon calculations. The small differences are similar for all phases and are not significant from the viewpoint of accuracy in the formation enthalpy.

Fig. 5. Vibrational free energy of phases in Al-Li system determined by full phonon calculations and predicted with the L-S relationships. (a) Al; (b) Al₃Li; (c) AlLi; (d) Al₂Li₃; (e) Al₄Li₉; (f) Li.

3.3. Temperature-dependent cluster expansions and ground state phases

Temperature-dependent CEs for fcc and bcc Al-Li systems were fitted and the ECI coefficients as well as the cluster features are listed in Tables S1 and S2 in the Supplementary Materials. The formation enthalpies, H^f , of different configurations determined from the combination of first principles calculations and the L-S relationships and predicted with the CEs are compared in Fig. 6 for three different temperatures: 0 K, 500 K and 1000 K. The red crosses and open symbols stand for the bcc configurations calculated using both strategies while the blue crosses and open symbols provide the same information for the fcc configurations. The formation enthalpies at other temperatures are plotted in Fig. S1 in the Supplementary Materials. The H^f predicted with the CE formalism are in good agreement with those obtained from first principles calculations and the L-S relationships. The cross-validation scores for the fcc and bcc configurations were 0.0067 eV/atom and 0.0148 eV/atom, respectively.

Fig. 6. Formation enthalpies H^f of different configurations in the Al-Li system at different temperatures. (a) 0 K; (b) 500K; (c) 1000K. Crosses stand for the enthalpies calculated using first principles calculations and the L-S relationships while open symbols provide the results given by the CE formalism. Red symbols stand for bcc configurations and blue symbols for fcc.

The ground state phases located on the convex hull at 0 K can be found in Fig. 6a. They are Al, Al₃Li (δ '), AlLi (δ), Al₂Li₃, AlLi₂, Al₄Li₉ and Li. Al and Al₃Li (δ ') have fcc structures while the others are bcc. At higher temperature, H^f provides information about the stability of the phases including the contribution from vibrational entropy and the same phases are found in convex hull at 500 K (Fig. 6(b)) and 1000 K (Fig 6(c)). Al₃Li (δ ') is located almost on the tie-line connecting Al and AlLi (δ) at 0K, and its formation enthalpy is only 4.17 meV/atom lower than that of the straight line connecting Al and AlLi, which is the same order of the accuracy in first principles calculations. Thus, it is difficult to establish whether Al₃Li (δ ') is ground state phase at 0 K. Nevertheless, the formation enthalpy of Al₃Li (δ ') with respect to the straight line connecting Al and AlLi is slightly increased with temperature up to 6.172 meV/atom at 500 K (Fig. 6(b)), and to 10.942 meV/atom at 1000 K (Fig. 6(c)).

3.4. Phase diagram

3.4.1. Al/Al₃Li phase boundary

The semi-grand canonical MC calculations were performed from each ground state phase in the direction of both increasing and decreasing $\Delta\mu$. In the Al-rich part, Al and Al₃Li are the two ground state phases which share the same fcc lattice (Fig. 6). Their phase boundaries can be determined by the grand potential \emptyset , which was obtained by thermodynamic integration from $\Delta\mu$ and T, as indicated in Section 2.4.

The grand potentials \emptyset are plotted as a function of $\Delta \mu$ at T=500 K in Fig. 7(a) as an example. The black curve is calculated from Al by increasing $\Delta \mu$, while the red one is calculated from Al₃Li by decreasing $\Delta \mu$. The intersection $\emptyset_{Al} = \emptyset_{\delta'}$ corresponds to $\Delta \mu$ where Al and δ' coexist. On the left of the intersection, $\emptyset_{Al} < \emptyset_{\delta'}$, which indicates that Al is the stable phase in this $\Delta \mu$ range, while $\emptyset_{\delta'} < \emptyset_{Al}$ on the right of the intersection, and Al₃Li is the stable phase. The two-phase equilibrium region of Al and Al₃Li, expressed by $\emptyset_{Al} = \emptyset_{\delta'}$, can be mapped on to the conjugated relationship between composition *x* and chemical potential $\Delta \mu$, as shown in Fig. 7(b), from which the composition of Al and Al₃Li at equilibrium can be determined. Thus, the phase boundary between Al and Al₃Li at 500K can be constructed and is marked by the dashed line in Fig. 7(c). Following the same methodology, the phase boundary between Al and Al₃Li can be determined as a function of temperature and the phase diagram in this region is constructed, as shown in Fig. 7(c). The two-phase equilibrium region of Al and Al₃Li exists up to T = 680 K. The $\emptyset - \Delta \mu$ and $x - \Delta \mu$ curves obtained by increasing $\Delta \mu$ and decreasing $\Delta \mu$ overlap when the temperature is higher than 680 K, which means Al and Al₃Li cannot be distinguished from a thermodynamic viewpoint.

Fig. 7. (a) Grand potentials \emptyset of Al and Al₃Li as a function of chemical potential $\Delta \mu$ at 500 K. (b) Li content (expressed by *x*) as a function of $\Delta \mu$ at 500 K. (c) Phase boundary between Al and Al₃Li.

3.4.2. Al₃Li/AlLi phase boundary

The other adjacent phase to Al₃Li is AlLi (Fig. 6), which has a bcc lattice structure. Therefore, the phase boundary between AlLi and either Al or Al₃Li can only be determined by the common tangent to their Gibbs free energy *G*, which were calculated by according to eq. (14). Since the Gibbs free energy of Al₃Li is almost on the tie-line connecting Al and AlLi at 0 K (Fig. 6(a)), it is difficult to establish whether Al₃Li (δ ') is ground state phase at 0 K, and the Gibbs free energy of Al₃Li is also compared. The dash lines in Fig. 8(a) stand for the common tangent to the Gibbs free energies of Al and AlLi at each temperature, and they indicate the chemical potential at equilibrium between Al and AlLi. The Gibbs free energies of Al₃Li are always above the common tangent to the Gibbs free energies of Al and AlLi at each temperature, and they indicate the chemical potential at equilibrium between Al and AlLi. The Gibbs free energies of Al₃Li are always above the common tangent to the Gibbs free energies of Al and AlLi at each temperature, and this result indicates the Al₃Li is a metastable phase, mainly due to the configurational entropic contribution to the free energy because the vibrational entropic contribution enhanced the stability of Al₃Li.

Fig. 8 (a) Gibbs free energy of Al, Al₃Li and AlLi phases as a function of the Li content (expressed by x) at different temperatures; (b) Phase boundary between Al and AlLi.

The composition of Al and AlLi at equilibrium can be obtained for each temperature from the common tangent at the Gibbs free energy curves, and the phase boundary between them is constructed (Fig. 8(b)). The two-phase equilibrium region of Al and AlLi exist up to T = 850 K, in good agreement with experimental results [27, 28]. The Gibbs free energies of Al and AlLi overlap at T > 850 K (Fig. 8(a)), and they become solid solutions above this temperature.

3.4.3. AlLi/Al₂Li₃ and Al₂Li₃/AlLi₂ phase boundaries

AlLi and Al₂Li₃ share the bcc lattice structure, and their phase boundary was determined from the thermodynamic grand potentials \emptyset , as in the case of Al and Al₃Li. Their grand potentials are plotted as a function of $\Delta \mu$ at T = 600 K in Fig. 9(a) as another example. The black curve is obtained from AlLi by increasing $\Delta \mu$, while the red one is obtained from Al₂Li₃ by decreasing $\Delta \mu$. On the left of the intersection, $\emptyset_{AlLi} < \emptyset_{Al_2Li_3}$, which indicates the Al₂Li₃ is the stable phase in this $\Delta \mu$ range, while $\emptyset_{AlLi} > \emptyset_{Al_2Li_3}$ on the right of the intersection, and Al₂Li₃ is the stable phase. The intersection of the grand potentials can be mapped on to the conjugated relationship between composition *x* and $\Delta \mu$, as shown in Fig. 9(b), which determines the composition of AlLi and Al₂Li₃ at equilibrium. Thus, the phase boundary between AlLi and Al₂Li₃ at T = 600 K can be constructed, and is indicated by the dashed line in Fig. 9(c). Following this strategy, the phase boundary between both phases was built as a function *T* and is plotted in Fig. 9(c).

Fig. 9. (a) Grand potentials \emptyset of AlLi and Al₂Li₃ as a function of the chemical potential $\Delta \mu$ at 600 K. (b) Li content (expressed by *x*) as a function of $\Delta \mu$ at 600 K. (c) Phase boundary between AlLi and Al₂Li₃.

The strategy to obtain the phase boundaries between Al₂Li₃ and AlLi₂ is identical to the one presented above for AlLi and Al₂Li₃. The ascending and descending curves of the thermodynamic grand potentials \emptyset as a function of $\Delta \mu$ at T = 500 K are plotted in Fig. 10(a). The composition of Al₂Li₃ and AlLi₂ at equilibrium could be determined from their intersection (Fig. 10(b)) and this construction is repeated at different temperatures to plot the phase boundaries, which are plotted in Fig. 10(c).

Fig. 10. (a) Grand potentials \emptyset of Al₂Li₃ and AlLi₂ as a function of the chemical potential $\Delta \mu$ at 500 K. (b) Li content (expressed by *x*) as a function of $\Delta \mu$ at 500 K. (c) Phase boundary between Al₂Li₃ and AlLi₂.

3.4.4. AlLi₂/Al₄Li₉ and Al₄Li₉/Li phase boundaries

The phase boundaries between AlLi₂ and Al₄Li₉ were also determined from their thermodynamic grand potentials \emptyset and they are plotted in Fig.11(a) as a function of $\Delta \mu$ at T = 450 K as an example. Again, the intersection between the ascending and

descending grand potentials was mapped on to the conjugated relationship between Li content (expressed by *x*) and chemical potential $\Delta\mu$, as shown in Fig. 11(b). Thus, the composition of AlLi₂ and Al₄Li₉ at equilibrium was determined and the phase boundary between AlLi₂ and Al₄Li₉ at T = 450 K was obtained and is plotted with the dashed line in Fig. 11(c). The phase boundary in this region was constructed from the grand potentials at each temperature and is shown in Fig. 11(c), from which the AlLi₂ and Al₄Li₉ are both line compounds. The two-phase equilibrium region of AlLi₂ and Al₄Li₉ exists up to T = 520 K, and Al₂Li₃ and AlLi₂ cannot be distinguished above 520 K.

Fig. 11. (a) Grand potentials \emptyset of AlLi₂ and Al₄Li₉ as a function of the chemical potential $\Delta \mu$ at 450 K. (b) Li content (expressed by *x*) as a function of $\Delta \mu$ at 450 K. (c) Phase diagram between AlLi₂ and Al₄Li₉.

Exactly the same construction was used to obtain the phase boundaries between Al₄Li₉ and Li. The corresponding ascending and descending \emptyset vs. $\Delta\mu$ curves (Fig. 12(a)), the composition at equilibrium of both phases at T = 400 K (Fig. 12(b)) and the phase boundaries as a function of temperature (Fig. 12(c)) were obtained. are shown in Fig.12(a). The two-phase equilibrium region of Al₄Li₉ and Li exists up to T=520 K.

4. Discussion

The phase boundaries between each two adjacent phases were integrated to build the Al-Li phase diagram which is plotted in Fig. 13(a) together with the previous one that was obtained including only the configurational entropy contribution to the free energy [29]. Al₃Li is considered as a stable phase in the previous phase diagram that only includes configurational disorder and, thus, there are two Al-Al₃Li and Al₃Li-Al two-phase equilibrium regions (in red). However, since Al₃Li is a metastable phase in the phase diagram including both vibrational and configurational entropy, the Al₃Li-AlLi two-phase equilibrium region has disappeared and only one Al-AlLi two-phase equilibrium region exists. Moreover, the critical temperature of Al-Al₃Li two-phase region (maximum of the red dashed line) was 730 K in the phase diagram with only configurational disorder, but this value is higher than the experimental ones (620 K) [28]. This discrepancy could be expected because neglecting the vibrational contribution often leads to overestimate of phase transition temperatures [50, 51]. The phase diagram including both vibrational and configurational contributions leads to a wider two-phase equilibrium region between Al and Al₃Li (black dashed lines) than the one without considering vibrational effect, and the critical temperature also decreases to 670 K, which is in better agreement with the experimental data.

AlLi₂ and Al₄Li₉ appear as line compounds in the phase diagrams with or without vibrational entropy. Nevertheless, AlLi₂ and Al₄Li₉ are only stable up to 300 K and 500 K, respectively, when vibrational disorder is not included. They reach 640 K and 520 K, respectively, when vibrational entropy is taken into account, which is much closer to the experimental data (600 K and 545 K, respectively). The solubilities of AlLi and Al₂Li₃ are also influenced by the vibrational entropy. The Li content in the two phase AlLi-Al₂Li₃ region reaches 0.6 at 700 K if only configurational disorder is included but is dramatically reduced at this temperature if vibrational entropy is taken into account. In addition, Al₂Li₃ is a line compound if only configurational disorder is included but it forms a two-phase region with AlLi₂ if vibrational entropy is considered.

The phase diagram calculated taking into account both vibrational and configurational entropic contributions is also compared with the accepted experimental phase diagram [27, 28] in Fig. 13(b). Both phase diagrams predict that Al₃Li is a metastable phase. The Al-AlLi two-phase equilibrium regions in the both phase diagrams are almost superposed and a small difference only appears at high temperature. The phase boundary between AlLi and Al₂Li₃ is also accurately predicted in the phase diagram. Moreover, AlLi₂ and Al₄Li₉ appear as lines compounds in both phase diagrams and the maximum temperatures at which both disappear are also very close in both phase diagrams. Al₂Li₃ is a line compound in the experimental phase diagram while it is only a line compound up to 500 K in the calculated phase diagram and forms a solid solution at higher temperature.

Fig. 13. (a) Comparison between Al-Li phase diagrams calculated in this work (black lines) and in a previous investigation (red lines) [29]. The phase diagram calculated in [29] only considered the configurational disorder contribution to the free energy. (b) Comparison between the Al-Li phase diagrams calculated in this work (black lines) and the experimental one (blue lines) [27, 28]. (c) Schematic illustration of the gap between the solvus lines of AlLi and Al₃Li.

Overall, the calculated phase diagram is in very good agreement with the experimental data and the only remarkable difference is the gap between the solvus lines of AlLi and Al₃Li, which is indicated by the arrow in Fig. 13(b). This gap is very small in our calculated phase diagram as compared with the experimental data. A schematic illustration in the formation of gap is displayed in Fig. 13(c), which shows the three curves of the Gibbs free energy of the stable Al and AlLi phases and of metastable Al₃Li at a given temperature. The gap is given by the difference in the composition of Al determined by the common tangent, which is marked by the arrows. A large gap will be formed if the Gibbs free energy of metastable Al₃Li is much higher than the common tangent between the Gibbs free energy of the stable Al and AlLi, (as shown in Fig. 13(c)). However, based on our accurate calculations, the Gibbs free energy of metastable Al₃Li is only slightly higher than the common tangent between

the Gibbs free energies of Al and AlLi (Fig. 8), and a large gap cannot be formed. The large gap in the experimental phase diagram is probably an error caused by sluggish kinetics and uncertainties during experiments. Therefore, our calculation provides an accurate solvus line for Al₃Li, which is very important for the heat treatment of Al-Li alloy.

5. Conclusions

The whole phase diagram of the Al-Li system is predicted from first principles calculations and statistical mechanics taking into account the influence of the configurational and vibrational entropy. To this end, the formation enthalpy of different configurations with either fcc or bcc lattices at different temperatures was accurately predicted by means of cluster expansion formalisms that were fitted from density functional theory simulations. The vibrational entropic contribution of each configuration was determined from the bond length *vs.* bond stiffness relationships for each type of bond (either Al-Al, Li-Li and Al-Li) for each lattice that were obtained from full phonon calculations of various compounds. Thus, the thermodynamic grand potential and the Gibbs free energy of the different phases in the convex hull were obtained as a function of temperature by means of Monte Carlo simulations and the phase diagram was determined.

The calculated phase diagram was in excellent agreement with the experimental data and provides accurate predictions of the stable (AlLi, Al₂Li₃, AlLi₂, Al₄Li₉) and metastable (Al₃Li) phases, of the phase boundaries between them and of the maximum stability temperature of AlLi₂ and Al₄Li₉ which are line compounds. In addition, the calculated phase diagram shows that Al₂Li₃ is a line compound only up to 500 K and forms a solid solution at higher temperature. It also indicates that gap between the solvus lines of AlLi and Al₃Li is narrower than that found in the accepted experimental phase diagram, an information that is important to design precipitation high treatments for these alloys. Finally, the large influence of the vibrational entropic contribution to assess the metastability of Al₃Li, the phase boundaries and the maximum stability

temperature of different phases is revealed by comparison with predictions of the phase diagram that only considered the configurational entropy contribution. Overall, the methodology presented in this paper shows that accurate phase diagrams of alloys of technological interest can be predicted from first principles calculations.
