# **Abstract**

In order to study the competition of pulling a long chain polymer with its other system properties models of lattice polymers accomodate an applied pulling force to some part of a lattice polymer in addition to features such as energetic interaction between the lattice polymer and a surface. However, the critical behaviour of the pulling force alone is less well studied, such as characterizing the nature of the phase transition and particularly the values of the associated exponents. We investigate a simple model of lattice polymers subject to forced extension, namely self-avoiding walks (SAWs) on the square and simple cubic lattices with one endpoint attached to an impermeable surface and a force applied to the other endpoint acting perpendicular to the surface. In the thermodynamic limit the system undergoes a transition to a ballistic phase as the force is varied and it is known that this transition occurs whenever the magnitude of the force is positive, i.e.  $f > f_c = 0$ . Using well established scaling arguments we show that the crossover exponent  $\phi$  for the finite-size model is identical to the well-known exponent  $v_d$ , which controls the scaling of the size of the polymer in d-dimensions. With extensive Monte Carlo simulations we test this conjecture and show that the value of  $\phi$  is indeed consistent with the known values of  $v_2 = 3/4$  and  $v_3 = 0.587597(7)$ . Scaling arguments, in turn, imply the specific heat exponent  $\alpha$  is 2/3 in two dimensions and 0.29815(2) in three dimensions.

#### I. INTRODUCTION

Lattice models of polymers have been extended to model a huge variety of different physical situations. One well studied addition to lattice polymer models is the application of an external force that acts to deform the polymer chain, possibly with reference to some surface to which it is attached. These models apply to real applications with atomic force microscopy [1–4] or optical tweezer experiments [5]. The standard for lattice polymer models is the self-avoiding walk (SAW) and its variants (self-avoiding trails, self avoiding polygons etc.) Typically, an applied force is included in a SAW model to complement some other interaction or geometric constraint. A force can be applied to a self-interacting SAW to transition from a collapsed to a stretched phase [6], or force desorption from an interacting surface [7–9]. The force can be applied in different ways such as applying it at the midpoint of the polymer [10] or an arbitrary interior point [11], or it can be applied to move two parallel slabs that confine the polymer [12]. A pulling force also appears in models of non-linear lattice polymers such as polygons [13], stars [14–16], or more general lattice animals as well as block copolymers [17].

The critical properties of this wide range of models have received a lot of attention, but less work has been applied to the behaviour of lattice polymer models that feature *only* the applied force [6, 12, 18], perhaps because it is among the simplest additions to the bare SAW model. When a force is applied to say the endpoint of a SAW, with the other end terminally attached to some surface, then the SAW behaves ballistically in that its size from endpoint to endpoint is proportional to the number of steps in the walk, i.e.  $R \sim n$ . In the thermodynamic limit of long lengths this occurs for any magnitude of force so there is a critical point at zero force, where the SAW does not behave ballistically. This location of this critical point at f = 0 has been proved exactly [6, 18], but further properties of this transition are less well understood. Some previous work [12] has included Monte Carlo simulation of SAW models with a force applied in slightly different ways but provided limited estimation of critical exponents.

In this paper we argue that standard (finite length) scaling arguments for a continuous transition applied to this transition leads directly to a conjecture for the crossover exponent  $\phi$  and strength of the phase transition (via the specific heat exponent  $\alpha$ ) when a pulling force is applied to the end of a polymer in two and three dimensions (in fact, in any dimension  $d \ge 2$ ). We support this conjecture with strong numerical evidence from Monte Carlo simulations of SAWs on the square and cubic lattices in half spaces where one end is attached to the surface (wall) and a force perpendicular to the wall is applied to the other end. If the size (say radius of gyration) scaling exponent of a free extended polymer in dilute solution is  $\nu_d$  in dimension d then our conjecture is that

$$\phi = \nu_d, \quad \alpha = 2 - \frac{1}{\nu_d}.\tag{1}$$

In particular, for two dimensions

$$\phi = \nu_2 = \frac{3}{4}, \quad \alpha = \frac{2}{3}$$
 (2)

whilst for three dimensions

$$\phi = v_3 = 0.587597(7), \quad \alpha = 0.29815(2),$$
 (3)

based on the best estimate of  $v_3$  [19]. It should be noted that  $v_d \ge 1/2$  for all dimensions  $d \ge 2$ . It is sometimes inferred [12] that this crossover exponent is close to 1/2 as it is for the adsorption transition but our numerical evidence discounts this assumption.

## II. MODEL AND SCALING ARGUMENTS

We consider single polymers in dilute solution modeled as self-avoiding walks (SAWs) on a square or simple cubic lattice lattice. If the coordinates of each vertex of the walk lie in the space of coordinated defined by  $(x_1, \ldots, x_d)$  with  $x_i \in \mathbb{Z}$  for  $i = 1, \ldots, d$ , giving a d-dimensional hypercubic lattice  $\mathbb{Z}_d$ , then we consider walks that are restricted to the half-space defined by  $x_d \geq 0$ . One endpoint of the walk is tethered to the surface at the origin and the other endpoint is pulled by a force f perpendicular to the impermeable surface at  $x_d = 0$ . This situation is illustrated for two dimensions in Fig. 1. Let the coordinates of the vertices be denoted as  $(x_{1,j}, \ldots, x_{d,j})$  for  $j = 0, \ldots, n$ . We denote by  $h = x_{d,n}$  the height of the pulled endpoint and by  $a_{nh}$  the number of such walks on the lattice that are of length (number of steps) n. The number of all walks of length n confined to one half-space is  $\sum_h a_{nh}$  and it is known that this quantity has the same large n limit as unrestricted SAWs on a hypercubic lattice [20]. That is,  $\lim_{n\to\infty} \frac{1}{n} \log \sum_h a_{nh} = \log \mu_d$ , where  $\mu_d$  is the growth constant of the d-dimensional hypercubic lattice [21].

If the height of the endpoint is due to a force f then we associate a Boltzmann factor  $y^h$  where  $y = \exp(f/k_BT)$ . The canonical partition function of such walks of length n with endpoint at height h is

$$Z_n(f) = \sum_h a_{nh} y^h. (4)$$

The (reduced) finite-length free energy is

$$\lambda_n(f) = -\frac{1}{n} \log Z_n(f). \tag{5}$$

FIG. 1. A self-avoiding walk on the square lattice with one endpoint attached to an impermeable surface and the other pulled away from that surface by a force f. The height of the pulled endpoint above the surface is h.

and we consider the average height per step

$$h_n(f) = \frac{\langle h \rangle (f)}{n} = \frac{1}{n} \frac{\sum_h h \, a_{nh} \, y^h}{Z_n(f)} = -\frac{d\lambda_n(f)}{df} \tag{6}$$

and its variance (also the specific heat)

$$c_n(f) = \frac{\operatorname{var}(h)}{n} = \frac{\langle h^2 \rangle - \langle h \rangle^2}{n} = \frac{dh_n(f)}{df}.$$
 (7)

#### A. Thermodynamic scaling

In the thermodynamic, or long-length, limit the free energy is  $\lambda(f) = \lim_{n\to\infty} \lambda_n(f)$  and it is known that  $\lambda(f)$  is singular at exactly  $f_c = 0$ , or equivalently  $y_c = 1$ , which is the location of the extended-ballistic transition [6, 18, 22]. This holds for all dimensions  $d \ge 2$ . Considering the thermodynamic limits

$$H(f) = \lim_{n \to \infty} h_n(f) \tag{8}$$

and

$$C(f) = \lim_{n \to \infty} c_n(f) \tag{9}$$

then the transition is signified by the behaviour

$$H(f) = C(f) = 0 \text{ for } f \le 0$$
 (10)

and

$$H(f) > 0 \text{ and } C(f) > 0 \text{ for } f > 0$$
 (11)

the average height per step can be considered an order parameter for the transition.

The standard scaling Ansätze for a continuous transition near a critical point  $f_c$  at large length n are

$$c_n(f) \sim n^{\alpha \phi} C\left( [f - f_c] n^{\phi} \right) \text{ as } n \to \infty \text{ as } f \to f_c$$
 (12)

where  $\phi$  < 1 is the crossover exponent, and

$$h_n(f) \sim n^{\alpha \phi - \phi} \mathcal{H}\left( [f - f_c] n^{\phi} \right) \text{ as } n \to \infty \text{ as } f \to f_c.$$
 (13)

A continuous transition is signified by  $\alpha < 1$ . Standard arguments give a relation between  $\phi$  and  $\alpha$ 

$$2 - \alpha = \frac{1}{\phi},\tag{14}$$

so that when  $f = f_c = 0$  we have

$$h_n(0) \sim H n^{\phi - 1} \tag{15}$$

and

$$c_n(0) \sim C n^{2\phi - 1}$$
. (16)

The constants H and C are the values of the scaling functions  $\mathcal{H}$  and C at f = 0.

Now at f = 0 given that the height of the polymer end will scale in proportion to the size of the polymer generally given the polymer has a free end it would also be expected that

$$\langle h \rangle (0) \sim A \ n^{\nu_d}, \tag{17}$$

where  $v_d$  is the isotropic free *d*-dimensional size scaling exponents: in two dimensions it is predicted that  $v_2 = 3/4$  and in three dimensions the best estimate is  $v_3 = 0.587597(7)$  [19]. Hence we can deduce a particular scaling relation for this pulling-pushing transition

$$\phi = \nu_d. \tag{18}$$

Although this relation is simple, it will hold in all models with a force that changes from pulling to pushing.

Away from the critical point where the endpoint is subject to a pulling or pushing force, the value of  $\nu$  can change and we should look at some other size-related quantities. Let the end point of our walks be at  $(x_{1,n}, h)$  or  $(x_{1,n}, x_{2,n}, h)$  for two and three dimensions respectively, and let the walk fit into a slab or slit of no less than  $s = \max\{x_{d,j}, j = 0, ..., n\}$  units high (that is, all sites of the walk have height less and or equal to s. We note  $s \ge h$ , and

$$r_{x} = \left[ \sum_{i=1}^{d-1} x_{i,n}^{2} \right]^{1/2} \tag{19}$$

is shorthand for the distance from the origin to the projection of the endpoint onto the impermeable surface, generalised for all dimensions d. Similar to the discussion above, we define size exponents  $v^{(h)}$ ,  $v^{(x)}$  and  $v^{(s)}$  at fixed f

$$\langle h \rangle (f) \sim H \, n^{\nu^{(h)}} \,, \tag{20a}$$

$$\langle r_x \rangle (f) \sim X n^{\nu^{(x)}},$$
 (20b)

$$\langle s \rangle (f) \sim S \, n^{\nu^{(s)}} \,.$$
 (20c)

The expected values of these exponents in each phase and at the critical point is summarised in Table I. In the extended phase, where f < 0, or equivalently y < 1, the endpoint is pushed into the surface, that is,  $\langle h \rangle = 0$  and hence  $v^{(h)} = 0$ . However, the pushing force is local to the endpoint and the size of the rest of the polymer is also characterised by the same exponents  $v_d$ . As

Phase	f	$v^{(h)}$	$v^{(x)}$	$v^{(s)}$
Extended (pushed)	$f < f_c$	0	$v_d$	$v_d$
Critical point	$f = f_c$	$v_d$	$v_d$	$v_d$
Ballistic (pulled)	$f > f_c$	1	$\frac{1}{2}$	1

TABLE I. Size exponent values for the phases in our model. The critical point is at  $f_c = 0$ , or equivalently  $y_c = 1$ .

 $f \to -\infty$ , or equivalently  $y \to 0$ , the pushed endpoint is effectively fixed in the surface, equivalent to a self-avoiding *loop* [23]. The ballistic phase, f > 0, is so named because it is characterised by the behaviour  $h_n \sim O(1)$  and thus it is known that  $v^{(h)} = 1$  for SAWs [22]. Since s is an alternate measure of the extension of the polymer when pulled away from the surface, we expect  $v^{(s)} = 1$  as well. The polymer is stretched in this phase so the component of the endpoint position parallel to the surface is small and we have  $v^{(x)} = 1/2$ .

#### B. Simulation details

Walks are simulated using the flatPERM algorithm [24], an extension of the pruned and enriched Rosenbluth method (PERM) [25]. The simulation works by growing a walk on a given lattice up to some maximum length  $N_{\text{max}}$ . At each step the number of bulk interactions m and straight segments s are calculated and the cumulative Rosenbluth & Rosenbluth weight [26] is compared with the current estimate of the weights of all samples  $W_{nh}$ . If the current state has relatively low weight the walk is 'pruned' back to an earlier state. On the other hand, if the current state has relatively high weight, then microcanonical quantities h are measured and  $W_{nh}$  is updated. The state is then 'enriched' by branching the simulation into several possible further paths (which are explored when the current path is eventually pruned back). When all branches are pruned a new iteration is started from the origin. FlatPERM enhances this method by altering the prune or enrich choice such that the sample histogram is flat in the microcanonical parameters n and h. Further improvements are made to account for the correlation between branches that are grown from the same enrichment point, which provides an estimate of the number of effectively independent samples. The main output of the simulation are the weights  $W_{nh}$ , which are an approximation to the athermal density of states  $a_{n,h}$  in Eq. (4), for all  $n \le N_{\text{max}}$ .

Once the simulation is finished thermodynamic quantities are determined by specifying the Boltzmann weight *y* and using the weighted sum

$$\langle Q \rangle_n = \frac{\sum_h Q_{nh} y^h W_{nh}}{\sum_h y^h W_{nh}}.$$
 (21)

In particular, we calculate  $h_n$  and its variance  $c_n$  according to Eqs. 6 and 7 as well as  $\langle x \rangle$  and  $\langle s \rangle$ . Similarly we also calculate the third derivative of the specific heat

$$t_n(f) = \frac{\langle h^3 \rangle - 3\langle h \rangle \langle h^2 \rangle + 2\langle h \rangle^3}{n}.$$
 (22)

We use the flatPERM algorithm to simulate walks up to length  $N_{\text{max}} = 1024$ . Because this model is simple we can afford to run very long simulations to obtain good statistics. For both 2D and 3D models we have  $1.2 \times 10^7$  iterations, obtaining  $5.2 \times 10^{12}$  samples for 2D walks and

FIG. 2. Thermodynamic quantities for pulled SAWs in 2D (top) and 3D (bottom), for several different lengths n. From left to right are the average extension above the surface  $h_n$ , the specific heat  $c_n$ , and the third derivative of the free energy  $t_n$ .

 $6.3 \times 10^{12}$  samples for 3D walks. For each case or simulation mentioned in this work the results are comprised of a composite of ten independent simulations in order to obtain some measure of statistical error. We ran separate smaller simulations ( $N_{\text{max}} = 512$ ) to obtain data for  $\langle s \rangle$  in order to verify scaling predications.

## III. RESULTS

We first show in Fig. 2 several thermodynamic quantities for the 2D walks (top row) and 3D walks (bottom row) as functions of the Boltzmann weight  $y = e^{f/k_BT}$ . The left plots show the average extension above the impermeable surface,  $h_n$ , the specific heat  $c_n$  and the third derivative of the free energy  $t_n$ . All plots show example curves for n = 256, 512, 1024. There is a clear signal of a transition near y = 1 (f = 0), most notably as a peak in  $c_n$  that grows with n. The behaviour of  $h_n$  is suggestive of a continuous transition.

In order to verify the type of transition we estimate the critical exponents using a correction-to-

lattice		$h_n$	$c_n$	$t_n$
squ	α	$0.6630 \pm 0.0024$	$0.6673 \pm 0.0031$	$0.638 \pm 0.020$
	φ	$0.7479 \pm 0.0009$	$0.7504 \pm 0.0011$	$0.734 \pm 0.007$
sc		$0.2997 \pm 0.0029$		
	φ	$0.5881 \pm 0.0009$	$0.5896 \pm 0.0010$	$0.5882 \pm 0.0026$

TABLE II. Critical exponents  $\alpha$  and  $\phi$  estimated from the scaling of thermodynamic quantities at the critical point  $f_c$  for pulled SAWs on the square and simple cubic lattices.

FIG. 3. The peak values of  $c_n$  as an estimate for the location of the transition  $y_c^{(n)}$  for (a) the square lattice and (b) the simple cubic lattice.

scaling method. That is, for a quantity  $Q_n$  that has power-law leading order behaviour  $n^b$  for some expected exponent b, we fit the data to

$$Q_n \sim A n^b \left( 1 + C n^{-\Delta} \right), \tag{23}$$

where A and C are fitting parameters and  $\Delta$  is a correction to scaling parameter. There are a range of corrections to scaling exponents that have been seen in the literature [19, 27–30] where  $n^{-\Delta}$  is only the first correction term of an infinite series, but for our purposes we have assumed that a single term with  $\Delta = 1/2$  for three dimensions and  $\Delta = 1$  for two dimensions is sufficient to take account of the total effect of correction to scaling terms. We do not have the necessary numerical precision to estimate  $\Delta$  independently for this model. All reported results for exponents  $\phi$  and  $\alpha$  are derived from a model of the form of Eq. (23), although in most cases the effect of adding the correction-to-scaling term is weak, usually in the third decimal place.

Three estimates of the exponents have been made using correction-to-scaling models with the following leading order exponents. First, we fit the average extension at the critical point  $h_n(f_c)$  with leading order exponent  $\phi - 1$ , as per Eq. (15). Second, we the specific heat at the critical point  $c_n(f_c)$  with leading order exponent  $2\phi - 1$ , as per Eq. (16). Third, we fit the critical point values of  $t_n(f_c)$ . By similar scaling arguments to the previous section the peak value of  $t_n$  is expected to scale with leading-order exponent  $(\alpha + 1)\phi = 3\phi - 1$ . In all cases the value of  $\alpha$  is then derived from the relation in Eq. (14).

The values of  $\alpha$  and  $\phi$  determined from these fits are reported in Table II. These estimates are consistent with  $\alpha \approx 2/3$  and  $\phi = 3/4$  for the square lattice, confirming that  $\phi = \nu_2$  in this case. For the simple cubic lattice the values of  $\phi$  are close to the expected  $\phi = \nu_3 \approx 0.587597(7)$ , or equivalently by the hyperscaling relation Eq. (14)  $\alpha = 0.29815(5)$ . For both two and three dimensions these exponents confirm that the extended-ballistic transition is continuous.

The location of the extended-ballistic transition is rigorously known so we have the luxury of immediately looking at the scaling of thermodynamic quantities at exactly  $y_c = 1$  ( $f_c = 0$ ). This saves a lot of additional work to accurately locate the critical point, for which one needs some easily identifiable signal of the transition. In general for a finite-size system, the critical point deviates from the long chain limit as

$$y_c^{(n)} - y_c \sim n^{-\phi},$$
 (24)

where the crossover exponent  $\phi$  appears again. An obvious choice for  $y_c^{(n)}$  is the *location* of the peak value of the specific heat  $c_n^{(\text{peak})}$ , which occurs near, but slightly above, the transition point.

FIG. 4. The size exponent  $\nu$  from several quantities across the ballistic transition for (a) 2D and (b) 3D. At the critical point  $y_c = 1$  the exponents coincide with value  $\nu_d$ .

In the thermodynamic limit the specific heat at the critical point diverges and so  $c_n(0)$  should also diverge with n if the crossover exponent  $\phi > 1/2$ . This is the case for our model and one could even approximate  $c_n(0) \approx c_n^{(\text{peak})}$ . By comparison, locating the critical point is a significant issue for other systems, e.g. polymer adsorption where  $\phi \le 1/2$  and so the peaks of the specific heat are not a good indicator of the transition [31, 32]. Thus, while our earlier estimates of the exponents are justified, it is nevertheless worth comparing the known exact value of the transition point to estimates from the simulations using the peak values of  $c_n$ . This also provides a further estimate of  $\phi$ .

In Fig. 3 we show a log-log plot of  $y_c^{(n)} - y_c = c_n^{(\text{peak})} - 1$ . First, it is clear that in both cases the long-length limit  $y_c = 1$  is good. The dashed lines are least-squares fits to a simple power law (without correction to scaling) to the larger values of n. Particularly for the the square lattice, this is the case where we see the largest finite-size effect at small n. Without the correction to scaling we find  $\phi = 0.705 \pm 0.008$  for the square lattice and  $0.557 \pm 0.001$  for the simple cubic lattice. When a correction-to-scaling model is used with expected leading order exponent  $-\phi$  according to Eq. (24), we find improved estimates of  $\phi = 0.76 \pm 0.05$  for the square lattice and  $\phi = 0.567 \pm 0.003$  for the simple cubic lattice. These values closely match the estimates from the scaling of thermodynamic quantities presented above and thus are again in good agreement with the relation  $\phi = v_d$ . Our results disagree with  $\phi \approx 1/2$  found in [12], which also estimated  $\phi$  from the shift of the critical point at finite lengths.

Lastly, we look at the size scaling of the walks via the quantities in Eq. (20). Additional simulations with smaller maximum length  $n_{\text{max}} = 512$  were run to obtain data for  $\langle s \rangle$ . Estimates for the scaling exponents of these quantities were obtained by simple power-law fits (without finite-size corrections to scaling) for a range of values of y spanning the extended-ballistic transition. In Fig. 4 we plot the exponents  $v^{(x)}$ ,  $v^{(x)}$  and  $v^{(x)}$  (bottom), for the square (top) and simple cubic (bottom) lattices. Broadly, the values of these exponents match what is outlined in Table I. In particular, the values of the different exponents coincide at the critical point  $y_c = 1$  where it is expected that all exponents have value  $v_d$ . However, the estimates for the simple-cubic lattice show a larger spread compared to the square lattice.

#### IV. CONCLUSION

We have investigated the critical behaviour of a pulled SAW near the known extended-ballistic transition at zero force  $f_c = 0$  ( $y_c = 1$ ). With standard scaling analysis we find that the exponent  $\phi$  governing the crossover from the finite size behaviour to the thermodynamic limit is the same as the size exponent  $\nu$ . The exponent  $\alpha$  governing the the scaling of the specific heat follows from standard scaling relations. Although this relation is simple, it has not been explicitly stated in the literature despite the widespread use of a pulling force in lattice polymer models. Monte Carlo simulation showed that this result is verified in the scaling of thermodynamic quantities at the critical point. It is also verified in the drift of the finite-size critical point  $y_c^{(n)}$  from the thermodynamic limit  $y_c = 1$ , as represented by a typical signature, namely the location of the specific heat peak. Furthermore, we looked at the size exponent in both the extended and ballistic phases by way of several quantities that are related to the extension of the polymer away from the surface. The scaling of these quantities shows consistent estimations of the size exponent  $\nu$ .
