(Dated: November 29, 2022)

Recently, charge density wave (CDW) order has been discovered in a magnetic kagome metal FeGe, providing a new platform to explore the possible connection between magnetism and CDW in a kagome lattice. Based on density functional theory and symmetry analysis, we present a comprehensive investigation of electronic structure, magnetic properties and possible structural distortion of FeGe. We estimate the magnetic parameters including Heisenberg and Dzyaloshinskii-Moriya (DM) interactions, and find that the ferromagnetic nearest-neighbor  $J_1$  dominates over the others, while the magnetic interactions between nearest kagome layers favors antiferromagnetic. The Néel temperature  $T_N$  and Curie-Weiss temperature  $\theta_{CW}$  are successfully reproduced, and the calculated magnetic anisotropy energy is also in consistent with the experiment. However, these reasonable Heisenberg interactions and magnetic anisotropy cannot explain the double cone magnetic transition, and the DM interactions, which even exist in the centrosymmetric materials, can result in this small magnetic cone angle. Unfortunately, due to the crystal symmetry of the high-temperature structure, the net contribution of DM interactions to double cone magnetic structure is absent. Based on the experimental  $2 \times 2 \times 2$  supercell, we thus explore the subgroups of the parent phase. Group theoretical analysis reveals that there are 68 different distortions, and only four of them (space group P622 or  $P6_322$ ) without inversion and mirror symmetry thus can explain the lowtemperature magnetic structure. Furthermore, we suggest that these four proposed CDW phases can be identified by using Raman spectroscopy. Since DM interactions are very sensitive to small atomic displacements and symmetry restrictions, we believe that symmetry analysis is an effective method to reveal the interplay of delicate structural distortions and complex magnetic configurations.

## I. INTRODUCTION

Kagome lattices are emerging as an exciting platform for the rich emergent physics, including magnetism, charge density wave (CDW), topology, and superconductivity [1-43]. Three key features have been identified in the electronic structure associated with its lattice geometry, which are flat band derived from the destructive phase interference of nearest-neighbour hopping, topological Dirac crossing at K point in the Brillouin zone (BZ), and a pair of van Hove singularities (vHSs) at M point [2-5]. When large density of states from the kagome flat bands are located near the Fermi level, strong electron correlations can induce magnetic order [2, 3]. There are several magnetic kagome materials, such as FeSn [6-10], Fe<sub>3</sub>Sn<sub>2</sub> [11-14], Mn<sub>3</sub>Sn [15], Co<sub>3</sub>Sn<sub>2</sub>S<sub>2</sub> [16] and  $AMn_6Sn_6$  (A=Tb, Y) [17, 18], which usually exhibit magnetic order with ferromagnetically ordered layers that are either ferromagnetically or antiferromagnetically stacked. Meanwhile, when vHSs are located near the Fermi level, interaction between the saddle points and lattice instability could induce symmetry-breaking CDW order [4, 5], such as the class of recently discovered kagome materials AV<sub>3</sub>Sb<sub>5</sub> (A=K, Rb, Cs) [19–41]. Significant interests have been focused on them since an unusual competition between unconventional superconductivity and CDW order has been found [19–41]. Note that in kagome system, magnetic order and CDW order have not been usually observed simultaneously within one material, probably due to the fact that they originate from the flat band and the vHSs respectively, which have the large energy difference and usually do not both appear near the Fermi level [44].

Very recently, a CDW order has been discovered to appear deeply in a magnetically ordered kagome metal FeGe, providing the opportunity for understanding the interplay between CDW and magnetism in a kagome lattice [44-49]. Isostructural to FeSn [6-10] and CoSn [42, 43], hexagonal FeGe consists of stacks of Fe kagome planes with both in-plane and inter-plane Ge atoms [50]. A sequence of magnetic phase transitions have been discussed in 1970-80s [51–56]. Below  $T_N = 410$  K, FeGe exhibits collinear A-type antiferromagnetic (AFM) order with moments aligned ferromagnetically (FM) within each plane and anti-aligned between layers, and becomes a c-axis double cone AFM structure at a lower temperature  $T_{canting} = 60$  K [55, 56]. Recent neutron scattering, spectroscopy and transport measurements suggest a CDW in FeGe which takes place at  $T_{CDW}$  around 100K, providing the first example of a CDW in a kagome magnet [45, 46]. The CDW in FeGe enhances the AFM ordered moment and induces an emergent anomalous Hall effect (AHE) possibly associated with a chiral flux phase similar with  $AV_3Sb_5$  [34–36], suggesting an intimate correlation between spin, charge, and lattice degree of freedom [45]. Though AHE is not usually seen in antiferro-

<sup>\*</sup> These authors contributed equally to this work.

 $<sup>^\</sup>dagger$  Corresponding author: diwang0214@nju.edu.cn

magnets in zero field, recent studies have shown that a breaking of combined time-reversal and lattice symmetries in the antiferromagnetic state results in the AHE [57–59]. In kagome FeGe, the AHE associated with CDW order indicates that, the combined symmetry breaking occurs via the structural distortion or magnetic structure transition below the CDW temperature. The CDW in FeGe was then extensively studied experimentally and theoretically [44–49], and the CDW wavevectors are identical to that of  $AV_3Sb_5$  [23–28]. However, sharply different from  $AV_3Sb_5$  [39–41], all the theoretically calculated phonon frequencies in FeGe remain positive [44, 48, 49], and the structural distortion of the CDW phase remain elusive. It is firstly suggested to be reduced to P622with the distortion of two non-equivalent Fe atoms [45], while the later works propose that FeGe shares the same space group of P6/mmm with the pristine phase [48, 49]. Based on first-principles calculations and scanning tunneling microscopy, Shao et al. show that the CDW phase of FeGe exhibits a generalized Kekulé distortion [60] in the Ge honeycomb atomic layers [48]. Meanwhile, using hard x-ray diffraction and spectroscopy, Miao et al. report an experimental discovery of charge dimerization that coexists with the CDW phase in FeGe [49]. Therefore, the understanding of the magnetism, and the intertwined connection between complex magnetism and structural distortion in kagome FeGe is an emergency issue, which we will address in this work based on firstprinciples study and symmetry analysis.

In this work, we systematically analyze the electronic and magnetic properties of kagome FeGe. Our numerical results show that this material is a magnetic metal exhibiting large magnetic splitting around 1.8 eV. Based on combining magnetic force theorem and linearresponse approach [61–63], the magnetic exchange parameters have been estimated. The results show that the nearest-neighbor  $J_1$  is FM and dominates over the others, while the magnetic interactions between nearest kagome layers favors AFM, consequently resulting in the A-type AFM ground-state configuration. Based on these spin exchange parameters, the calculated Néel temperature and Curie-Weiss temperature also agree well with the experiments. Using the method in Ref. [64, 65], we also calculate the magnetic anisotropic energy (MAE) to be around 0.066 meV per Fe atom with easy axis being out of the kagome layers, which is in reasonable agreement with the experimental results [56]. However, the double cone magnetic transition at  $T_{canting} = 60$  K cannot be reproduced by these reasonable magnetic parameters. We find that Dzyaloshinskii-Moriya (DM) interactions [66, 67] are much more efficient than Heisenberg interactions for causing this canted spin structure. Unfortunately, the space group P6/mmm of high-temperature phase in FeGe has inversion symmetry and mirror symmetries, and all of them eliminate the net contribution of DM interactions to the double cone magnetic structure. It is well known that DM interactions are very sensitive to atomic displacements, while small structural

distortion usually has little effect on Heisenberg interactions. Therefore we explore the possible CDW distortions which can explain the low-temperature magnetic structure. Symmetry theoretical analysis reveals that there are 68 different distortions, which are the subgroups of the parent P6/mmm phase with  $2 \times 2 \times 2$  supercell [45, 46, 48, 49]. Based on the group theoretical analysis, we find that only four structures (space groups P622and  $P6_322$ ) without inversion and mirror symmetry thus can have double cone spin structure. We further propose that using Raman spectroscopy, these four CDW phases can be identified from their different numbers of Raman active peaks.

#### II. METHOD

The first-principles calculations have been carried out by using the full potential linearized augmented planewave method as implemented in the Wien2k package [68]. The converged k-point Monkhorst-Pack meshes are used for the calculations depending on materials. The selfconsistent calculations are considered to be converged when the difference in the total energy of the crystal does not exceed 0.01mRy. We adopt local spin-density approximation (LSDA) [69] as the exchange-correlation potential, and include the spin orbit coupling (SOC) using the second-order variational procedure [70].

The spin exchange interactions, including Heisenberg and DM interactions [66, 67], are calculated using first principles based on combining magnetic force theorem and linear-response approach [61–63], which have successfully applied to various magnetic materials [62, 63, 71–73].

Monte Carlo (MC) simulations are performed with Metropolis algorithm for Heisenberg model [74–76]. The size of the cell in the MC simulation are  $16 \times 16 \times 16$ -unit cells with periodic boundary conditions. At each temperature we carry out 400000 sweeps to prepare the system, and sample averages are accumulated over 800000 sweeps.

#### III. RESULTS

## A. The electronic and magnetic properties

The pristine phase of FeGe crystallizes in the hexagonal structure with space group P6/mmm (No. 191) [50], where the coordinates of the atoms are shown in table II and Fig. 1. Firstly we perform nonmagnetic local-density approximation (LDA) + SOC calculation, and show the band structures in Fig. 2(a). While Ge-2p states are mainly located between -6.0 and -2.0 eV, the main contribution around the Fermi level comes from the 3d orbitals of Fe ions, as shown in Fig. 4 of Appendix. Consistent with previous first-principle calculations [44, 47], the kagome flat bands around the Fermi level exhibit a large

FIG. 1. Crystal and magnetic structures of FeGe. Yellow and purple spheres represent Fe and Ge atoms respectively, while arrows denote magnetic moments of Fe atoms. (a) Top view of FeGe. The exchange interactions  $J_i$  denote the *i*th-nearestneighbor interactions between Fe ions within kagome layers. (b) The exchange interactions  $J_{ci}$  denote the *i*th-nearest-neighbor interactions between Fe ions on the nearest kagome layers. (c) The exchange interactions  $J_{ci}$  denote the *i*th-nearest-neighbor interactions between Fe ions on the nearest kagome layers.

FIG. 2. (a) Band structure of nonmagnetic FeGe from LDA + SOC calculation. (b),(c) Orbital-resolved band structure of  $\operatorname{Fe-}d_{xy}/d_{x^2-y^2}$  and  $\operatorname{Fe-}d_{xz}/d_{yz}$  for A-type AFM configuration with spin orientations along the (001) direction from LSDA + SOC calculation.

peak in the density of states, which indicates the magnetic instability. Therefore, LSDA + SOC calculations are performed based on the A-type AFM configuration and the band structures are shown in Figs. 2(b) and 2(c). The magnetic moment of Fe ions is estimated to be 1.55  $\mu_B$ , which is in agreement with the previous experimental value around 1.7  $\mu_B$  [52, 54]. Note that each kagome layer is FM and the key signatures of electronic structures in kagome lattice are remained. The magnetic splitting is around 1.8 eV (see Fig. 4 of Appendix), which makes that the flat bands above and below Fermi level correspond to the spin minority bands and spin majority bands respectively. Meanwhile, the vHSs that are relatively far from the Fermi level in the nonmagnetic state, are brought near the Fermi level by the spin splitting, as shown in Figs. 2(b) and 2(c). We present orbital-resolved band structures, and find that the vHSs near the Fermi level, which marked as vHS-1 and vHS-2 in Figs. 2(b) and 2(c), are mainly contributed by the  $d_{xy}/d_{x^2-y^2}$  and  $d_{xz}/d_{yz}$  orbitals respectively. These vHSs near the Fermi level are suggested to induce symmetry-breaking CDW order in kagome metal FeGe [44].

To quantitatively understand the rich magnetic phenomenon in kagome FeGe, a microscopic magnetic model with proper parameters is extremely important. Based on the calculated electronic structures, we estimate the exchange parameters including Heisenberg and DM interactions using the linear-response approach [61–63] and summarize the results in table I. As shown in Fig. 1, we divide the magnetic interactions considered into three

TABLE I. Spin exchange parameters (in meV) including Heisenberg and DM interactions of FeGe evaluated from LSDA+SOC calculations, respectively. The Fe-Fe distances and the corresponding number of neighbors NN are presented in the second and third columns.

	Distance(Å)	NN	J	DM
$J_1$	2.50	4	-41.97	(0, 0, 0.03)
$J_2$	4.33	4	5.49	(0, 0, -0.12)
$J_{c1}$	4.05	2	8.44	(0, 0, 0)
$J_{c2}$	4.76	8	-2.04	(0.01, -0.02, -0.07)
$J_{c3}$	5.93	8	1.81	(0.07, -0.04, -0.09)
$J_{c'1}$	8.11	2	-0.66	(0, 0, 0)
$J_{c'2}$	8.49	8	0.09	(-0.04, -0.09, -0.03)

types: the exchange interactions  $J_i$ ,  $J_{ci}$  and  $J_{c'i}$  represent the *i*th-nearest-neighbor interactions between Fe ions within kagome layers, on the nearest kagome layers, and on the next nearest kagome layers respectively. As shown in table I, the in-plane nearest neighbor coupling  $J_1$ favors FM order and is estimated to be -41.97 meV, which has the similar value with the one in kagome FeSn (around -50 meV) [7–10]. Note that the distance in  $J_1$  is 2.5 Å while the others are all greater than 4 Å. Though there are also AFM in-plane magnetic interactions such as in-plane next-nearest neighbor coupling  $J_2$ , they are at least an order of magnitude smaller than  $J_1$ , resulting in each FM kagome layer. As the out-of-plane nearest neighbor coupling,  $J_{c1}$  is estimated to be 8.44 meV. It makes the magnetic moments stacked antiferromagnetically between kagome layers, consequently resulting in the A-type AFM order in kagome FeGe, which is consistent with the experiment [51]. It is worth mentioning that, SOC always exists and leads to the DM interactions even in the centrosymmetric compound FeGe, since not all Fe-Fe bonds have inversion symmetry. For the equivalent DM interactions connected by the crystal symmetry (see table III-V in Appendix), we only present one of them as a representative. As shown in table I, the inplane nearest neighbor  $\mathbf{D}_1$  has the form of  $(0, 0, D_1^z)$ according to the crystal symmetry, and  $D_1^z$  is estimated to be 0.03 meV. Meanwhile, the in-plane next nearest neighbor  $\mathbf{D}_2$  is estimated to be (0, 0, -0.12) meV. For the out-of-plane nearest neighbor,  $\mathbf{D}_{c1}$  is zero because its bond has an inversion center. The other calculated DM interactions are also listed in table I, and most of them are small in the order of 0.01 meV.

To explore the magnetic anisotropy in kagome FeGe, we consider the MAE with the expression  $E_{MAE} = K_2 \sin^2 \theta + K_4 \sin^4 \theta$  [51, 54–56] neglecting terms of order higher than four, where  $\theta$  is the angle between the magnetic moment and the z-axis. The values of  $K_2$  and  $K_4$  are estimated to be 0.066 meV and 0.018 meV respectively based on the approach of Ref. [64, 65], which are in reasonable agreement with the experimental values 0.021 meV [56] and 0.012 meV [51]. Here  $K_2$  and  $K_4$ are both positive, making out-of-plane magnetization favored, which is different from the easy-plane anisotropy in FeSn [8]. Note that positive  $K_4$  is the requirement for the stability of the double cone magnetic structure, which will be discussed below.

According to the experiments [51], the Curie-Weiss temperature  $\theta_{CW}$  in kagome FeGe is -200 K while the Néel temperature  $T_N$  is 410 K. The relative low value of the frustration index  $|\theta_{CW}|/T_N$  (smaller than 1) reveals the interplay of the FM and AFM interactions [77]. As shown in table I, our calculated results of spin exchange couplings also verify the coexistence of the FM and AFM interactions. Based on these calculated spin exchange parameters, we calculate Néel temperature and Curie-Weiss temperature by MC simulations [74–76]. The  $\theta_{CW}$ and  $T_N$  are calculated to be -219 K and 370 K respectively, which agrees well with the experiment [51].

Similar to the electronic structure of a kagome lattice, the spin wave for a localized spin model with FM nearestneighbor magnetic exchange also yields a flat magnetic band and a Dirac magnon [78]. Using the calculated spin model parameters, one can obtain the magnon spectrum [79, 80]. The calculated spin-wave dispersion along the high-symmetry axis is shown in Fig. 3, which basically captures the key features of kagome lattice geometry. Similar with FeSn case [7–10], strongly dispersive magnons in the xy-plane extend to about 260 meV, where the magnon dispersion along the out-of-plane direction has relatively small bandwidth of less than 15 meV, reflecting the quasi-two-dimensional magnetic properties in kagome FeGe. Meanwhile, the Dirac-like node appears at the K point at about 107 meV, and we find that DM interactions introduce a gap around 1 meV at the Dirac point, as shown in the inset of Fig. 3. Furthermore, the single-ion anisotropy produces a spin gap of about 2 meV, which could be verified in future inelastic neutron scattering experiments.

FIG. 3. Calculated spin-wave dispersion curves along the high-symmetry axis for FeGe. The insets show the spin gap at  $\Gamma$  point induced by easy-axis anisotropy, and the gap located at about 107 meV of K point induced by DM interactions.

#### B. The double cone magnetic structure

At  $T_{canting} = 60$  K, the kagome lattice FeGe becomes a c-axis double cone AFM structure [51, 52, 54–56] where the magnetic ground state could be written as Eq. (10) in Appendix. Considering the magnetic interactions and the MAE, the total energy of the double cone spin structure could be written as Eq. (12) in Appendix. When DM interactions are not considered, the extremum condition of the total energy gives the equilibrium value of wave vector  $\delta$  and the cone half angle  $\theta$  (i.e. Eq. (13) and (14) in Appendix)

$$\cos\delta = \frac{\sum_{i} N_{ci} J_{ci}}{4\sum_{i} N_{c'i} J_{c'i}} \tag{1}$$

$$\sin^2 \theta = -\frac{K_2 - \frac{1}{2N} \sum_i N_{c'i} J_{c'i} \delta^4}{2K_4}$$
(2)

Note that the minimum of the total energy requires that the second derivative of Eq. (12) in Appendix is positive, thus  $K_4$  must be positive. Hence  $K_2 - \frac{1}{2N} \sum_i N_{c'i} J_{c'i} \delta^4$  (i.e. the numerator of Eq. (2)) must be negative. However, our reasonable magnetic parameters cannot explain the double cone magnetic ground state. The value of wave vector  $\delta$  is small in experimental measurement (0.17 in Ref. [51] and 0.25 in Ref. [53]), thus  $\delta^4$ is around 0.001. Meanwhile, the value of  $\frac{1}{2N} \sum_i N_{c'i} J_{c'i}$ is of the order of 1 meV, which obviously cannot explain the double cone magnetic structure [51].

We thus consider the effect of DM interactions on double cone spin structure. Since the exchange interactions between two next nearest neighbor kagome layers are relatively small, we only consider the Heisenberg and DM interactions between two nearest neighbor kagome layers, i.e.  $J_{ci}$  and  $\mathbf{D}_{ci}$ . We find that wave vector  $\delta$  and the cone half angle  $\theta$  have the expressions as (i.e. Eq. (15) and (16) in Appendix)

$$\tan \delta = \frac{\sum_{i,j} D_{ci,j}^z}{\sum_i N_{ci} J_{ci}} \tag{3}$$

$$\sin^2 \theta = -\frac{K_2 - \frac{1}{2N} \sum_{i,j} D^z_{ci,j} \delta}{2K_4} \tag{4}$$

It should be noted that, comparing Eq. (2) and (4), DM interactions are more efficient than Heisenberg interactions for causing double cone spin structure since  $\delta$  is small. Though the space group P6/mmm of hightemperature phase in FeGe has a global inversion center, not all Fe-Fe bonds have inversion symmetry and DM interactions could exist. However, according to the inversion symmetry of space group P6/mmm, the total contribution of DM interactions to the energy of double cone magnetic structure in Eq. (12) is absent, i.e.  $\sum_{i,j} D_{ci,j}^z = 0$  (see Appendix D). Meanwhile, mirror symmetries in space group P6/mmm would also eliminate the contribution of DM interactions based on the symmetry analysis. Therefore, DM interactions have no net contribution to double cone magnetic structure with the symmetry of high-temperature phase. For the CDW phases with the space group of P6/mmm suggested by Ref. [48, 49] (the first two structures of the table VI in Appendix), the total contribution of DM interactions is still absent and cannot explain the magnetic ground state of double cone spin structure.

## C. The interplay of CDW and double cone structure

As mentioned above, DM interactions play a more important role in the double cone spin structure. Meanwhile, it is very sensitive to atomic displacements. Therefore, in the following we explore the CDW phases with symmetry-allowed DM contribution to double cone spin structure which may explain the canted magnetic ground state.

The  $2 \times 2 \times 2$  supercell structure of CDW phase (compared with the nonmagnetic pristine phase) is suggested experimentally [45, 46, 48, 49]. Considering all CDW phases whose associated point group in the maximal subgroups of  $D_{6h}$ , we find 68 different possible CDW phases which are the subgroups of the parent P6/mmm phase with  $2 \times 2 \times 2$  supercell (see details in Appendix D). The corresponding relations of atomic positions between the pristine phase and these proposed CDW phases are all summarized in table VI-X of Appendix.

Note that the inversion symmetry and mirror symmetries would all eliminate the net contribution of DM interactions as disscussed above. We find that among these 68 proposed CDW phases, only four distorted structures break all these symetries above, and can lead to non-zero DM contribution in Eq. (12) of Appendix. We list the corresponding Wyckoff positions (WP) and the coordinates of the atoms in the pristine phase and these four CDW phases in table II. They comes from two space groups P622 and P6<sub>3</sub>22. It should be mentioned that there are two different CDW phases for each of these two space groups, which are labeled as (type I) and (type II) in table II. Note that the CDW phase with P622 space group is also suggested in Ref. [45].

Raman spectroscopy is a fast and usually nondestructive technique which can be used to characterize the structural distortion of materials. Based on the atomic coordinates in table II, we predict the irreducible representation of the Raman active modes of these four proposed CDW phases using symmetry analysis [81]. For P622 (type I) and (type II) CDW phases, the Raman active modes are  $8A_1 + 26E_1 + 22E_2$  and  $10A_1 + 26E_1 + 22E_2$ . Meanwhile, for  $P6_322$  (type I) and (type II), the Raman active modes are  $8A_1 + 24E_1 + 24E_2$  and  $10A_1 + 24E_1 + 24E_2$ , respectively. Note that even within the same symmetry of space group P622, the different structural distortion of CDW phases P622 (type I) and (type II) could result in the different number of Raman active

modes (56 and 58 respectively), which could be identified by Raman spectroscopy.

#### IV. CONCLUSION

In conclusion, we systematically analyze the electronic and magnetic properties of kagome FeGe. Our numerical results show that this material is a magnetic metal exhibiting large magnetic splitting around 1.8 eV. The magnetic splitting makes the flat bands away from Fermi level, and bring two vHSs near the Fermi level. We estimate the magnetic parameters, and find that the ferromagnetic nearest-neighbor  $J_1$  dominates over the others, while the magnetic interactions between nearest kagome layers favors antiferromagnetic. Based on these spin exchange parameters, the calculated Néel temperature and Curie-Weiss temperature also agree well with the experiments. Furthermore, the magnetic excitation spectra are calculated using linear spin wave theory and a spin gap about 2 meV is predicted. Note that the double cone magnetic transition at a lower temperature cannot be reproduced by these reasonable magnetic parameters. Meanwhile, due to the inversion symmetry and mirror symmetries in the space group P6/mmm of hightemperature phase, the total contribution of DM interactions to the double cone magnetic structure is absent. Since DM interactions are very sensitive to small atomic displacements and symmetry restrictions, and also much more efficient than Heisenberg interactions for causing this canted spin structure, we propose that the double cone spin structure may arise from the structural distortion. We explore 68 possible CDW phases of kagome FeGe which are subgroups of the pristine phase with  $2 \times 2 \times 2$  supercell, and symmetry-allowed four CDW structures which have non-zero DM contribution and may result in double cone spin structure are proposed. These four CDW phases belong to two space groups P622 and  $P6_{3}22$ , and we further propose that they can

be identified from their different numbers of Raman active peaks. Therefore, we believe that symmetry analysis plays an important role in exploring the possible structural distortion in complex magnetic configurations.

			,		

spectively, meanwhile the transformation of spin becomes  $\mathbf{S}_{mp} = M(\alpha)\mathbf{S}_{ln}$ , where  $M(\alpha)$  is the representation matrix of the proper rotation part of the operation  $\alpha$  in the coordinate system, we get the following expression:

$$H = \sum_{l,n,l',n'} \mathbf{S}_{ln} \mathbf{J}_{\mathbf{R}_l + \boldsymbol{\tau}_n, \mathbf{R}_{l'} + \boldsymbol{\tau}_n'} \mathbf{S}_{l'n'}$$
  
$$= \sum_{l,n,l',n'} \mathbf{S}_{ln} M^{\dagger}(\alpha) M(\alpha) \mathbf{J}_{\mathbf{R}_l + \boldsymbol{\tau}_n, \mathbf{R}_{l'} + \boldsymbol{\tau}_n'} M^{\dagger}(\alpha) M(\alpha) \mathbf{S}_{l'n'}$$
  
$$= \sum_{m,p,m',p'} \mathbf{S}_{mp} \left[ M(\alpha) \mathbf{J}_{\mathbf{R}_l + \boldsymbol{\tau}_n, \mathbf{R}_{l'} + \boldsymbol{\tau}_n'} M^{\dagger}(\alpha) \right] \mathbf{S}_{m'p'}$$
(6)

Then the exchange interactions should satisfy the following condition:

$$\mathbf{J}_{\mathbf{R}_m + \boldsymbol{\tau}_p, \mathbf{R}_{m'} + \boldsymbol{\tau}_{p'}} = M(\alpha) \mathbf{J}_{\mathbf{R}_l + \boldsymbol{\tau}_n, \mathbf{R}_{l'} + \boldsymbol{\tau}_n} M^{\dagger}(\alpha) \quad (7)$$

After decomposing the  $3 \times 3$  tensor **J** into scalar Heisenberg term J and vector DM term **D** as in the maintext, we obtain the following results:

TABLE V. The distances, the bond information and the symmetry restricted interactions of corresponding Fe ions between next-nearest-neighbor (001)-planes. Here n, n' and  $R_l$  correspond to  $\mathbf{J}_{\tau n, \tau_{n'}+\mathbf{R}_l}$ , where  $R_l$  and  $\tau_n$  represent the lattice translation vector and the position of magnetic ions in the lattice basis. Three magnetic ions are located at  $\tau_1$  (1/2, 0, 0),  $\tau_2$  (0, 1/2, 0), and  $\tau_3$  (1/2, 1/2, 0). The equivalent  $\mathbf{D}_{c'i}$ 's are labeled as the sub-index of j, i.e. the  $\mathbf{D}_{c'i,j}$  in the table.

-					
Distance(Å)	n	n'	$R_l$	J	DM

	3	1	(0,1,2)		$\mathbf{D}_{c'2,12}(D_{c'2}^x, -\sqrt{3}D_{c'2}^x, -D_{c'2}^z)$
	_				

$$J_{\mathbf{R}_{m}+\boldsymbol{\tau}_{p},\mathbf{R}_{m'}+\boldsymbol{\tau}_{p'}} = J_{\mathbf{R}_{l}+\boldsymbol{\tau}_{n},\mathbf{R}_{l'}+\boldsymbol{\tau}_{n'}}$$
$$\mathbf{D}_{\mathbf{R}_{m}+\boldsymbol{\tau}_{p},\mathbf{R}_{m'}+\boldsymbol{\tau}_{p'}} = M(\alpha)\mathbf{D}_{\mathbf{R}_{l}+\boldsymbol{\tau}_{n},\mathbf{R}_{l'}+\boldsymbol{\tau}_{n'}}$$
(8)

Meanwhile, it is should be noted that the Heisenberg and DM interactions obey the following commutation relations

$$J_{\mathbf{R}_{l'}+\boldsymbol{\tau_{n'}},\mathbf{R}_{l}+\boldsymbol{\tau}_{n}} = J_{\mathbf{R}_{l}+\boldsymbol{\tau}_{n},\mathbf{R}_{l'}+\boldsymbol{\tau_{n'}}}$$
$$\mathbf{D}_{\mathbf{R}_{l'}+\boldsymbol{\tau_{n'}},\mathbf{R}_{l}+\boldsymbol{\tau}_{n}} = -\mathbf{D}_{\mathbf{R}_{l}+\boldsymbol{\tau}_{n},\mathbf{R}_{l'}+\boldsymbol{\tau_{n'}}}$$
(9)

According to the above equations (i.e. Eq. (8) and (9)), one can obtain the symmetry restricted magnetic interactions for kagome FeGe with space group P6/mmm, as shown in table III, IV and V. Note that the equivalent  $\mathbf{D}_i$ 's are labeled as the sub-index of j, i.e. the  $\mathbf{D}_{i,j}$  in table III, IV and V.

#### C. The details of double cone structure

According to the experimental works [51, 54–56], in hexagonal FeGe there is a transition from a uniaxial spin system to a double cone spin structure at  $T_{canting} = 60$ K [51], which is expressed by the following equations:

$$\langle S^x \rangle = S \sin \theta \cos \left( (\pi \pm \delta) \frac{z}{c} + \varphi \right)$$

$$\langle S^y \rangle = S \sin \theta \sin \left( (\pi \pm \delta) \frac{z}{c} + \varphi \right)$$

$$\langle S^z \rangle = S \cos \theta \cos \left( \frac{\pi z}{c} \right)$$

$$(10)$$

where  $\theta$  is the cone half angle, and c represents the lattice parameter. If  $\delta = 0$  there will be a simple tilting of the spins. When  $\delta$  represents the small angle, Eq. (10) gives a double cone spin structure. Following the previous works [51, 54–56], here we consider the MAE with the expression neglecting terms of order higher than four written as

$$E_{MAE} = K_2 \sin^2 \theta + K_4 \sin^4 \theta \tag{11}$$

Therefore the total energy of Eq. (5) and Eq. (11) in double cone spin structure per unit cell could be written as

$$E(\delta, \theta) = \sum_{i} N_{ci} J_{ci} (-\sin^2 \theta \cos \delta - \cos^2 \theta) + \sum_{i} N_{c'i} J_{c'i} (\sin^2 \theta \cos 2\delta + \cos^2 \theta) - \sum_{i,j} D_{ci,j}^z (\sin^2 \theta \sin \delta) - \sum_{i,j} D_{c'i,j}^z (\sin^2 \theta \sin 2\delta) + N(K_2 \sin^2 \theta + K_4 \sin^4 \theta)$$
(12)

where  $N_{ci}$  and  $N_{c'i}$  are the corresponding number of neighbors of  $J_{ci}$  and  $J_{c'i}$ , and N represents the number of magnetic ions in one unit cell. When DM interactions are not considered, the extremum condition in total energ gives the equilibrium value of wave vector  $\delta$  with following equation [51, 56]:

$$\cos \delta = \frac{\sum_{i} N_{ci} J_{ci}}{4 \sum_{i} N_{c'i} J_{c'i}} \tag{13}$$

While the cone half angle  $\theta$  has the expression as

$$\sin^2 \theta = -\frac{K_2 - \frac{1}{2N} \sum_i N_{c'i} J_{c'i} \delta^4}{2K_4}$$
(14)

A minimum in the total energy (see Eq. (12)) will occur only if  $K_4$  is positive, and Eq. (14) requires that  $K_2 - \frac{1}{2N} \sum_i N_{c'i} J_{c'i} \delta^4$  must be negative. When the magnetic interactions including Heisenberg

When the magnetic interactions including Heisenberg and DM interactions between two nearest neighbor xyplanes, i.e.  $J_{ci}$  and  $\mathbf{D}_{ci}$ , are considered, the equilibrium value of wave vector  $\delta$  is obtained by the minimum in total energy written as

$$\tan \delta = \frac{\sum_{i,j} D_{ci,j}^z}{\sum_i N_{ci} J_{ci}} \tag{15}$$

where j is the sub-index of the equivalent  $\mathbf{D}_{ci}$ 's. Meanwhile, we find the following expression for  $\theta$ 

$$\sin^2 \theta = -\frac{K_2 - \frac{1}{2N} \sum_{i,j} D_{ci,j}^z \delta}{2K_4}$$
(16)

Note that in Eq. (16), DM interactions are combined with only the first order of  $\delta$ , and may have much more efficient than  $J_{c'i}$  in Eq. (14) since  $\delta$  is small around 0.2 [51, 53]. This implies that DM interactions may be the origin of double cone structure.

## D. The symmetry analysis of CDW phases

The high-temperature phase FeGe crystallizes in space group P6/mmn, which has the generators  $\{3^+_{001}|0\}$ ,  $\{2_{001}|0\}, \{2_{110}|0\}$  and  $\{-1|0\}$ , where the left part represents the rotation and the right part means the lattice translation (here -1 denotes the inversion symmetry). According to the inversion symmetry, the total contribution of DM interactions to the energy of double cone magnetic structure in Eq. (12) is absent, i.e.  $\sum_{i,j} D_{ci,j}^z = 0$ , which is easy to see from the table IV-V. Firstly, each kagome layer is still FM in the double cone magnetic state, thus the in-plane DM interactions are ineffective. For interlayer DM interactions with an inversion center such as  $\mathbf{D}_{c1}$ , the inversion symmetry restricts it to be zero as shown in table IV. Meanwhile, for other interlayer DM interactions, the inversion symmetry combine the equivalent DM interactions in pairs. For example, as shown in table IV, the  $\mathbf{D}_{c2,1}$  and  $\mathbf{D}_{c2,7}$  are connected by the inversion symmetry, and have opposite values. Therefore, the summation over equivalent interlayer DM interactions are all zero due to the inversion symmetry. Note that not only inversion symmetry, but mirror symmetries such as  $\{m_{001}|0\}, \{m_{110}|0\}, \{m_{100}|0\}, \{m_$  $\{m_{010}|0\}, \{m_{1-10}|0\}, \{m_{120}|0\}$  and  $\{m_{210}|0\}$  in space group P6/mmm, would also make the DM contribution to the canted magnetic ground state to be zero based on the similar analysis above. Therefore, DM interactions have no contribution to double cone magnetic structure with the symmetry of high-temperature phase.

As mentioned in the maintext, since the  $2 \times 2 \times 2$ supercell structure of CDW phase (compared with the nonmagnetic pristine phase) is suggested experimentally [45, 46, 48, 49], we present the possible CDW phases of kagome FeGe with  $2 \times 2 \times 2$  supercell. The  $2 \times 2 \times 2$ supercell without distortion has the symmetry of space group P6/mmm, the non-primitive translation operations  $t_x \{1|1/2,0,0\}, t_y \{1|0,1/2,0\}, t_z \{1|0,0,1/2\}, \text{ and }$ many symmetry operations from their combinations. As the subgroups compatible with  $2 \times 2 \times 2$  supercell of pristine FeGe, the structural distortion of CDW phases would break the non-primitive translation operations  $t_x$ ,  $t_y$  and  $t_z$ , and possibly break other symmetry operations as well. Since the point group associated with hightemperature phase FeGe (P6/mmm) is  $D_{6h}$ , we consider all CDW phases whose associated point group is  $D_{6h}$  itself or in maximal subgroups of  $D_{6h}$  ( $D_{2h}$ ,  $D_6$ ,  $C_{6h}$ ,  $C_{6v}$ ,  $D_{3d}, D_{3h}$ ). In total we find 68 different possible CDW phases, and list the corresponding relations of atomic positions in the high-temperature phase and all types of

proposed CDW phases in table VI-X. Note that the inversion symmetry and mirror symmetries in parent group P6/mmm would all eliminate the contribution of DM interactions based on the symmetry analysis. Among these 68 proposed CDW phases, only four distorted structures do not have the inversion symmetry and mirror symmetries, which can lead to non-zero DM contribution to double cone spin structure and may explain this magnetic ground state. They belong to two space groups P622 and  $P6_322$ , and we list the corresponding Wyckoff positions and the coordinates of the atoms in the pristine phase and these four CDW phases in table II of the maintext.

TABLE VI. The corresponding Wyckoff positions and the coordinates of the atoms in the pristine phase and CDW phases with different symmetries. (PART I).
