Key Points:

- Temporal scales of electron precipitating flux variations are studied with ELFIN CubeSats
- Main patterns include microbursts of \sim 1s, modulated precipitation of \sim 1min, and equatorial parameter variations of \sim 10min
- Possible explanations of such time scales are discussed

Abstract

Electron resonant scattering by whistler-mode waves is one of the most important mechanisms responsible for electron precipitation to the Earth's atmosphere. The temporal and spatial scales of such precipitation are dictated by properties of their wave source and background plasma characteristics, which control the efficiency of electron resonant scattering. We investigate these scales with measurements from the two low-altitude ELFIN CubeSats that move practically along the same orbit, with along-track separations ranging from seconds to tens of minutes. Conjunctions with the equatorial THEMIS mission are also used to aid our interpretation. We compare the variations in energetic electron precipitation at the same L-shells but on successive data collection orbit tracks by the two ELFIN satellites. Variations seen at the smallest inter-satellite separations, those of less than a few seconds, are likely associated with whistler-mode chorus elements or with the scale of chorus wave packets (0.1 - 1 s in)time and ~ 100 km in space at the equator). Variations between precipitation L-shell profiles at intermediate inter-satellite separations, a few seconds to about 1 min, are likely associated with whistler-mode wave power modulations by ultra-low frequency (ULF) waves, i.e., with the wave source region (from a few to tens of seconds to a few minutes in time and ~ 1000 km in space at the equator). During these two types of variations, consecutive crossings are associated with precipitation L-shell profiles very similar to each other. Therefore the spatial and temporal variations at those scales do not change the net electron loss from the outer radiation belt. Variations at the largest range of inter-satellite separations, several minutes to more than 10 min, are likely associated with mesoscale equatorial plasma structures that are affected by convection (at minutes to tens of minutes temporal variations and $\approx [10^3, 10^4]$ km spatial scales). The latter type of variations results in appreciable changes in the precipitation L-shell profiles and can significantly modify the net electron losses during successive tracks. Thus, such mesoscale variations should be included in simulations of the radiation belt dynamics.

1 Introduction

Energetic electron scattering by whistler-mode waves is the main mechanism responsible for sub-MeV electron flux depletion deep inside the Earth's inner magnetosphere (Millan & Thorne, 2007; Thorne et al., 2021). There are two main regimes of such scattering: quasi-linear diffusion by low-amplitude, low-coherence waves (Lyons & Williams, 1984; Schulz & Lanzerotti, 1974) and nonlinear resonant transport by intense, highly coherent waves (Hsieh & Omura, 2017; Hsieh et al., 2020; Artemyev, Neishtadt, & Angelopoulos, 2022). Such a classification in two distinct regimes is oversimplified. Actual wave-particle interactions are more complex, including, e.g., non quasi-linear diffusion by intense waves (Karpman & Shklvar, 1975; Shklvar, 2021), destruction of nonlinear resonant interactions due to wave-packet amplitude, frequency or phase modulation (Tao et al., 2013; Mourenas et al., 2018; Hiraga & Omura, 2020; An et al., 2022; Gan et al., 2022) and decoherence (X. J. Zhang, Mourenas, et al., 2020; X. J. Zhang, Agapitov, et al., 2020), and breach of the quasi-linear diffusion approximation by highly coherent (Allanson et al., 2022), intense (Karimabadi et al., 1992; Cai et al., 2020) waves. Many of these effects have been predicted and described theoretically (see reviews by Shklyar & Matsumoto, 2009; Albert et al., 2013; Artemyev et al., 2018, and references therein) based on near-equatorial whistler-mode wave measurements, but their contribution to electron losses relative to classical quasi-linear diffusion and nonlinear resonant transport cannot be easily evaluated from electron flux measurements around the equator, due to the smallness of the loss cone there. However, the temporal and spatial properties of the precipitation resulting from the aforementioned scattering regimes and processes can be assessed from low-altitude satellite measurements, and can be used to differentiate them from each other, as well as to assess their relative contribution to electron losses. There exist three typical spatio-temporal scales of near-equatorial whistler-mode wave-electron resonant interactions: (i) $\sim 10^2$ km, < 1s scale variations of individual coherent wave-packets, or chorus elements (Santolík et al., 2004; Agapitov et al., 2010, 2017; Turner, Lee, et al., 2017); (ii) $\sim 10^3$ km, ~ 1 min scale variations of whistler-mode wave source regions (Agapitov, Mourenas, Artemyev, Mozer, Bonnell, et al., 2018); and (iii) ~ 10^4 km, \geq a few min scale variations of equatorial gradients of plasma sheet density, and flux of injected electrons (e.g., typical injection scale Tao et al., 2011; Runov et al., 2011). At a low-altitude, polar-orbiting spacecraft, moving at ≈ 8 km/s, microburst precipitation of a sub-second duration (assumed spatial) would map to a $\lesssim 10^2 \ \rm km$ structure at the equator (O'Brien et al., 2004; Douma et al., 2019). Comparison of such measurements at two low-altitude spacecraft with time-resolution of seconds, full L-shell coverage and time-separation of a few seconds to many minutes, can reveal equatorial variations of precipitation on scales from a few hundred km to several $\times 10^4$ km (depending on L-shell), and establish statistical or multi-case study trends of their temporal variations from seconds to minutes. In this study, we use such dual, low-altitude satellite measurements from the ELFIN mission (Angelopoulos, Tsai, et al., 2020). A variety of time separations allow us to investigate the variations of whistler-mode wave-driven electron precipitation on these three spatio-temporal scales.

More specifically, we expect that the smallest spatio-temporal scale of electron precipitation corresponds to the coherence scale of a chorus element (Santolík & Gurnett, 2003; Agapitov et al., 2017; Turner, Lee, et al., 2017). Chorus waves, nonlinearly generated whistler-mode waves (Nunn et al., 2005; Demekhov, 2011; Tao et al., 2020; Omura, 2021), propagate in the form of wave packets forming elements with increasing (rising tone) or decreasing (falling tone) frequency. The duration of such elements does not exceed one second (Teng et al., 2017, 2019), whereas the cross-field coherence of the wave field in such elements does not exceed a few hundreds of km (note that low-altitude spacecraft would cross this scale within less than one second). Thus, the time scale of the resultant microburst precipitation should be within one second, which can only be distinguished by two low-altitude, polar orbiting spacecraft that are separated by a sub-second time difference (Blake & O'Brien, 2016; Shumko et al., 2020). On the other hand, chorus elements are often generated in series, one after another, and their properties often do not vary significantly from element to element within a few seconds (e.g., SantolíK et al., 2003; W. Li, Thorne, Bortnik, Shprits, et al., 2011; Demekhov et al., 2017). Therefore, similar bursty precipitation patterns (microbursttype) can be seen by spacecraft separated by a few seconds. In this study, we will examine the pitch-angle (precipitating and trapped fluxes) and energy distributions of such second-scale precipitation events using the highest temporal resolution of ELFIN, a spin-sector cadence of ~ 0.175 s, at full energy resolution.

We hypothesize that the spatial scale of the whistler-mode wave equatorial excitation (source) region (Agapitov et al., 2010; Aryan et al., 2016), from one to a few thousand km, which varies on time scales of minutes (from tens of seconds to several minutes), should be recognizable as 3-30 s precipitation structures which would fluctuate in consecutive precipitation spectra on ELFIN separation time-scales of the order of (but no shorter than) tens of seconds (say, 1 - 10 min). The temporal and spatial variations of the wave source region are mainly attributed to the modulation of the wave's free energy source (anisotropy in the electron velocity distribution) by ULF waves (having wavelengths below $1R_E$ and periods below a few minutes, as discussed e.g., in W. Li, Thorne, Bortnik, Nishimura, and Angelopoulos (2011); W. Li, Bortnik, et al. (2011); Watt et al. (2011); Xia et al. (2016); L. Li et al. (2022)). Accordingly, we anticipate observations of a stable electron precipitation pattern at ELFIN on a spatial scale of a few to a few tens of seconds, and with similar profiles and intensity on consecutive passes separated by less than 30 seconds. However such profiles of precipitating fluxes should vary (potentially in absolute intensity, location or extent) temporally (from one crossing to the next), in events as the inter-satellite separation increases from 0.5 min to a few minutes. In this study, we will confirm our hypothesis that such 3-30s long, minute-scale precipitation pattern variations are indeed consistent with observations by the two ELFIN satellites.

Whistler-mode chorus waves are typically generated by perpendicularly anisotropic electrons produced by injections (Tao et al., 2011; Fu et al., 2014; X. Zhang et al., 2018; Frantsuzov et al., 2022). The spatial scale of injected electrons is about $\sim 10^4$ km (Nakamura et al., 2004; Liu et al., 2013). These injections also cause large density variations in the background plasma sheet and plasmaspheric plasma (Malaspina et al., 2014, 2015) on a similar spatial scale. Because the injections are spatially localized, the anisotropic electron flux and associated waves, as well as the ambient density have significant gradients, which will be also manifest in the regions of resonant wave-electron interactions and scattering, affecting the precipitation patterns. The aforementioned spatial structures map to a time scale of precipitation lasting about $\sim 0.5 - 1.5$ min on a polar orbiting satellite at low altitudes, depending on L-shell. Moreover, these injected electrons can persist for a long time, slowly drifting azimuthally towards the dawn (Tao et al., 2011; Turner, Fennell, et al., 2017). Based on the duration of such injections and density variations at the equator (a few minutes), we expect that the region of associated electron precipitation can also be repeated at successive ELFIN passes with inter-satellite separations of a few minutes but no longer. At longer separations, we expect the precipitation patterns of such duration to change significantly. In this study, we confirm this interpretation using examples of such long-lived regions of precipitation and conjunctions with equatorial THEMIS satellites.

The remainder of this paper is structured as follows: Section 2.1 describes ELFIN instruments and criteria for event selection; Section 2.2 shows two examples of consecutive observations by ELFIN satellites with second-scale separations; Section 2.3 shows an example of consecutive observations at minute-scale separations, in conjunction with near-equatorial measurements of whistler-mode waves; Section 2.4 shows observations of ELFIN CubeSats with ~ ten-minute-scale separations, in conjunction with near-equatorial measurements of whistler-mode waves; Section 3 discusses the results and summarizes our main findings. Although the main text only includes detailed analysis of a few representative events, the Supporting Information (SI) includes analysis of multiple similar events in each category, supporting our conclusions.

2 ELFIN Observations

We examine ELFIN A and B observations with inter-satellite time delay ranging from a few seconds to tens of minutes. The entire list of such events can be found in the Supporting Information, whereas in this section we show typical examples of electron precipitation patterns.

2.1 Dataset and instruments

The two identical ELFIN CubeSats, A and B, are equipped with energetic particle detectors (EPD). Here we use the electron detector (EPDE) measurements (Angelopoulos, Artemyev, et al., 2020) covering the [50, 5000] keV energy range with an energy resolution of $\Delta E/E \sim 40\%$ (16 channels), a pitch-angle resolution of $\Delta \alpha \approx 22.5^{\circ}$, at ≈ 2.8 s temporal resolution. The pitch-angle resolution of $\Delta \alpha \approx 22.5^{\circ}$ (FWHM) is sufficient to separate the locally trapped (between the local loss-cone angle $\alpha_{LC} \sim 65^{\circ}$ at the ELFIN altitude and $\alpha = 90^{\circ}$) electrons from precipitating (at local pitch-angles $\alpha < \alpha_{LC} \sim 65^{\circ}$) electrons (Angelopoulos, Artemyev, et al., 2020). We use three standard data products from this instrument: the spectrum of locally trapped (outside the local bounce loss cone) electron fluxes $j_{trap}(E)$, the spectrum of precipitating (moving toward the ionosphere within the local bounce loss cone) electron fluxes $j_{prec}(E)$, and precipitating-to-trapped flux ratio j_{prec}/j_{trap} . The latter

ratio gives a natural and physically meaningful measure of the precipitation rate. All events analyzed in this study are characterized by precipitation of 50 keV electrons (as well as of higher energy electrons), indicative of electron scattering into the loss cone by resonant interaction with whistler-mode waves (see details of analysis of whistler-mode driven precipitation events observed by ELFIN in, e.g., Mourenas et al., 2021, 2022; Artemyev, Demekhov, et al., 2021; Tsai et al., 2022).

2.2 Examples of small-separation events

This subsection describes two events with a few seconds of separation between the two ELFIN spacecraft. Figure 1 shows an overview of the first event: Panels (a.d) show precipitating electron fluxes, Panels (b,e) show trapped electron fluxes, and Panels (c,f) show the precipitating-to-trapped flux ratio. ELFIN spacecraft move from low L-shell to higher L-shell at the dayside, and observe the outer radiation belt between 09:10-09:14 UT. This region is characterized by high trapped electron fluxes with energies reaching 3-4 MeV at $L \in [4,6]$. At the outer edge of the outer radiation belt, $L \sim 7$, both ELFIN A & B observe bursts of electron precipitation with a time-scale of about one or two ELFIN spins ($\sim 3-6$ s) and typical energies below 300 keV. The precipitating-to-trapped flux ratio reaches ~ 0.3 at $\lesssim 100$ keV, consistent with intense precipitation, but still below the strong diffusion limit (Kennel, 1969). The ratio decreases monotonically with energy above 100 keV. These precipitation bursts are recorded over a region of $\Delta L \sim 0.3 - 0.8$, corresponding to the typical scale of plasma sheet injection drifting to the dayside (Tao et al., 2011), but each individual burst size is $\Delta L \sim 0.025 - 0.08$ (and some may be even smaller, because ELFIN's full pitch-angle distribution cadence is limited by its spin; though, sub-spin observations of similar precipitation bursts can be made with examination of individual spin sectors as in X.-J. Zhang, Angelopoulos, et al. (2022)). Thus, the spatial scale of individual precipitation bursts (160 - 500 km, and occasionally less) is comparable to the chorus wave element size (Agapitov et al., 2017; Agapitov, Mourenas, Artemyev, Mozer, Bonnell, et al., 2018). Based on their duration, these bursts would qualify to be called low-energy microburst precipitation. Such precipitation bursts could be caused by cyclotron resonance interaction with intense, quasi-parallel chorus waves near the equator. But on the dayside during moderately disturbed periods as here (with Kp = 1.3), field-aligned chorus waves often propagate with relatively mild damping to middle (and even high) latitudes (Meredith et al., 2012; Agapitov, Mourenas, Artemyev, Mozer, Hospodarsky, et al., 2018), where cyclotron resonance with intense waves can cause efficient precipitation (with $J_{prec}/J_{trap} > 0.1$) of relativistic electrons up to ~ 300 - 500 keV (X.-J. Zhang, Angelopoulos, et al., 2022). However, during the observed precipitation bursts, efficient precipitation (with $J_{prec}/J_{trap} > 0.1$) is limited to low energies (< 200 keV). It suggests that these precipitation bursts could be driven by electron scattering via Landau resonance with very-oblique chorus waves, which is expected to result in a similar low-energy microburst precipitation (X.-J. Zhang, Artemyev, et al., 2022; Artemyev, Zhang, et al., 2022).

To further explore the properties of the precipitation quantitatively, we compare, in Figure 2, the precipitating electron fluxes and precipitating-to-trapped flux ratios measured by ELFIN A and B. We organize the ELFIN A (blue) & B (red) measured fluxes as a function of *L*-shell. ELFIN A & B cross the same *L*-shell with just a small and constant time delay of 5.4s. Individual precipitation bursts are clearly seen at both spacecraft, but the precipitating flux magnitude and the precipitating-to-trapped flux ratio are different at the two spacecraft, even with such small time-separation (a few seconds). We examine below the possible causes of these variations.

During the very short time elapsed between the ELFIN A and B measurements at the same location, the cold plasma density is expected to remain unchanged, as well as the latitude of Landau (for very oblique waves) or cyclotron (for quasi-parallel waves) resonance with electrons of a given energy (Kennel & Petschek, 1966; W. Li et al., 2013; Mourenas et al., 2021, 2022). Note that for nonlinear Landau resonance (the phase trapping effect) the resonance latitude means the latitude of escape from the resonance, but not the latitude of trapping, because energies of precipitating electrons and latitudes where electrons appear within the loss-cone can be much higher than energies/latitudes of trapping into the resonance (e.g., Agapitov et al., 2015; X.-J. Zhang, Artemyev, et al., 2022). However, for nonlinear Landau resonance, the latitudes of trapping and escape from resonance (as well as initial and final electron energies) are controlled by magnetic field configuration and background plasma density (e.g., Agapitov et al., 2014; Artemyev, Zhang, et al., 2022) and, thus, are not expected to change within the short time interval between ELFIN A and B measurements. Accordingly, for both cyclotron and Landau resonances, the chorus wave power at the latitude of resonance is the only quantity affecting the precipitating-to-trapped electron flux ratio J_{prec}/J_{trap} , and the latter quantity should be a monotonic function of the former. Therefore, at each L, the fraction W of precipitating flux variations ΔJ_{prec} between ELFIN A and B that is directly due to a variation of chorus wave intensity can be evaluated as

$$W = x \quad \text{for } 0 \le x \le 1,$$

$$W = \frac{x}{(2x-1)} \quad \text{for } x < 0, \text{ or } x > 1,$$
(1)
with $x \simeq \left(\frac{\Delta (J_{prec}/J_{trap})}{J_{prec}/J_{trap}}\right) \cdot \left(\frac{\Delta J_{prec}}{J_{prec}}\right)^{-1}.$

To obtain this expression of x, the total variation of the measured precipitating flux between ELFIN-A and ELFIN-B at the same *L*-shell $(\Delta J_{prec} = J_{prec}(ELFIN - A) - J_{prec}(ELFIN - B))$ has been decomposed into two contributions, $\Delta J_{prec} = \Delta((J_{prec}/J_{trap})J_{trap}) = \Delta(J_{prec}/J_{trap}) \cdot J_{trap} + (J_{prec}/J_{trap}) \cdot \Delta J_{trap}$. The first contribution corresponds to the variation of J_{prec}/J_{trap} for a constant J_{trap} , i.e., the part of the measured J_{prec} variation which is solely due to variations in the efficiency of wave-induced electron precipitation (Kennel & Petschek, 1966). The second contribution comes from variations of J_{trap} for a constant J_{prec}/J_{trap} , i.e., for a constant efficiency of wave-induced electron precipitation. The ratio of the first contribution to the measured total ΔJ_{prec} variation can be rewritten as

$$\frac{\Delta(J_{prec}/J_{trap}) J_{trap}}{\Delta J_{prec}} = \frac{\Delta(J_{prec}/J_{trap}) J_{prec}}{\Delta J_{prec} (J_{prec}/J_{trap})} = x.$$
(2)

Finally, the sum of the absolute values of all contributions to the variation of J_{prec} can be written as $S = |\Delta(J_{prec}/J_{trap})J_{trap}| + |\Delta J_{prec} - \Delta(J_{prec}/J_{trap})J_{trap}|$. Accordingly, the ratio of the contribution from $|\Delta(J_{prec}/J_{trap})J_{trap}|$ over the sum of all contributions is W = x for $0 \le x \le 1$ and W = x/(2x-1) for x < 0 or x > 1, as in Equation (1). W is a quantitative measure of the portion of J_{prec} variations that is solely attributable to J_{prec}/J_{trap} variations, which are themselves controlled by wave intensity variations. Thus, W shows how significantly J_{prec} varies due to the sole changes in wave intensity. The remaining portion (1 - W) of J_{prec} variations between ELFIN A and B is due to a variation of trapped electron fluxes J_{trap} during the event. For a constant J_{trap} , the entire variation of the precipitating flux is due to variations in the wave intensity: when x = 1, $W \to 1$. For a constant J_{prec}/J_{trap} variations: when $x = 0, W \to 0$.

W, plotted as a function of L for select energies in Figure 2(i), has high average values for this event, $\langle W \rangle \sim 0.66 - 0.73$ at 63 - 183 keV. During the main bursts of electron precipitation at L = 6.6 - 6.7 and L = 6.9 in Figures 2(a-c), W reaches even higher values, $W \simeq 0.80 - 0.95$. This implies that such bursts are associated with a stable (at least on a time scale of a few seconds) whistler-mode wave source,

where the variation of precipitating electron flux is principally due to a variation of the wave intensity within a time scale of a few seconds. This time scale is too short to be due to whistler wave source modulation by dayside compressional ultra-lowfrequency waves (such modulation is observed on time scales of tens of seconds to several minutes, see X. J. Zhang, Angelopoulos, et al., 2020). Therefore, variations between precipitation profiles at second-scale separations should indeed be attributed to wave power variations within individual chorus elements, produced by the whistlermode chorus wave generation processes themselves (see discussions of such wave power variations in theories of chorus wave generation, e.g., in Demekhov et al., 2017; Nunn et al., 2021).

A second event with a small (~ 3s) inter-spacecraft separation is shown in Figures 3 and 4, in the same format as Figures 1 and 2. Again, the figures depict dayside ELFIN observations exhibiting a series of bursty precipitation outside the plasmapause, at L > 5, within the outer radiation belt. However, in this event, the energies of precipitating electrons reach 700 keV, i.e., these are relativistic precipitation bursts, resembling ELFIN observations of relativistic microbursts (X.-J. Zhang, Angelopoulos, et al., 2022). At the ~ 3s inter-spacecraft separation of this event, the spacecraft show similar L-shell profiles of precipitating electron fluxes and precipitating flux ratios (Figure 4): one event at $L \sim 5.4$ is nearly unchanged after 2.8s, several events at L>6 are modified, and one event, at $L \sim 5.8$, is only seen on ELFIN A. The fraction W of precipitating electron flux variation between ELFIN A and B that can be ascribed to chorus wave intensity variation is on average lower than during the preceding event, $\langle W \rangle \simeq 0.36 - 0.45$, but it reaches again high levels $W \sim 0.55 - 0.90$ during 4 of the main precipitation bursts, at $L \simeq 5.8$, L = 6.0, L = 6.4, and L = 6.6 in Figure 4(i).

Based on these two events, we can conclude that bursty electron precipitation can sometimes remain relatively stable over a time-scale of the order of one second (Shumko et al., 2021), although that should represent an upper bound for the duration of chorus wave phase coherence. This could be partly due to the $\sim 1s$ (~ 6 spin sector) time-averaging of the measured precipitating flux employed in this paper, which smooths faster variations. This time-averaged precipitating flux should result from wave-particle interactions with at least one full chorus element, including many different sub-packets. Therefore, it should be more stable than sub-second bursts produced by individual intense wave packets. It should mainly correspond to scattering by waves with the average amplitude of a chorus rising tone element, within a series of similar elements often lasting a few seconds or more in total (SantolíK et al., 2003; Nunn et al., 2009; W. Li, Thorne, Bortnik, Shprits, et al., 2011; Demekhov et al., 2017). During such time-scale of several seconds, the characteristics of the fine structure of the precipitation pattern measured by ELFIN A & B, including the multiple bursts distributed in $L \in [5, 8]$, indeed remain the same, including the recurrence rate versus L and the energy spectrum of the precipitating electrons.

2.3 Example of medium-separation event

The two preceding examples, with only a few seconds of inter-spacecraft separation, established a baseline for further comparisons at larger separations. Figure 5 shows an example of such observations with an ~ 8 min spacecraft separation. Both spacecraft measured multiple precipitation bursts over a significant portion of the outer radiation belt and the inner-edge of the plasma sheet at $L \in [4.5, 12]$. The most intense precipitation events are observed at L > 6. A comparison of ELFIN A and B trapped and precipitating fluxes in this event shows that at ~ 8 min delay there is significant evolution of the electron distributions, both above and inside the loss cone: they are both reduced considerably with the elapsed time (at ELFIN B compared to at ELFIN A). However, the energy range of most significant precipitation (based on the precipitation ratio spectrogram in Panels (c,f), does not vary between ELFIN A and B. It has similar profile and remains limited to energies less than ~ 300 keV. This suggests that the plasma frequency to gyrofrequency ratio f_{pe}/f_{ce} , which controls the latitude of resonance and the energy of precipitating electrons (e.g., see Agapitov et al., 2019; Artemyev, Zhang, et al., 2022; L. Chen et al., 2022), probably did not change significantly over 8 min at most locations.

Comparing line plots of the precipitating fluxes and precipitating-to-trapped flux ratios at several energies in Figure 6, we see more clearly that the pattern of precipitating fluxes is similar for both spacecraft: spatially quasi-periodic precipitation peaks between $L \in [4.5, 14]$. Figure 6(i) further shows that most of these precipitation peaks $(L \sim 6.0, 6.5, 8.5, 9.5, 13.)$ correspond to a high fraction $W \sim 0.7 - 0.9$ of precipitating flux variation (as opposed to trapped flux variation) attributable to chorus wave intensity variation at the latitude of Landau or cyclotron resonance with precipitating electrons, compared to the moderate average level $\langle W \rangle \sim 0.5$ during the entire event. However, these peaks are located at different *L*-shells for ELFIN A and B. Moreover, where ELFIN A observed precipitation peaks ELFIN B occasionally observed local minima of precipitation.

This is likely an effect of precipitation modulation by ULF waves (Motoba et al., 2013). Such waves preferentially originate from the dawn flank magnetopause due to foreshock transients (Hartinger et al., 2013, 2014), propagate to lower L (Wright & Elsden, 2020; Klimushkin et al., 2019; X. J. Zhang, Angelopoulos, et al., 2020), and modulate the equatorial generation of whistler-mode chorus waves (W. Li, Thorne, Bortnik, Nishimura, & Angelopoulos, 2011; Watt et al., 2011; Xia et al., 2016; X.-J. Zhang et al., 2019; L. Li et al., 2022) responsible for electron precipitation. As a result, precipitation patterns should be quasi-periodic in time and space (L), at the typical temporal period of ULF waves (several minutes) and with a spatial period similar to the ULF wavelength ($\sim R_E$). To verify this conjecture, we plot in Figure 7 the conjugate equatorial observations from THEMIS E, D, and A. The whistler-mode chorus waves observed by THEMIS E at $f \sim 0.15 f_{ce}$ (with f_{ce} being the electron gyrofrequency) over a wide L-shell range are indeed quasi-periodic in wave power (a temporal effect at the slowly moving THEMIS spacecraft). Similarly, quasi-periodic whistler-mode waves have been measured by THEMIS A, D at the same L-shell range, but 30 min ahead of THEMIS E measurements (due to the time difference in their orbits). The wave spectra at THEMIS A, D have low frequency resolutions (6 channels instead of 32 channels for THEMIS E); but presence of quasi-periodic whistler-mode waves at all three THEMIS spacecraft demonstrates that these waves occupy a large MLT, L-shell domain and can lead to the electron precipitation bursts at ELFIN. Moreover, the energy range of precipitating electrons (from 300 keV and down to the lowest energy channel at 50 keV) agrees well with the expected energy range of electrons resonating with $f \sim 0.15 f_{ce}$ whistler-mode waves (see Horne et al., 2013; Ni et al., 2014, for diffusion rates evaluated based on observed whistler-mode wave characteristics).

ULF fluctuations of the parallel (compressional) component of the background magnetic field are simultaneously measured by THEMIS E, reaching amplitudes of ~ 1.5 nT, with a period of ~ 5-6 min which is typical of Pc5 waves. A comparison of Figures 7(a,b) shows that most bursts of chorus wave intensity occur at minima of the variations of the parallel component of the magnetic field. This is consistent with a modulation of the distribution of 5-50 keV electrons by ULF waves that, in turn, modulates the growth of chorus waves below ~ 0.3 f_{ce} (W. Li, Thorne, Bortnik, Nishimura, & Angelopoulos, 2011; Xia et al., 2016). This suggests that the precipitation on time-scales of minutes may be due to ULF wave-driven modulation of whistler-mode wave power at the equator.

2.4 Example of large-separation event

Figure 8 shows an example of an event with inter-spacecraft separation ~ 13.5 min. It shows multiple bursts of precipitation in the outer radiation belt (between the plasmashere at $L \sim 4$ and plasma sheet at $L \geq 8$; the latter is characterized by isotropic precipitation with low level of trapped fluxes). As during the previous event, here too there is a significant decrease of the precipitating flux magnitude from ELFIN A to ELFIN B. But contrary to the previous event, the precipitating-to-trapped flux ratio also exhibits a decrease in time and in the energy of significant precipitation, during the ~ 13.5 min elapsed between ELFIN A's to ELFIN B's observations. Figure 9 confirms in line-plot format that the precipitating fluxes at ELFIN A are much higher than those at ELFIN B, and this effect increases with energy. Figure 9(i) further shows that the highest peaks of precipitating flux at L = 5.7 and L = 6.3 - 6.8 have a significantly higher value of $W \sim 0.95$ compared to the average during the event. This signifies that at these two L-shell regions, there is an increase in the fraction of precipitating flux variation which is potentially attributable to chorus wave intensity variation at the latitude of resonance (rather than to trapped flux variation) for higher electron energy $\sim 300 \text{ keV}$ than for lower energy $\sim 100 \text{ keV}$. Such variations of both the energy range and efficiency of electron precipitation cannot be explained by a quasi-periodic modulation of whistler-mode waves by ULF waves. Some mesoscale (~ 10 min, ~ R_E) variations of the background plasma parameters should be involved.

To examine the equatorial plasma and wave variations during the time elapsed between the two ELFIN crossings, we take advantage of measurements from multiple THEMIS probes (THEMIS D, A and E) that were in conjunction with ELFIN at the time, as evidenced by their ionospheric projections in Figure 10(d). THEMIS D, A and E were moving along almost the same orbit (ordered from the leading to the trailing spacecraft) with an MLT separation of ~ 0.5 hour and along-track separation of ~ 30 min (also evident in Figure 10(d)). THEMIS E observed continual (though intermittent) power enhancements of whistler-mode waves (Figure 10(a)), accompanied by variations in the background plasma density (not shown). Figure 10(a) shows the high-resolution magnetic field spectrum (32 frequency channels at \sim [1Hz, 4kHz], at 1s cadence, see Cully et al. (2008) for details of this fff dataset), which was not available at THEMIS D and A during this interval. The low-resolution magnetic field spectrum (the fbk dataset with 3s cadence, 6 frequency channels at \sim [1Hz, 4kHz]) at THEMIS A shows the same whistler-mode waves as in Fig. 10(a). Therefore, these whistler-mode waves occupy a large MLT sector in space (quite typical for the dawn flank, see Meredith et al., 2012; Agapitov, Mourenas, Artemyev, Mozer, Hospodarsky, et al., 2018) and can explain the electron precipitation observed by ELFIN. Moreover, only whistler-mode waves can resonantly scatter and precipitate electrons over such a wide energy range (from ~ 1 MeV and down to the lowest available energy channel of 50 keV).

The measured density (not shown) and magnetic field (shown in Figure 10(c) for THEMIS E, and in good agreement with the Tsyganenko magnetic field model) allow us to infer the equatorial magnetic field and to compute the ratio of equatorial plasma frequency to the electron gyrofrequency, f_{pe}/f_{ce} in Figure 10(b). Most variations in that quantity reflect local density variations - they are observed at THEMIS on \gtrsim several minute time scales, which is a mixture of temporal and spatial effects. Like the wave power, f_{pe}/f_{ce} too shows significant variability. The spatial and temporal localization effects can be appreciated from the 3 equatorial satellite measurements but the important point here is that large variations in these parameters can be observed at a single point in time due to plasma density and velocity variations. Since f_{pe}/f_{ce} controls the energy range of electrons resonating with whistler-mode waves, it determines both the wave generation at the equator (hence the observed wave power) (e.g., W. Li, Bortnik, et al., 2011) and the resonance energy range of scattering (hence the precipitation efficiency) (Agapitov et al., 2019; Artemyev, Zhang, et al., 2022). Moreover, such mesoscale density variations may cause whistler-mode wave ducting (Hanzelka & Santolík, 2019; Hosseini et al., 2021; Ke et al., 2021; R. Chen et al., 2021), allowing them to propagate along the field line without strong damping to higher (middle) latitudes (Bortnik et al., 2007; L. Chen et al., 2013), where these ducted waves can scatter relativistic electrons (e.g., L. Chen et al., 2022). The event shown in Figures 8-10 is a good example of strong variations of electron precipitation due to mesoscale variations of the equatorial plasma density and the dynamic and complex phenomena that arise as a result of such variations on timescales greater than several minutes.

Figures S1-S3 in the Supporting Information (SI) show a similar event with ELFIN A and B separated by ≥ 10 minutes and conjugate observations of mesoscale plasma density (or f_{pe}/f_{ce}) variations from THEMIS A, D, E. *L*-shell profiles of precipitating-to-trapped fluxes on ELFIN A and B are quite different, and this difference is larger for higher energy electrons which are scattered and precipitated by the waves farther from the equator. Therefore, this event too supports our conclusions derived from ELFIN and THEMIS observations in Figs. 8-10. Six additional events in SI present ELFIN A and B measurements with inter-satellite separations ~ 10 min, but without conjugate equatorial THEMIS measurements. These events are shown in Figs. S4-S15 and confirm that a ≥ 10 min separation is sufficiently large to provide quantitatively different net precipitation of energetic electrons.

3 Discussion and Conclusions

In this study we show variations of electron precipitating fluxes over three different temporal and spatial scales. Comparison of ELFIN A and B measurements at inter-satellite separations from \sim a few seconds to \sim 15 min reveals the existence of three types of precipitation patterns and associated variability. Differences on the shortest time-scale of separation, $\lesssim 5$ s, corresponds to variations of individual precipitation bursts most likely due to variation of whistler-mode waves over the typical scale of chorus elements, or series of such elements. Such short-scale variations are usually observed during electron microburst precipitation events (Blake & O'Brien, 2016; Shumko et al., 2020). Their fast timescale suggests they are due to electrons precipitating after a single resonant interaction with whistler-mode wave packets, i.e., they are likely due to nonlinear resonant interactions with very intense chorus wave packets quickly scattering electrons into the loss cone (L. Chen et al., 2022; X.-J. Zhang, Artemyev, et al., 2022; Hsieh et al., 2022). Our study shows that the spacecraft provide very similar precipitating fluxes and precipitating-to-trapped flux ratios over such a small time delay (< 5 s) between measurements, even though individual bursts are usually not identical on consecutive passes. The general agreement of the spectra also demonstrates that ELFIN A and B measurements are well inter-calibrated and may be used to quantify precipitation variations on longer time-scales as well. The medium temporal scale of inter-spacecraft separations, \sim a few minutes, reveals ULF wave associated variations of the equatorial whistler-mode source region. ULF waves with period of a few minutes cause the whistler-mode wave power (driven by ULF wave peaks or troughs) to move radially and hence can displace the associated whistler-mode chorus wave driven precipitation bursts in latitude. However, they do not change the intensity of precipitation bursts within a wide L-shell range where the ULF waves propagate. In other words, the location of peaks of precipitating-to-trapped flux ratio may change but their magnitude remains approximately the same. The largest intersatellite separations that we examined, $\gtrsim 10$ min, reveal variations of precipitating fluxes which are associated with equatorial mesoscale variations of background plasma and magnetic field characteristics (potentially also related to simultaneous variations of trapped electron fluxes). Contrary to ULF wave-driven variations, these mesoscale variations change the equatorial density and energetic electron flux responsible for

for whistler-mode wave generation. Such changes occur due to convection (including corotation) and injections that modify drastically the plasma density and electron flux over timescales of many minutes and spatial scales $\approx 1 R_E$. This can cause both the intensity of precipitating fluxes and the energy range of precipitating electrons (which depends critically on the equatorial plasma density) to vary significantly within a ≥ 10 min interval. These three temporal scales are still below the ~ 1 hour time scale of substorm dynamics, and thus all three scales should not be related to any significant magnetic field reconfiguration.

Let us discuss the importance of such temporal variations for electron precipitation. The smallest time-scales (≈ 1 s) of variations of precipitating fluxes are simply a consequence of the transient nature of chorus wave generation, but likely do not change the total amount of electron losses. Despite the general interest in such variations and their importance for the investigation of the fine wave-particle resonant effects (see discussion in Shumko et al., 2021), their inclusion into radiation belt models remains a topic of debate (see discussion in Thorne et al., 2005). Although the nature of microbursts is likely dominated by nonlinear electron resonant interactions, the long-term effect of these nonlinear interactions can probably be described as a diffusive process with diffusion rates differing somewhat from the quasi-linear ones (Artemyev, Neishtadt, et al., 2021; Artemyev, Mourenas, et al., 2022). Therefore, after being averaged, such multiple microbursts effects, may be incorporated into the classical Fokker-Plank equations via renormalization of electron diffusion rates (Artemyev, Mourenas, et al., 2022).

The medium-scale variations (likely driven by ULF wave modulation of the equatorial whistler-mode source, see, e.g. W. Li, Thorne, Bortnik, Nishimura, and Angelopoulos (2011); Xia et al. (2016); X.-J. Zhang et al. (2019)) are mostly responsible for quasi-periodic spatial and temporal dynamics of the precipitating bursts, but also do not alter the number of such bursts and their intensity within the outer radiation belt. One of the main effects of such variations is the appearance of quasi-periodic pulsations of precipitating electron fluxes and diffuse aurora (see review by Nishimura et al., 2020, and references therein). However, with regard to the net electron losses from the outer radiation belt, these variations can be averaged. The main question raised by such variations is the consequence of whistler-mode modulation by ULF waves for electron losses. Is it a simple spatial variation of the precipitation rate with an average equal to the same net precipitation as in the absence of ULF waves? Or can the ULF wave variation render previously marginally stable electron distributions unstable to wave generation, thus increasing the net precipitation above what it would have been without the ULF waves? In other words, can ULF waves generate whistler-mode waves and the associated electron precipitation from a marginally stable plasma?

The large-scale ($\geq 10 \text{ min}$) variations of electron precipitation are likely due to mesoscale temporal and spatial variations of the equatorial plasma density and energetic electron fluxes, both responsible for whistler-mode wave generation, and precipitating electron fluxes. Scales of ~ $1R_E$ are typical for plasma injections (Nakamura et al., 2002; Liu et al., 2013) and cold plasma density plumes (e.g., Darrouzet et al., 2009; Goldstein et al., 2014). These spatial structures which evolve (at an approximately fixed MLT) over > 10min due to convection or injections, can be observed in precipitation patterns as differences in precipitating fluxes measured by consecutive ELFIN passes over the same MLT sector. Such large-scale precipitation variations should be quite important for the evaluation of net electron losses, because the intensity of precipitation may vary significantly with the combined variations of equatorial plasma density and whistler-mode characteristics. Empirical models of waves and plasma density are constructed independently, and their combination does not include the effect of mesoscale plasma density structures correlated with wave activity. Therefore, such plasma density and wave intensity models will not describe variations of energy range and intensity of electron precipitation observed by ELFIN. This means that Fokker-Plank simulations of energetic electron fluxes may underestimate the role of whistler-mode waves in, e.g., losses of relativistic electrons or acceleration of subrelativistic electrons, as both these processes are strongly dependent on local plasma density and wave characteristics. A new generation of more detailed plasma density models (e.g., Chu et al., 2017; Zhelavskaya et al., 2021) may describe some mesoscale density structures, but these models do not include any correlation with wave activity. Recently, however, several statistical studies of electron quasi-linear diffusion rates have started to take more accurately into account the correlations between wave intensity and local plasma density (Agapitov et al., 2019; Ross et al., 2021). In addition, further investigations of mesoscale wave and background plasma variations and their role for electron precipitation are needed for construction of a next generation wave-plasma models for radiation belt simulations.

Figure 1. The overview of ELFIN A and B observations with a 5.4s time separation. Panels (a,d) show precipitating electron fluxes, Panels (b,e) show trapped fluxes, Panels (c,f) show the precipitating-to-trapped flux ratio.

Figure 2. (a-d) Precipitating electron fluxes versus *L*-shell for the event from Fig. 1. Four energy channels are shown for ELFIN A (blue) and B (red). (e-h) Same as (a-d) but showing the precipitating-to-trapped flux ratio. (i) Fraction *W* of precipitating flux variation between ELFIN A & B measurements due to variation of chorus wave intensity, for selected energies (colors) indicated on the right with the corresponding average $\langle W \rangle$ values.

Figure 3. The overview of ELFIN A and B observations with 2.8s separation between spacecraft. Panels (a,d) show precipitating electron fluxes, Panels (b,e) show trapped fluxes, Panels (c,f) show precipitating-to-trapped flux ratio.

Figure 4. (a-d) Precipitating electron fluxes versus *L*-shell for the event from Fig. 3. Four energy channels are shown for ELFIN A (blue) and B (red). (e-h) Same as (a-d) but showing the precipitating-to-trapped flux ratio. (i) Fraction *W* of precipitating flux variation between ELFIN A & B measurements due to variation of chorus wave intensity, for selected energies (colors) indicated on the right with the corresponding average $\langle W \rangle$ values.

Figure 5. Overview of ELFIN A and B observations with \sim 7.7min separation between spacecraft. Panels (a,d) show precipitating fluxes, Panels (b,e) show trapped fluxes, Panels (c,f) show precipitating-to-trapped flux ratio.

Figure 6. (a-d) Precipitating electron fluxes versus L-shell for the event from Fig. 5. Four energy channels are shown for ELFIN A (blue) and B (red). (e-h) Same as (a-d) but showing the precipitating-to-trapped flux ratio. (i) Fraction W of precipitating flux variation between ELFIN A & B measurements due to variation of chorus wave intensity, for selected energies (colors) indicated on the right with the corresponding average $\langle W \rangle$ values.

Figure 7. THEMIS E equatorial measurements within the *L*-shell, *MLT* region crossed by ELFIN A&B: (a) magnetic field spectrum in the whistler-mode frequency range; black curves show fractions of the electron gyrofrequency, (b) ULF fluctuation $B_{\parallel ULF}$ of the parallel component of the background magnetic field, (c) f_{pe}/f_{ce} ratio, (d) B_z and $B_{xy} = \sqrt{B_x^2 + B_y^2}$ magnetic fields. The bottom panel, (e), shows projections of ELFIN A&B orbits and THEMIS E orbit.

Figure 8. The overview of ELFIN A and B observations with ~ 13.5 min separation between spacecraft. Panels (a,d) show precipitating electron fluxes, Panels (b,e) show trapped fluxes, Panels (c,f) show precipitating-to-trapped flux ratio.

Figure 9. (a-d) Precipitating electron fluxes versus *L*-shell for the event from Fig. 8. Four energy channels are shown for ELFIN A (blue) and B (red). (e-h) Same as (a-d) but showing the precipitating-to-trapped flux ratio. (i) Fraction *W* of precipitating flux variation between ELFIN A & B measurements due to variation of chorus wave intensity, for selected energies (colors) indicated on the right with the corresponding average $\langle W \rangle$ values.

Figure 10. THEMIS equatorial measurements within the *L*-shell, *MLT* region crossed by ELFIN A&B: (a) magnetic field spectrum in the whistler-mode frequency range measured by THEMIS E; black curves show fractions of the electron gyrofrequency, (b) f_{pe}/f_{ce} ratio for THEMIS A, D, and E, (c) B_z and $B_{xy} = \sqrt{B_x^2 + B_y^2}$ magnetic fields measured by THEMIS E, (d) projections of ELFIN A&B orbits and THEMIS A, D, and E orbits.
