Abstract

We intend to give life to a software agent. A software agent is a computer program that acts on a user's behalf. We create a reproductive part for an *agent* that make the agent act and decide independently. Denote this part by *DNA*. We look at an agent as a cell in the body of an alive creature. The operations and behavior of an agent will be determined by *DNA*. There could be several types of agents. The *DNA* illustrates the agent's duties and communication protocols. By defining different *DNA* structures, one can establish new agents and, consequently, different nets for different usage. We initiate such thinking as *DNA programming*. This strategy could lead to a new field of programming. This type of programming can help us manage large systems with various elements with an incredibly more organized customizable structure. An agent can fork another agent. We put one or a few agents around a given network, and the agents will reproduce themselves till they can reach others and pervade the whole network. An agent's position or other environmental or geographical characteristics make it possible for an agent to know its duties based on its *DNA*. There is a database that includes a list of functions. Each function is an implementation of a *gene* already exist in the *DNA*. The *genome* (the set of all the genes) is the same for all the agents, but the environmental or geographical conditions make only a subset of genes active for a specific agent. To utilize a decentralized database, we may use a blockchain-based structure.

This design can adapt itself to a system that deals with managing many static and dynamic networks. This network could be a distributed system, a decentralized system, a telecommunication network such as a 5G monitoring system, an IoT management system, or an energy management system. The system creates a net between the agents. The final system is the combination of all the agents and the overlay net that connects the agents. We denote the final net as the *body* of the system.

1 Introduction and Related Works

Biological and nature-inspired algorithms were considered previously [1, 13, 18]. Nature-inspired optimization algorithms (NIOAs) are defined as a group of algorithms that are inspired by natural phenomena, including biological systems and physical and chemical systems (A. Baskaran. et al. [4]). NIOAs lead to essential branches of artificial intelligence (AI). A large number of NIOAs have been proposed, such as genetic algorithm (M. Chawla. et al. [7]), particle swarm optimization algorithm (A. Colorni. et al. [9]), differential evolution algorithm (I. Fister. et al. [15]), artificial bee colony algorithm (D. Karaboga et al.[8]), ant colony optimization algorithm (A. Colorni et al. [3]), firefly algorithm (X.S. Yang [19]), and harmony search algorithm (Zong Woo Geem et al. [5]). NIOAs have been reviewed comprehensively [2, 11, 12].

Meanwhile, we know that Agent-oriented Programming (AOP) is a kind of computer programming that focuses on agents and their behavior (for more details see [14] presented by Yoav Shoham). AOP differs mainly from object-oriented programming in that it relies on

externally specified agents instead of objects. The agents can be considered as abstractions of objects.

To the best of our knowledge, equipping a software agent with a *DNA* structure is initiated with this paper. This perspective was valuable when we tried to devise a strategy to move from a 4G telecommunication system to 5G, where there are quite a few elements. Each element needs a different set of functional operations with tight deadlines. For example, an IoT device may have different requirements than a battery controller in an antenna. Decision-making and setting operational functions to be run for monitoring and controlling a device made us use software agents. The idea began when we wanted to provide an agent that could fork itself and spread throughout a network. Each agent was supposed to run a subset of a list of functions. This subset of functions may depend on a few characteristics, such as the agent's position in the given network. If we create an agent that contains the whole set of functions so that it can detect the position and run the corresponding subset of functions, there got to be a considerable code carried by every agent. This is not appropriate for coding and designing systems. We do not want to put a bunch of impractical codes in each network node. So, this idea comes to mind to see an agent as a living creature cell that carries a data structure denoted by *DNA*. This structure consists of information demonstrated as a text. *DNA* has coding that specifies the functions an agent should do. The actual implementation of the required subset of functions is not at the core of the agent. Every agent, after being born, should load the related and required subset of functions from a shared database. Even the software architecture of an agent can be presented in its *DNA*. The idea can be used to manage and monitor many distributed or decentralized systems. To provide a specification for a given network, we only need to design an appropriate *DNA* or create a new set of genes for a *DNA*. We will see a few examples in this article.

The agents reproduce themselves and propagate to the whole given network. Finally, an overlay net of agents is constructed. Based on the list of functions designated with the *DNA* structure, the agents, in each specific position in the net, load their required corresponding functions to know their operations.

All in all, we introduce a dynamic fractal construction. There could be various agents in each position of the network that works on different duties. An agent can decide and act accordingly; it can reproduce and make more co-workers. By programming, a new *DNA*, a new set of functions and structures are designed for the final overlay net of the agents (the body). So, an administrator only worries about the ways of programming a *DNA*. In this paper, we only introduce the new perspective and we do not consider details of implementation.

Section 2 deals with the definition of an agent and a few characteristics of the agents. Section 3 suggests a strategy for presenting a *DNA*, and Section 4 explains a few characteristics one can provide for a network.

2 Agent

As we know, a cell is the basic functional unit of life. Here, agents are the cells of the body of the network. The agents are the functional units that can operate autonomously and without human intervention. This view provides a fractal system. A fractal system is an interactive system that can adapt to a changing environment. Such systems are characterized by the potential for self-recovery, self-organization, and even self-optimization. In a fractal system, semi-autonomous agents interact according to certain rules of interaction, evolving to maximize some measure like fitness or, here, the maintenance of the network. The agents

are diverse in both form and capability, and they adapt by changing their rules and, hence, behavior as they gain experience. Neural networks and deep learning can help us develop more intelligent agents. Their adaptability can either be increased or decreased by the rules shaping their interaction. This can lead to the case that a fractal system has the potential of a great deal of creativity that was not programmed into them from the beginning.

In the system introduced in this paper, we define several *types* of agents based on the set of functions that are required to be done in each node of a network while using this protocol. For example, a network that includes batteries may need a few functions to be set on an agent that is responsible for controlling a battery. So, we need an agent type for the batteries. Or, an agent type may deal with sending messages over the network.

The required functions are stored in a database, and the *DNA* of an agent reveals what functions are required for a specific type of agent. An agent has two layers; Core, Membrane. The core contains the *DNA* and perhaps other more crucial and private information. The core is better be implemented in a secure way.

The membrane contains the codes of the required functions the agent has to run as its duties. In other words, the membrane contains the codes or information that a newly born agent should receive from database.

3 DNA Structure

A *DNA* consists of numerical codes standing side by side on a list. Each code represent a function or a structure. Every agent has a *DNA*. The *DNA* of an agent specifies the functionality of that agent, its behavior, and connection rules. In other words, a *DNA* structure is a list of digits. A set of numbers in this list determines the operations that the corresponding agent should do. An operation is implemented as a function. We have a set of functions in a database, and every function has a unique code. A function's code is the same as the digits in a *DNA* structure. A function's code is called a *gene*. There could be other additional structural and managing codes in a *DNA*.

A *DNA* of an alive creature encompasses biological information. It contains a sequence that encodes genetic information. Here, we use a list of digits as the operational information for an agent. We have several types of agents that; each one enables a unique specific subset of genes in the *DNA*. By defining different genes in the *DNA* list, we can manage to have various different types of agents throughout a network.

Different system designers may need completely different structures to be defined as *DNAs*. For a multilayer network equipped with several elements, each of which has requirements and operations with several tight deadlines, a well-designed *DNA* structure can assign specific agents to manage each equipment individually and make real-time decisions faster. An example of one strand of a *DNA* structure is illustrated in Figure 1.

A *DNA* structure consists of two strands of codes. Each strand holds approximately the same information. The *main strand* holds the information on the current status of the body, the neighbor agents, the agents' children, the agent's duties, the agent's type, and any other information that may be required for an agent in a specific network. For example, the agents should communicate with each other with a specific, well-defined, secure protocol, and without human guidance or intervention. This protocol is specified as a part of the leading strand of the *DNA*. The second strand is used for the reproductive system.

■ **Figure 1** This is an example of one strand of *DNA* of an agent.

3.0.0.1 Reproducing

Every agent has several pieces of code in its core. One part is called the *membrane code* which loads the functions from the database corresponding to the active genes in *DNA*. The genes are active based on an agent's location and structural position in the given network. There is another part of core denoted as *sequencer* that creates a child out of the *DNA* of the agent. As mentioned before, *DNA* has two strands that are mainly similar to each other. The first strand is denoted as the *main strand*, and the *reproductive strand*, which contains the information that is required for making children for the agent. A sequencer reads the reproductive strand of an agent and makes a newly born agent. In fact, the sequencer makes a *main strand* for the newly born child. A newly born child owns a core and an empty membrane. The new sequencer in the newly born agent also creates a new reproductive strand for the agent. So, the *DNA* of the newly born agent gets complete.

The membrane code of the newly born agent loads the corresponding functions of the active genes of the new agent. The code of the implemented functions coming from the database formed the membrane of the child agent. So, the new child gets ready for acting.

All these codes work based on the given network's environmental conditions, location, and characteristics. That is, for example, a sequencer determines the type of a gene (enable/disable) in the new strand based on the position of the child agent on the network.

3.0.0.2 Type of an Agent:

As mentioned previously, every agent has a type. Different agent types use different subset of genes in *DNA*. The type of an agent is determined via a code number in an entry in the main strand of the *DNA* of an agent. The reproductive strand also contains the type of the children of an agent. The sequencer can read this part of the reproductive strand and decide the type of a child for the agent.

3.0.0.3 Age of an Agent:

There is a specific entry in the *DNA* of an agent which specifies the *age* of an agent. The age is a positive integer. Each run of a function in the membrane of the agent increase the add by one. So, the agents who work hard get old sooner. The importance of this entry gets more evident in the networks where the agents are equipped with a neural network. The older an artificially intelligent agent is, the better it got learned. An agent who is old enough can be counted as a well-learned agent. So, the children of the old agents could handle the same set of operations significantly better.

3.1 Special Agents

This section mentions two special agents. Adverse environmental effects may cause the system to be encountered challenging, non-expected situations. Specific agents can be designed to handle such situations. Let denote such agents as *emergency agent*. An agent which is

encountered with such an effect calls an emergency agent to move to the location where an event occurred and handle the situation. Such a movement should be handled in the *DNA* of an emergency agent.

Any agent has a *backup* twin, and the twin has no work to do; it just gets the information of the leading agent periodically. If something happens to the leading agent, the backup agent will work in the place of its twin agent. A flag in the *DNA* specifies which of the twins is enabled. There is a method in the core of an agent that sends a message to the twin agent if something happens to the agent and it could not work correctly. The same message can call the emergency agents to inform admins about the situation. Emergency agents and backup agents made the overall system to be more reliable.

To make the system secure one may check the attacks discovered previously [6, 10, 17] and add appropriate types of agents to the system, or may use a reliable platform introduced previously [16, 20] for the body of the system.

4 System Specifications

Different programming of the *DNA* strands provides a different set of distinctive characteristics for the final body of the system. So, the system is quite flexible. This section mentions a few characteristics that an administrator may need to provide for a network.

4.1 Scalability

The reproductive system makes the proposed system highly scalable. This is, in fact, a highly under-control automated, scalable system whose scale does not affect its quality. Scalability is one of the biggest benefits of distributed systems. It is not just about adding more elements and resources. It is about controlling a big system as well as a small one. The agent cells can reproduce and monitor the system autonomously. To control a large-scale system with tight deadlines, the problem gets even more challenging. In the proposed protocol here, every agent can use an artificial intelligence built-in subsystem to get itself compatible with the environment and learn from the environmental conditions. Combining this system with a reliable previous management system such as blockchain or [16] makes it secure on a large scale.

4.2 Self-Monitoring

We can add a particular type of agent that is like a token and moves around the body of the overlay network to monitor the system. To have a more secure system, we may let some monitoring agents move randomly and check the behavior of other agents. An agent-based system whose agents are equipped with AI and *DNA* has, in fact, a built-in management and monitoring system. Considering to each element of a network, there could be an exclusive agent that watches the behavior of that element. The correct behavior of an element can be defined as rules. There are equivalent functions corresponding to the operations of the element. These functions are stored in the database. The genes in the *DNA* specify the functions of the agent. So, the agent loads the functions from the database and monitors the element's behavior.

4.3 Adaptability

For a system to be adaptable, it should detect the environment and its position, the requirements and its level of power, a few rules, and its security level. So, for a system that

works based on the agent cells, perhaps a class of agents is required in every node of the system. Denote such a class as a cluster. Each cluster can have a shared memory and inner communication protocol. The network that contains the clusters as nodes may use another outer communication approach. This system defines a set of genes in *DNA* for the agents inside the cluster and another set of genes in *DNA* for agents which monitor the outside network. In such a system, corresponding to each specific element, there is a cluster that checks the element and its environment and adapts itself to the situation of that element, and the cluster has the power to change itself with the changes of the network around that element. Controlling, monitoring and managing are among the duties the agents join in a cluster have in their set of functional operations.

4.4 Resource Management

The agent-based protocol proposed here can be considered as an energy management system. To improve the energy performance of a whole network, particular agents may be assigned to control the performance or energy consumption of every network's machinery, device, or component. Every device has the best state that can perform perfectly if we set it to be in that state. The states of an element can be monitored and managed by particular agents. The efficient status of a device can be detected and set by those particular agents that are assigned to that device.

5 Discussion

We introduced a platform where there is an agent with a *DNA* structure. This agent reproduces itself through a network. Consequently, the crowd of agents will spread through the network. The agents can decide individually or via a voting mechanism with each other to manage a specific part or element. These agents may be equipped with an AI system or any advanced programming strategy.

One can create an entirely different system by programming a different *DNA*. Agents can decide to program their children to have a different *DNA*. The first *DNA* for the very first agent in a network can change the whole behavior of the network. This is the idea that we initiate and denote as *DNA* programming.

We will empower this point of view in the future with more biological algorithms and strategies that can help agents act smarter and quicker in a dynamic network. This research introduces the fundamental basics of *DNA* programming. The exact implementations and applications can be described accordingly in collaboration with the industry.
