(Dated: December 29, 2022)

Thermalization and its breakdown in isolated systems has led to a deeper understanding of non-equilibrium quantum states and their dependence on initial conditions. This is prominently highlighted by the existence of quantum scars, special athermal states with an underlying effective superspin structure, embedded in an otherwise chaotic many-body spectrum. Spin  $XXZ$  models and their variants in one and higher dimension have been shown to host exact quantum scars, exhibiting perfect revivals of spin helix states that are realizable in synthetic and condensed matter systems. Motivated by these advances, we propose experimentally accessible local, time-dependent protocols to explore the spatial thermalization profile and highlight how different parts of the system thermalize and affect the fate of the superspin. We identify distinct parametric regimes for the ferromagnetic ( $X$ -polarized) initial state based on the interplay between the driven spin and the rest, including local athermal behavior where the driven spin effectively decouples, acting like a “cold” spot while being instrumental in heating up the other spins. We develop a real and Floquet space picture that explains our numerical observations, and make predictions that can be tested in various experimental setups.

In a set of pioneering papers [1–4] the question of thermalization of isolated quantum systems was posed sharply and addressed. It is now understood that generic isolated quantum systems satisfy the eigenstate thermalization hypothesis. Broadly said, local observables are insensitive to the choice of eigenstate at a given energy density and the system is “self-thermal” i.e. it acts as its own heat bath. However, there are important exceptions, among them “emergent integrable” systems e.g. many-body localized systems [5–9] and systems which are “partially integrable” or those with “quantum scars”. [10–13] The search for quantum scars, athermal states embedded in the spectra of otherwise chaotic systems, has seen recent activity [12–35] because of fundamental interest and due to proposals for using them for quantum sensing [34, 36]. Scar states frequently occur when the Hilbert space is fragmented due to kinetic constraints [23, 37–40]. In a time-dependent setting, the presence of a global periodic drive can either destabilize or stabilize athermal behaviour [41, 42] - e.g. under certain conditions it can exhibit slow thermalization and dynamical freezing [43].

In previous work, some of us identified the  $XXZ$  model as a simple platform for realizing quantum scars and Hilbert-space fragmentation (HSF) [22, 23]. The model shares a common unifying theme with other models of scars (including the widely studied PXP one [13, 44]) - there is a “superspin” whose precession is responsible for revivals in various numerically computed and experimentally measured physical observables. Such a superspin can be realized as the ferromagnetic state in the middle of the energy spectrum (the exact  $SU(2)$  degeneracy being split by a magnetic field) by “staggering” the  $XXZ$  model i.e. by alternating the sign of interaction on even/odd bonds (or more generally on different motifs) [22]. When the spins are prepared in a collective coherent state (e.g. in the all  $X \equiv \Pi_i \otimes |\rightarrow\rangle_i$  state) their dynamics corresponds to that of a superspin.

But how do such scars thermalize when subjected to time-

FIG. 1. Schematic of (a) Local kick protocols and (b) the system studied in this work. The alternating (staggered) interactions place the ferromagnetic state in the middle of the spectrum. For the local delta kick we show two characteristic behaviors for a  $N = 51$  site system with open boundary conditions with the kick at the central site (c,d) show  $\langle S_i^x \rangle$  and (e,f) the Von-Neumann entanglement entropy of representative sites. Results are for  $\tau/2\pi = 0.13$  and (c,e)  $\phi_k/2\pi = 0.1$  and (d,f)  $\phi_k/2\pi = 0.5$ . For the case of weak kick, the driven site thermalizes, for stronger kicks it remains athermal.

dependent fields? Our motivation for answering this stems from expanding the existing dichotomy of classifying a system as thermalized vs athermal - after all, could it be that there are parts of the system that are athermal while the rest have thermalized? We explore this question in the context of a periodic, local drive [45–47], and demonstrate the crossover

FIG. 2. Floquet overlap profile and (inset) survival probability/Loschmidt echo starting from the fully polarized  $X$  state, for representative cases of the local delta kick protocol for  $N = 12$  sites with periodic boundary conditions (a)  $\phi_k/\tau = 5$  (b)  $\phi_k/\tau = 1$  and (c)  $\phi_k/\tau = 0.1$ . For ease of visualization (and to account for situations with near or exact degeneracies), quasienergies are binned with a spacing of  $10^{-2}$ , and the total overlap on the (nearly) degenerate manifold is reported.

between regimes of weak HSF and quantum scarring where the system locally remains prethermal due to the interplay between the dynamics of the driven spin with the rest of the system. We investigate two time-dependent potentials, schematically depicted in Fig. 1, whose similarities and differences we highlight especially in the context of the effective Floquet Hamiltonian they realize. In both cases the Hamiltonian is given by  $H = H_0 + H_D(t)$  where,

$$H_0 \equiv J \sum_i (-1)^i \vec{S}_i \cdot \vec{S}_{i+1} - h \sum_i S_i^z \quad (1)$$

$J$  (set to 1 throughout) is the alternating (staggered) ferro- and antiferromagnetic interaction strength,  $h$  is the strength of the magnetic (Zeeman) field, and  $i$  is a site index,  $i + 1$  is taken modulo  $N$  for periodic boundary conditions. (For open boundary conditions the bond to the  $(N + 1)^{th}$  spin does not exist and is not counted). We note that study of  $H_0$ , primarily in the context of its ground state properties, has a long history due to its relevance to Haldane spin chains [48–50].

In the first “delta kick” protocol, we have,

$$H_D(t) \equiv - \sum_{n>0} \sum_i \phi_i S_i^x \delta(t - n\tau) \quad (2)$$

where  $\phi_i$  denote the applied transverse field strengths local to site  $i$ . While there is a considerable amount of work on models where a collective spin is kicked [51–53], we emphasize that  $H$  here has only local interactions, and the system behaves as a collective spin degree of freedom only for certain initial conditions. In practice, the delta kick is just an approximation to a transverse field pulse applied for a time much shorter than the time between two such pulses. Here we focus on  $\phi_k$  non-zero (a kick applied at the  $k$ -th site) and the rest zero.

The second protocol is that of a symmetric square pulse i.e. the transverse field has opposite sign for  $[0, \tau/2]$  and  $[\tau/2, \tau]$  and is periodic,

$$H_D(t) \equiv \sum_i \gamma_i \text{Sgn}\left(\sin\left(\frac{2\pi t}{\tau}\right)\right) S_i^x \quad (3)$$

A similar drive pulse protocol (but with different  $H_0$ ) was considered recently for global drives in the context of conditions for resonant scars [43]. Here we consider the case of  $\gamma_k$  non zero on the driven site and the rest zero. For both the delta kick and square pulse protocols, we have identified regimes where the driven spin either collectively thermalizes with the rest of the spins (as shown in Fig. 1 (c,e)) or essentially disentangles itself from the remainder of the spins (Fig. 1(d,f)). The latter case serves as an example of a system that is locally kept athermal (or “cold”) by driving whereas the rest of the system “heats up” and thermalizes.

*Floquet and real space pictures:* We discuss both the Floquet (“quasienergy”) space and local (real space) picture of this phenomenon by first placing its behavior in the context of a familiar picture of quantum scars. The Floquet spectrum now assumes the role of eigenenergies of the (time independent) Hamiltonian where identification of an isolated manifold with large overlap on the initial state revealed the existence of scars. For stroboscopic times the unitary Floquet operator encodes the time evolution, which for a single period is given by  $F(\tau) \equiv e^{-iH_F\tau} = \sum_j e^{-i\epsilon_j\tau} |f_j\rangle\langle f_j|$  with  $H_F$  the effective Hermitian “Floquet Hamiltonian”,  $|f_j\rangle$  the  $j^{th}$  Floquet eigenvector and  $\epsilon_j$  is the corresponding quasienergy. For our two drive protocols we have,

$$F(\tau) = e^{+i \sum_i \phi_i S_i^x} e^{-iH_0\tau} \quad \text{delta} \quad (4)$$

$$F(\tau) = e^{-i(H_0 - \sum_i \gamma_i S_i^x) \frac{\tau}{2}} e^{-i(H_0 + \sum_i \gamma_i S_i^x) \frac{\tau}{2}} \quad \text{square} \quad (5)$$

Knowing  $f_j$  and  $\epsilon_j$  and hence  $c_j \equiv \langle f_j | \psi(0) \rangle$ , one can infer many properties of the dynamics, for example, the survival probability (Loschmidt echo) is  $|\langle \psi(0) | \psi(n\tau) \rangle|^2 = \sum_{j,k} |c_j|^2 |c_k|^2 e^{-in(\epsilon_j - \epsilon_k)\tau}$  and since the quasienergies typically have more or less random spacings, it goes to zero by virtue of the superposition of the (almost) random phases. However, this is not always the case - a regularity in states with dominant  $|c_i|$  leads to robust revivals of the survival probability (and other observables). We thus plot  $c_j$  as a function of  $\epsilon_j$  and refer to it as the “Floquet overlap profile” as in

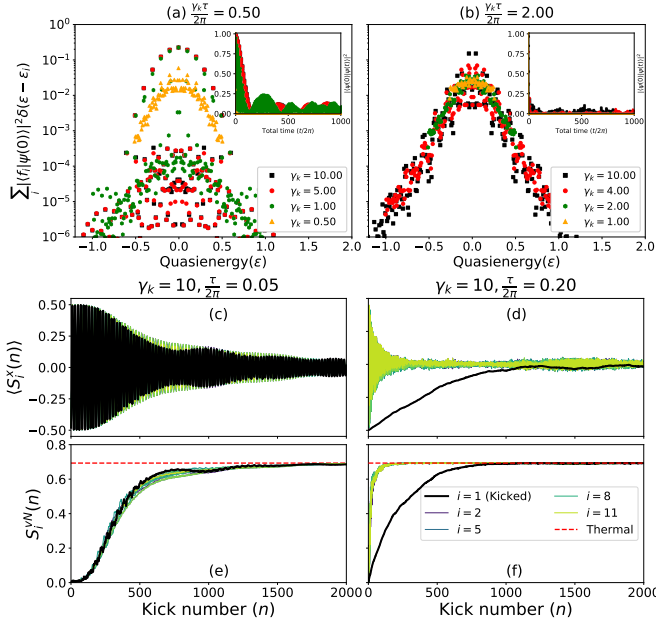

FIG. 3. (a,b) Floquet overlap profile and (inset) survival probability/Loschmidt echo starting from the  $X$  state, for representative parameters of the local square pulse protocol for  $N = 12$  sites with periodic boundary conditions.  $\gamma_k \tau / 2\pi$  was fixed to the value of (a) 0.50 and (b) 2, while individually varying  $\gamma_k$  and  $\tau$ . The value in (b) satisfies the resonant condition, see text. Quasienergies are binned with a spacing of  $10^{-2}$ , and the total overlap on the (nearly) degenerate manifold is reported. Panels (c,d) show  $\langle S_i^x(t) \rangle$  and panels (e,f) show the Von-Neumann entanglement entropy  $S_i^{vn}(t)$  for all sites ( $i$ ) for the cases of (c,e)  $\gamma_k = 10, \tau/2\pi = 0.05$  and (d,f)  $\gamma_k = 10, \tau/2\pi = 0.20$ . The left panels (c,e) show that a single site drive is sufficient to thermalize all the sites. The right panels (d,f) show slow relaxation of local properties at the driven site due to the resonant condition obtained from  $H_F^{(0)}$ .

Figs. 2 and 3.

Consider first the case of the local delta kick. On performing a BCH expansion of Eq. 4, the Floquet Hamiltonian to lowest order is shown to be  $H_F = H_0 - \frac{\phi_k}{\tau} S_k^x$  (see SM). This suggests that the Floquet overlap profile and survival probability must be approximately a function of  $\phi_k/\tau$ , the fact that our data collapse onto each other (for weak  $\phi_k$ ) show that this is indeed the case. (This collapse breaks down for larger  $\phi_k$  since there are higher order terms in the Floquet Hamil-

tonian, see SM. Also  $\phi_k = 2n\pi$  is special and corresponds to the situation where there is no kick). When  $\phi_k/\tau$  is large, the Floquet quasienergies are  $+\phi_k/2\tau$  and  $-\phi_k/2\tau$ , half the Floquet eigenvectors have  $S_k^x = 1/2$  and the other half have  $S_k^x = -1/2$ . Strictly speaking,  $S_k^x$  is not an exact integral of motion for finite  $\phi_k/2\tau$ , this is a realization of weak HSF, the system is divided into two weakly coupled fragments in Hilbert space. The  $X$  state has overlap only onto the manifold of states with  $S_k^x = 1/2$ . On lowering  $\phi_k/\tau$  the  $X$  state begins to have overlap with both values of  $S_k^x$ , the Floquet overlap profile now broadens around the “bands” at  $\pm\phi_k/2\tau$ . When these bands do not overlap (as in Fig. 2(a) corresponding to  $\phi_k/\tau = 5$ ) the kicked spin is athermal. The survival probability (in the inset) does not show any prominent oscillations, and since it is a global property it does not capture the lack of thermalization of the driven spin. The lack of any regular structure in the Floquet overlap profile is ultimately at the heart of thermalization of the undriven spins.

On weakening  $\phi_k/\tau$ , the isolated Floquet “bands” broaden and eventually begin to merge with one another. When this happens, the driven spin does not act significantly differently from the rest of the spins. The notion of this collective thermalization is corroborated in Fig. 1. When the local delta kick is weakened even further, a long thermalization scale emerges due to the vicinity to a “perfect scar” since the  $X$  state is in the null space of the staggered Heisenberg term - it has a decomposition onto the tower of  $2(N/2) + 1$  states. The Floquet overlap profile for  $\phi_k/\tau = 0.1$  demonstrates this very clearly, the quasienergy spacing between states with non-zero overlap is  $h$  arising from the Zeeman splitting of the embedded ferromagnet. (The limit  $\phi_k \rightarrow 0$  corresponds to the undriven case i.e.  $H_F = H_0$ .)

The Floquet framework (coupled with either the BCH expansion of the participating operators or the Floquet-Magnus expansion) offers a way to understand (and hence engineer) the lifetime of the scar like state. For example, consider a driven spin with a kick that alternates in sign - in the limit of high frequency the kicks of opposite sign “effectively cancel out” and the system is essentially undriven (to lowest order). The “symmetric” square pulse we consider next also satisfies this criterion. As shown in the SM, the Floquet Hamiltonian for the local square pulse to lowest order is,

$$\begin{aligned}
 H_F^{(0)} = & (-1)^k [S_k^x S_{k+1}^x + \frac{2 \sin(\frac{\gamma_k \tau}{2})}{\gamma_k \tau} (S_k^y S_{k+1}^y + S_k^z S_{k+1}^z) - \frac{2(1 - \cos(\frac{\gamma_k \tau}{2}))}{\gamma_k \tau} (S_k^x S_{k+1}^y - S_k^y S_{k+1}^x)] \\
 & - (-1)^k [S_{k-1}^x S_k^x + \frac{2 \sin(\frac{\gamma_k \tau}{2})}{\gamma_k \tau} (S_{k-1}^y S_k^y + S_{k-1}^z S_k^z) - \frac{2(1 - \cos(\frac{\gamma_k \tau}{2}))}{\gamma_k \tau} (S_{k-1}^x S_k^y - S_{k-1}^y S_k^x)] \\
 & - \frac{2h}{\gamma_k \tau} (\sin(\frac{\gamma_k \tau}{2}) S_k^z + (1 - \cos(\frac{\gamma_k \tau}{2})) S_k^x) + \sum_{i=1, i \neq (k-1, k)}^{N-1} (-1)^i S_i \cdot S_{i+1} - h \sum_{i=1, i \neq k}^N S_i^z
 \end{aligned} \tag{6}$$

Two important takeaways are (1)  $H_F^{(0)}$  just depends on  $\gamma_k \tau$ ,

a finding confirmed by the collapse seen in the Floquet over-

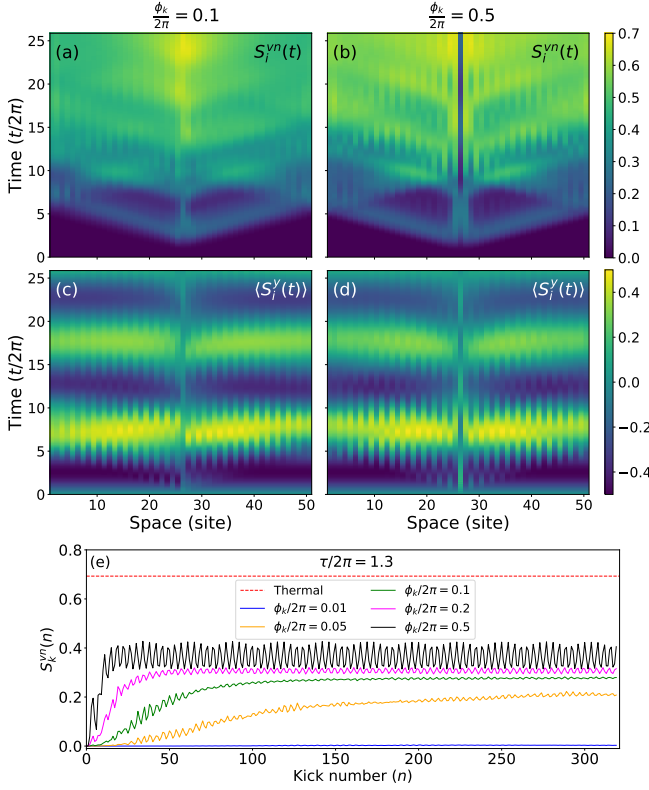

FIG. 4. Space-time thermalization profile for a  $N = 51$  site delta kicked staggered  $XXZ$  chain with open boundary conditions, showing the Von-Neumann entanglement entropy (a,b)  $S_i^{vn}(t)$  of each site and (c,d)  $\langle S_i^y(t) \rangle$ . Space and time correspond to the horizontal and vertical axes respectively and the color represents the value of the physical quantity. Results are shown for  $\tau/2\pi = 0.13$  and (a,c)  $\phi_k/2\pi = 0.1$  and (b,d)  $\phi_k/2\pi = 0.5$ . (e) The Von-Neumann entanglement entropy of the kicked site for the case of  $\tau/2\pi = 1.3$  and a few representative values of  $\phi_k$ .

lap profile in Fig. 3 (a,b) and (2) there are special values of drive frequency and strength - the so called “resonant condition” ( $\gamma_k = 4\pi n/\tau$ ) where the system is locally athermal, a phenomenon referred to as dynamic freezing. Since the F-M expansion is most accurate at high drive frequency ( $1/\tau \gg 1$ ), we expect the Floquet Hamiltonian to be well approximated by  $H_F^0$  only in those regimes.

At extremely high frequencies, the drive is rendered ineffective leading to oscillations starting from the  $X$ -polarized state (not shown). At intermediate frequencies, single site driving is sufficient to thermalize all the sites including the driven site (see Fig. 3(c,e)), reminiscent of the behavior of the delta kicked system for intermediate  $\phi_k/\tau$ . At the resonant frequencies however, unlike the case of global drive [43], the driven spin is not entirely frozen out, but does relax slowly compared to the others (see Fig. 3(d,f)). This ruining of dynamic freezing is caused by higher order terms in the F-M expansion of  $H_F$ . (We will present further subtleties elsewhere.)

*Real-space, real-time profile of thermalization.* We now take a more refined look at the real-space, real-time picture of thermalization for an open chain where the central site is sub-

ject to a periodic delta kick. In Fig. 4 we construct a space-time plot of the Von-Neumann entanglement entropy of the site and the onsite expectation value of  $S_i^y$ . The calculations were done with the matrix product state based time evolution block decimation algorithm [54] on a  $N = 51$  site system with open boundary conditions with a maximum bond dimension of 400.

Since the system is initially prepared in the  $X$  state, the entanglement of each spin is exactly zero to begin with. As time progresses, the entanglement spreads out in a “cone”, distant regions begin to feel the kick as time progresses and the cone reaches the edges of the system. This can be seen prominently for  $\tau/2\pi = 0.13$  for both  $\phi_k/2\pi = 0.1$  and  $\phi_k/2\pi = 0.5$  at short times. After this initial phase, the regions around the central spin show a prominent dip in their entanglement (i.e. they get cold after an initial phase of heating up), this appears as two blue lobes around the kicked spin, as time progresses these regions heat up. (Note that the system is not inversion symmetric because of the alternating  $J$ ’s, but approximately appears to be so for the entanglement entropy). The entire plot shows oscillatory behavior both in space and time, similar observations although for a different model and observables have been reported recently in Ref. [55]. On the time scale of the plot  $\langle S_i^y \rangle$  appears to show robust collective revivals (which eventually do decay), however the central driven spin shows weakened oscillations. These oscillations, at short times, are largely in phase with the other spins for  $\phi_k/2\pi = 0.1$ , but out of phase for  $\phi_k/2\pi = 0.5$ .

Finally, we consider the case of effectively weaker kicks by fixing the kick frequency to a value 10 times smaller i.e.  $\frac{\tau}{2\pi} = 1.3$  and a few representative values of  $\phi_k$  in Fig. 4 (e). After an initial stage of entanglement growth, we see entanglement oscillations for the kicked spin (and other spins, not shown) which remain robust and oscillate about a non zero value. The value of this plateau and the strength of the oscillations both grow with  $\phi_k$ . The fact that this value is far from the thermal expectation of  $\ln 2$ , and that its value is similar for all spins, suggests that despite the breaking of translational symmetry, the superspin picture is intact after the information from the kicked site has reached the boundaries of the system. This reflects the resilience of the superspin to local driving. On the time scale of our TEBD simulations we can not determine if this is truly athermal or prethermal behavior. We must clarify though that the existence of finite entanglement for every site is considerably different from the limit of no kick where the system always remains in a product state during the time evolution - one can simply think of the interactions as ineffective due to the choice of initial condition. However, in the weakly driven case the system appears to have self-organized itself (after an initial period of entanglement growth) to collectively remain as a superspin.

*Outlook:* In summary, we have explored the different dynamic regimes of a locally driven  $XXZ$  spin chain hosting exact quantum scars for drive protocols that should be experimentally accessible. For the  $X$ -polarized initial state, which shows perfect revivals for the time-independent case,

the driven spin crosses over from full thermalization to athermal dynamics, effectively decoupling from the rest of the spins, as the rest of the system thermalizes. Both our protocols showed the existence of an effectively decoupled spin, however the origin of this effect was different for the delta and square pulses, which we highlighted in the text. We believe these predictions can be tested - there are now many synthetic realizations of spin systems: in addition to Rydberg atoms, ytterbium-171 has been recently used to realize an effective transverse Ising model [56] and hyperfine states of lithium realize  $XXZ$  models with tunable anisotropy [57]. Our observation of the local breakdown of thermalization in an otherwise thermal system for a certain initial state provides a non-trivial mechanism for protecting information in a periodically driven system and sheds light on the novel behaviour of dynamics of many-body entanglement.

*Acknowledgements:* We thank Kyungmin Lee for useful discussions in the initial stages of the project and for a previous collaboration. R.M., P.S. and H.J.C. acknowledge support from Grant No. NSF DMR- 2046570 and Florida State University (FSU) and the National High Magnetic Field Laboratory. The National High Magnetic Field Laboratory is supported by the National Science Foundation through Grant No. DMR-1644779 and by the state of Florida. A.P. and B. M. were funded by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (Grant Agreement No. 853368). We also thank the Planck cluster and the Research Computing Center (RCC) at FSU for computing resources. The MPS based TEBD calculations were based on the ITensor library [58]

*Note added:* During the preparation of this work, we became aware of arXiv:2211.00040 which realizes cold and hot regions in a driven system.

# Supplemental Material for “Real space thermalization of locally driven quantum magnets”

In this supplemental material we provide a detailed calculation of the Floquet effective Hamiltonian ( $H_F$ ) for both the periodic delta kick and square pulse protocol.

## $H_F$ FOR THE PERIODIC DELTA KICK PROTOCOL

Here we obtain the Floquet effective Hamiltonian ( $H_F$ ) for periodic delta kick protocol using the truncated BCH expansion. Note that  $H_F$  for the kicked protocol is given by,

$$e^{-iH_F\tau} = e^{i\phi_k S_k^x} e^{-iH_0\tau} \quad (S1)$$

Set  $X \equiv i\phi_k S_k^x$ ,  $Y \equiv -iH_0\tau$  and  $Z \equiv -iH_F\tau$ , then  $H_F$  is given by

$$\begin{aligned} H_F &= \frac{iZ}{\tau} \\ &= \frac{i}{\tau} \ln(e^X e^Y) \\ &= H_F^{(0)} + H_F^{(1)} + H_F^{(2)} + \dots \end{aligned} \quad (S2)$$

where  $H_F^{(n)}$  s can be determined using the BCH formula,

$$\begin{aligned} H_F^{(0)} &= \frac{i}{\tau} (X + Y) = H_0 - \frac{\phi_k}{\tau} S_k^x \\ H_F^{(1)} &= \frac{i}{\tau} \frac{[X, Y]}{2} = \frac{\phi_k}{2} (S_{k-1}^y S_k^z + S_k^y S_{k+1}^z - S_{k-1}^z S_k^y - S_k^z S_{k+1}^y - h S_k^y) \end{aligned} \quad (S3)$$

## $H_F$ FOR THE SQUARE PULSE PROTOCOL

Here we provide a detailed calculation of stroboscopic Floquet effective Hamiltonian ( $H_F$ ) for the square pulse protocol using the Floquet-Magnus (F-M) expansion in a rotating frame. The F-M method yields  $H_F$  as a perturbative expansion in inverse drive frequency ( $\tau$ ). However, transition to a rotating frame automatically ensures an infinite order resummation in  $\tau$ . Thus finally we get a series expansion of  $H_F$  in inverse drive-amplitude ( $1/\gamma_k$ ) where all the terms are resummed in  $\tau$  [59–62]. This extends the validity of  $H_F$  to the low drive frequency regime but limits it to the high drive amplitude regime.

The Hamiltonian for the driven system is given by,

$$H(t) = H_0 + H_D(t) \quad (S4)$$

where  $H_0 = \sum_i (-1)^i S_i \cdot S_{i+1} - h \sum_i S_i^z$  and we apply a local drive at the  $k$ -th site  $H_D(t) = \gamma_k \text{Sgn}(\sin(\omega t)) S_k^x$  with  $\omega = 2\pi/\tau$ . For open chains, we consider  $k$  to be a site in the bulk (e.g. the central site as was considered in the main text).

We now transform the time-dependent Hamiltonian to a rotating frame as follows,

$$H_{rot}(t) = W^\dagger H(t) W - iW^\dagger \partial_t W \quad (S5)$$

where

$$W(t) = e^{-i \int_0^t dt' H_D(t')} = e^{-i\theta(t) S_k^x} \quad (S6)$$

$\theta(t) = \gamma_k t \Theta(\tau/2 - t) + \gamma_k (\tau - t) \Theta(t - \tau/2)$ . This transformation removes the driving term ( $H_D(t)$ ) from the Hamiltonian in rotating frame ( $H_{rot}(t)$ ) and we get

$$\begin{aligned} H_{rot}(t) &= W^\dagger H_0 W \\ &= \mathcal{H}(k-1, k) + \mathcal{H}(k, k+1) - h(\cos(\theta) S_k^z + \sin(\theta) S_k^y) + \sum_{\substack{i=1 \\ i \neq (k-1, k)}}^{N-1} (-1)^i S_i \cdot S_{i+1} - h \sum_{\substack{i=1 \\ i \neq k}}^N S_i^z \end{aligned} \quad (S7)$$

where  $\mathcal{H}(k, k+1) = (-1)^k [S_k^x S_{k+1}^x + \cos(\theta)(S_k^y S_{k+1}^y + S_k^z S_{k+1}^z) - \sin(\theta)(S_k^z S_{k+1}^y - S_k^y S_{k+1}^z)]$  and we have used that  $W^\dagger S_k^z W = \cos(\theta)S_k^z + \sin(\theta)S_k^y$  and  $W^\dagger S_k^y W = -\sin(\theta)S_k^z + \cos(\theta)S_k^y$ .

The stroboscopic Floquet Hamiltonian in F-M expansion is given by

$$H_F = \sum_{n=0}^{\infty} H_F^{(n)} \quad (\text{S8})$$

The zero-th order Floquet Hamiltonian is just the time averaged  $H_{rot}(t)$  over one time period.

$$\begin{aligned} H_F^{(0)} &= \frac{1}{\tau} \int_0^\tau H_{rot}(t) dt \\ &= \mathcal{H}_F^{(0)}(k-1, k) + \mathcal{H}_F^{(0)}(k, k+1) + h_F^{(0)}(k) + \sum_{\substack{i=1 \\ i \neq (k-1, k)}}^{N-1} (-1)^i S_i \cdot S_{i+1} - h \sum_{\substack{i=1 \\ i \neq k}}^N S_i^z \end{aligned} \quad (\text{S9})$$

where

$$\begin{aligned} \mathcal{H}_F^{(0)}(k, k+1) &= (-1)^k [S_k^x S_{k+1}^x + \frac{2 \sin(\frac{\gamma_k \tau}{2})}{\gamma_k \tau} (S_k^y S_{k+1}^y + S_k^z S_{k+1}^z) - \frac{2(1 - \cos(\frac{\gamma_k \tau}{2}))}{\gamma_k \tau} (S_k^z S_{k+1}^y - S_k^y S_{k+1}^z)] \\ h_F^{(0)}(k) &= -\frac{2h}{\gamma_k \tau} [\sin(\frac{\gamma_k \tau}{2}) S_k^z + (1 - \cos(\frac{\gamma_k \tau}{2})) S_k^y] \end{aligned} \quad (\text{S10})$$
