## ABSTRACT

We report the multi-wavelength study for a high-synchrotron-peaked BL Lac 1ES 1218+304 using near-simultaneous data obtained during the period from January 1, 2018, to May 31, 2021 (MJD 58119-59365) from various instruments including Fermi-LAT, Swift-XRT, AstroSat, and optical from Swift-UVOT & TUBITAK observatory in Turkey. The source was reported to be flaring in TeV  $\gamma$ -ray band during 2019, but no significant variation is observed with Fermi-LAT. A sub-hour variability is seen in the SXT light curve, suggesting a compact emission region for their variability. However, hour scale variability is observed in the  $\gamma$ -ray light curve. A "softer-when-brighter" trend is observed in  $\gamma$ -rays, and an opposite trend is seen in X-rays suggesting both emissions are produced via two different processes as expected from an HBL source. We have chosen the two epochs in January 2019 to study and compare their physical parameters. A joint fit of SXT and LAXPC provides a constraint on the synchrotron peak, roughly estimated to be ~1.6 keV. A clear shift in the synchrotron peak is observed from ~1 keV to above 10 keV revealing its extreme nature or behaving like an EHBL-type source. The optical observation provides color-index variation as "blue-when-brighter". The broadband SED is fitted with a single-zone SSC model, and their parameters are discussed in the context of a TeV blazar and the possible mechanism behind the broadband emission.

Key words: galaxies: active – galaxies: jets – gamma-rays: galaxies – radiation mechanisms: non-thermal – BL Lacertae objects: individual: 1ES 1218+304

## **1 INTRODUCTION**

Active galactic nuclei (AGN) host a supermassive black hole (SMBH) at the center, which accretes matter from the surrounding. The matters are in Keplerian orbit and fall into the SMBH via an accretion disk. The mechanism proposed in (Blandford & Znajek (1977)) suggests that the magnetic field lines from the accretion disk get twisted and collimated due to the high spin of SMBH and eject the matter through a bipolar jet perpendicular to the accretion disk plane. Later, the AGNs were classified based on how they are viewed, commonly known as the AGN unification scheme (Urry & Padovani 1995). Blazars are a subclass of active galactic nuclei that have their relativistic jet pointed to the observer. They are characterized by rapid variability from hours to days timescales across all wavelengths, high polarization, and superluminal jet speeds. Blazars can be subdivided

into flat spectrum radio quasars (FSRQs) and BL Lacertae (BL Lac) objects. The broadband continuum spectra of blazars are dominated by non-thermal emission. The spectral energy distribution of blazars is characterized by a double hump structure: the first hump is generally attributed to the synchrotron radiation in the radio to X-ray bands, whereas there is intense debate about the origin of the second hump. The commonly accepted emission mechanism is via inverse Compton scattering of the low-energy photons by high-energy electrons in the system from GeV to TeV energies. There are alternative scenarios proposed by several authors which involve hadronic interactions producing neutral pions. These pions decay to generate photons in the GeV-TeV energies (Mannheim 1993; Aharonian 2000; Böttcher et al. 2013). The BL Lac-type sources are further subdivided into three main classes depending on the position of their low-energy peak. If the synchrotron peak is observed at  $< 10^{14}$  Hz, those BL Lacs are called low-frequency peaked BL Lacs (LBLs). If the synchrotron peak is observed between 10<sup>14</sup> Hz and 10<sup>15</sup> Hz, they are called intermediate-frequency peaked BL Lacs (IBLs). Finally, BL

Lacs with synchrotron peak  $\geq 10^{15}$  Hz are called high-frequency peaked BL Lacs (HBLs). There is also a newly defined class of ultrahigh-frequency peaked BL Lacs (UHBLs) with the spectral peak of the second bump (high energy peak) in the SED located at an energy of 1 TeV or above. These blazars are also known as "extreme blazars" or EHBLs. (Abdo et al. 2010).

Multiwavelength observation of blazars is a very important tool for investigating the various properties of the blazars and the jet. For example, the shortest variability timescale allows one to put strong constraints on the size of the emission region of the blazar. The location of the emission region along the jet axis is another challenging problem in blazar physics. Many studies have been done in the past to locate the emission region; in some cases, it has been found that the emission happens very close to the SMBH within the broad-line region (BLR) (Prince 2020; Prince et al. 2021). However, in some studies, it has been proposed to be at higher distances beyond the broad-line region (Cao & Wang 2013; Nalewajko et al. 2014; Barat et al. 2022). The break or curvature in the  $\gamma$ -ray spectrum above 10-20 GeV suggests the emission region within the BLR as the BLR is opaque to high energy photons above 10 GeV (Liu & Bai 2006). The cross-correlation studies among the various wavebands are another way to locate the emission region along the jet axis. In many studies, it has been reported that simultaneous broadband emissions generally have a co-spatial origin. However, a significant time lag has been reported in some cases, strongly suggesting the different locations for the different emissions (Prince 2019). In the first case scenario, one zone emission model is favored to explain the broadband SED, and in the later case, the multi-zone emission model is preferred (Prince et al. 2019).

The production of high-energy  $\gamma$ -rays in blazar suggests an acceleration of charged particles to very high energy, and many models have been proposed to explain the acceleration. The most accepted mechanisms are the diffusive shock acceleration (Bell 1978, Blandford & Ostriker 1978, Drury 1983, Krymskii 1977, Schlickeiser 1989a,b) and the magnetic reconnection (Shukla & Mannheim 2020). In many studies, shock acceleration has been favored, which also demands the emission region close to the SMBH within the BLR because the shocks are produced and are strong at the base of the jet. On the other hand, the magnetic reconnection happens due to external perturbation and hence demands the jet to be less collimated, i.e., the emission region is farther from the base.

In this paper, we report on a multiwavelength study of the TeV blazar 1ES1218+304 to understand the broadband properties of the source. It is located at a redshift, z = 0.182 with R.A. = 12 21 26.3 (hh mm ss), Dec = +30 11 29 (dd mm ss). It has been observed in TeV energy with VERITAS (Fortin 2008, Acciari et al. 2009) and MAGIC (Albert et al. 2006, Lombardi et al. 2011) and is part of the TeV Catalog<sup>1</sup>.

## 2 MULTIWAVELENGTH OBSERVATIONS, DATA ANALYSIS AND DATA REDUCTION

#### 2.1 Fermi-LAT γ-ray Observatory

Large Area Telescope (LAT) is a gamma-ray telescope placed on Fermi gamma-ray space observatory<sup>2</sup> launched in 2008. It has a working energy range of 20 MeV to 1 TeV with a field of view of 2.4 Sr (Atwood et al. 2009). The orbital period of the telescope is around ~ 96 mins in each hemisphere and covers the entire sky in a total ~ 3 hr. Blazar 1ES 1218+304 is continuously being monitored since 2008. In this study, we have analyzed the data from 1st January 2018 - 31st May 2021, when the source was reported to be flaring in  $\gamma$ -rays (January 2019). The analysis was performed using Fermipy v0.17.4<sup>3</sup>(Wood et al. 2021) and the standard Fermi tools software (Fermitools v1.2.23)<sup>4</sup> between 0.3-300 GeV. A 15° ROI was chosen around the source to extract the photon events with evclass=128 and evtype=3, and the time intervals were restricted using '(DATA\_QUAL>0)&&(LAT\_CONFIG==1)' as recommended by the Fermi-LAT team in the fermitools documentation. The source model file was generated using the Fermi 4FGL catalog (Abdollahi et al. 2020), and the background  $\gamma$ -ray emission was taken care of by using the gll\_iem\_V07. fits file along with the isotropic background emission by using the iso\_P8R3\_SOURCE\_V2\_v1.txt file. In addition, the zenith angle cut was chosen as  $90^{\circ}$  to reduce the contamination from the Earth limb's  $\gamma$ -ray. The source and background were modeled by the binned Likelihood method. Initially, the spectral parameters of all the sources along with those of galactic and isotropic background were kept free to optimize the  $\gamma$ -ray emission. Then to extract lightcurve and perform spectral fitting normalization of the sources only within 2° of ROI were kept free, and the rest of the parameters and other source models were frozen, except that of Source of Interest, in this case, blazar 1ES 1218+304 and a high flux source 4FGL J1217.9+3007, with an offset of 0.753° from 1ES 1218+304. Isotropic and Galactic background parameters were also kept free which in total constitutes to 10 parameters for likelihood analysis. PowerLaw model was used for the source as given below:

$$\frac{dN(E)}{dE} = N_o \times \left(\frac{E}{E_o}\right)^{-\alpha} \tag{1}$$

where  $E_o$  and  $N_o$  are the scale factor and the prefactor, respectively, provided in the 4FGL catalog, and  $\alpha$  is the spectral index. Eventually, we generated the  $\gamma$ -ray light curves for 1, 3, 7, 14, and 30 days of binning for our scientific purpose.

#### 2.2 AstroSat

On January 03, 2019, MAGIC reported a gamma-ray activity and detection of very high energy  $\gamma$  -ray from the blazar 1ES 1218+304 (Mirzoyan 2019). Later, VERITAS also detected a  $\gamma$ -ray flare from this source (Mukherjee & VERITAS Collaboration 2019). Following these two events, we proposed a target of opportunity proposal in India's first space-based multi-wavelength observatory, AstroSat<sup>5</sup>. Observations were carried out from 17th to 20th January with a Soft X-ray telescope (SXT) and Large Area X-ray Proportional Counter (LAXPC).

## 2.2.1 SXT

The SXT working energy range is 0.3-7.0 keV, and the observation was performed with photon counting mode (PC). The level-1 data was downloaded from the webpage, and further reduction was

<sup>1</sup> http://tevcat.uchicago.edu/

<sup>2</sup> https://fermi.gsfc.nasa.gov/

<sup>&</sup>lt;sup>3</sup> Fermipy webpage

<sup>&</sup>lt;sup>4</sup> Fermtools Github page

<sup>&</sup>lt;sup>5</sup> https://www.isro.gov.in/AstroSat.html

performed with the latest SXT pipeline, sxtpipeline1.4b (Release Date: 2019-01-04). It produces the cleaned level-2 data products used for further analysis (Singh et al. 2016, Singh et al. 2017). The observations were done in various orbits; therefore, they were merged with the help of SXTEVTMERGERTOOL. The X-ray light curve is extracted using XSELECT with a circular region of 16' centered on the source. The energy selection of 0.3-7.0 keV was applied in XSELECT using the channel filtering through the pha\_cutoff filter. The source spectrum was extracted for 0.3-7.0 keV energy range, and the background spectrum file used was provided by the AstroSat SkyBkg\_comb\_EL3p5\_Cl\_Rd16p0\_v01.pha. The spectrum was grouped in GRPPHA in order to have good photon statistics in each bin. The ancillary response file (arf) was generated using sxtARFModule, and the RMF file (sxt\_pc\_mat\_g0to12.rmf) was provided by the SXT-POC (Payload Operation Center) team. Eventually, the X-ray spectra from 0.3-7.0 keV with proper background and response files were loaded in XSPEC and fitted with the simple absorbed power-law and log-parabola spectral models. We use the galactic value,  $N_H = 1.91 \times 10^{20}$  cm<sup>-2</sup>, for the correction of the ISM absorption model (HI4PI Collaboration et al. 2016).

## 2.2.2 LAXPC

LAXPC works in the hard X-ray energy range from 3.0-80.0 keV (Yadav et al. 2016), consisting of three identical detectors namely LAXPC10, LAXPC20, and LAXPC30. Unfortunately, LAXPC10 was operating at a lower gain during the time of observation period. Also, the LAXPC30 detector has a gain instability issue caused by substantial gas leakage. Therefore, we used only LAXPC20 for the analysis, and the corresponding results are presented here.

The Level-1 data were processed using the LaxpcSoft package available in AstroSat Science Support Cell (ASSC)<sup>6</sup>. We generated the Level-2 combined event file using the command laxpc\_make\_event. During the data processing, a good time interval was applied to exclude the time intervals corresponding to the Earth occultation periods, SAA passage, and standard elevation angle screening criteria by using the laxpc\_make\_stdgti tool. Finally, the tools laxpc\_make\_spectra and laxpc\_make\_lightcurve were used to produce the spectra and lightcurve of the source using the gti file. We restricted the spectra to the 4-20 keV energy range since the background dominates the spectra above this energy. In the spectral analysis, 3% systematic uncertainty was added to the data. The obtained lightcurve is not background subtracted, therefore, we estimated the background following the faint source routine (Misra et al. 2021). However, due to insignificant variations observed in the extracted lightcurve from LAXPC20, we did not use them in our study.

#### 2.3 The Neil Gehrels Swift Observatory

Simultaneous to AstroSat, blazar 1ES 1218+304 was also observed in X-rays with Swift-XRT and in optical-UV by Swift-UVOT telescopes<sup>7</sup>.

# 2.3.1 XRT

X-ray telescope (XRT) works in an energy range between 0.3-10.0 keV. Multiple observations were done during this period with an

average of 2ks exposure. We have analyzed the data following the standard Swift xrtpipeline, and the details can be found on Swift webpage<sup>8</sup>. The cleaned event files were produced, and a circular region of 10" was chosen for the source and background around the source and away from the source. Tool XSELECT was used to extract the source light curve and the spectrum. The spectrum was binned using the tool GRPPHA to have a sufficient number of counts in each bin. A proper ancillary response file (ARF) and the redistribution matrix files (RMF) were used to model the X-ray spectra in XSPEC. A simple unabsorbed power law was used to fit the X-ray (0.3-10.0 keV spectra and extract the X-ray flux. The soft X-rays (below 1 keV) are affected by interstellar absorption in Milky-way and hence a correction is applied with N<sub>H</sub> =  $1.91 \times 10^{20}$  cm<sup>-2</sup> (HI4PI Collaboration et al. 2016).

## 2.3.2 UVOT

Having an ultraviolet-optical telescope has the advantage of getting simultaneous observations to X-rays. UVOT has six filters: U, B, and V in optical and W1, M2, and W2 in the ultraviolet band. The image files were opened in DS9 software, and the source and background region of 5" and 10" were selected around the source and away from the source, respectively. The task UVOTSOURCE has been used to get the magnitudes, which were later corrected for galactic reddening, E(B-V)=0.0176 (Schlafly & Finkbeiner 2011) and converted into the fluxes using zero points and the conversion factor (Giommi et al. 2006).

## 2.4 Optical

The optical observations of our source were performed in the Johnson BVRI bands using the three ground-based facilities in Turkey, namely, 0.6m RC robotic (T60) and the 1.0m RC (T100) telescopes at TUBITAK National Observatory and 0.5m RC telescope at Ataturk University in Turkey. Technical details of these telescopes are explained in Agarwal et al. (2022). The standard data reduction of all CCD frames, i.e., the bias subtraction, twilight flat-fielding, and cosmic-ray removal, was done as mentioned in (Agarwal et al. 2019a).

#### 2.5 Archival

We have used the archival optical data from ASAS-SN (All-Sky Automated Survey for Supernovae) (Shappee et al. 2014; Kochanek et al. 2017) hown in lightcurve (Fig 4 last panel). We have also used long-term high flux observation in UV/Optical range from NASA/IPAC Extragalactic Database (NED)<sup>9</sup> for providing the reference points in our SED analysis. We have also extracted the NuSTAR SED data points from (Sahakyan 2020) and plotted them alongside our SED analysis.

#### **3 RESULTS**

#### 3.1 Astrosat results

Astrosat observations in SXT and LAXPC were done during 17-20 January 2019 after two weeks of TeV detection. We have produced

```

the SXT light curve and the spectrum as shown in Figure 1 and Figure 2 for the 0.3-7.0 keV energy band. The source appears to be variable on a short-time scale and the corresponding fractional variability and variability time is estimated in section 3.2. A spectrum is extracted in the energy range of 0.3-7 keV and fitted with the power law and log-parabola models. The best-fit parameters are presented in Table 1. We started with a power-law model with fixed hydrogen column density,  $N_H = 1.91 \times 10^{20}$  cm<sup>-2</sup> and next, we keep  $N_H$  as a free parameter. The fit gave the better-reduced chi-square in the latter case. We repeat the same procedure with the log parabola model and with both fixed and free  $N_H$ , it gives a better fit than the power law. The details about the other parameters are provided in Table 1.

We could not get a good light curve in LAXPC but extracted the spectrum from 4-20 keV. The simple power-law fit to LAXPC data alone gives a best fit power-law index,  $\Gamma = 2.38\pm0.07$  with fixed hydrogen column density. The SXT and LAXPC spectra are jointly fitted with Power-law and Log-parabola models with free and fixed N<sub>H</sub> values. The log-parabola model provided a better fit to the spectrum (Table 1). For the joint fit, we used the total model as constant\*tbabs\*logpar. The constant factor is fixed at 1.0 for data group 1 and kept as a free parameter for data group 2. The bestfit value for the constant factor is  $0.95\pm0.04$  for both fixed and free N<sub>H</sub>. The overall reduced- $\chi^2$  is improved when the N<sub>H</sub> is free and it is estimated as  $4.2\pm1.0 (\times 10^{20} \text{ cm}^{-2})$ . Figure 3 shows the best-fit plot with a log-parabola model. The mathematical representation of the log-parabolic model is given as,

$$F(E) = K(E/E_1)^{(-\alpha + \beta \log(E/E_1))} ph \ cm^{-2} \ s^{-1} \ keV,$$
(2)

where K is the normalization, and  $E_1$  is the reference energy fixed at 1 keV. Using the best-fit parameters of the log-parabola model, we can estimate the location of the synchrotron peak, which is given as  $E_p = E_1 \ 10^{(2-\alpha)/2\beta}$  keV, where  $E_1 = 1.0$  keV. For  $\alpha = 1.88$  and  $\beta = 0.29$ , the  $E_p$  is estimated as 1.6 keV or  $3.9 \times 10^{17}$  Hz. We also jointly

Figure 1. AstroSat-SXT light curve for energy 0.3-7.0 keV. The bin size is taken as 856 sec.

fitted the SXT & LAXPC with eplogpar model (total model as constant\*tbabs\*eplogpar) to estimate the location of the synchrotron peak and the estimated value is  $1.54\pm0.34$  keV which is consistent with  $E_p$  estimated above.

## 3.2 Broadband Light curves

We have analyzed the  $\gamma$ -ray data between 2018 to 2021. the source was found to be in a flaring state in  $\gamma$ -ray band during Jan 2019. Furthermore, simultaneous observation in Swift-XRT and UVOT also confirms the flaring behavior in X-ray band as well as in optical-UV band. On 02 January 2019, the source was reported to be in a flaring state in very high energy  $\gamma$ -rays by MAGIC (Mirzoyan 2019), which was followed by VERITAS (Mukherjee & VERITAS Collaboration

**Figure 2.** Upper panel shows the 0.4 - 7.0 keV energy spectrum of 1ES 1218+304 fitted with Logparabola spectral model (green) with free galactic absorption. The SXT data (red) were taken during the period of 17-20 January 2019. Lower panel shows the ratio of data divided by folded model.

**Figure 3.** In the upper panel the joint SXT (red) and LAXPC (blue) spectra are modeled together. The SXT energy range is taken as 0.3 - 7.0 keV and LAXPC is taken from 3.0-20.0 keV. The joint spectra are fitted with a log parabola spectral model (green + light blue). Both spectra were taken simultaneously during the period of 17-20 January 2019. The lower panel shows the ratio of data divided by folded model.

2019). The observation done on 4, 5, and 6 January 2019 shows a high flux state above 100 GeV. We identified this period as Flare A, marked by red color in Figure 4. In X-rays and the optical range, the source was reported to be historically bright with flux around  $\sim 2 \times 10^{-10}$ erg cm<sup>-2</sup> s<sup>-1</sup> in X-ray band and with R band flux 2.35±0.05 mJy (Ramazani et al. 2019). Based on this, we also proposed observation of this source using India's first space mission, AstroSat, for broadband observation. Our observation was done between 17-20 January 2019. This period is marked as a vertical green line in Figure 4 and identified as Flare B. The first two panels of Figure 4 represent the long-term  $\gamma$ -ray (GeV) light curve and corresponding photon spectral index. The source is not very bright in Fermi-LAT, but slight variability in the flux is seen. Panel 3 & 4 represent the long-term Swift-XRT light curve and corresponding photon spectral index. A clear X-ray brightening is observed during Jan 2019. During this period, we do not have many optical observations (panel 5), and hence

Waveband	$F_{var}$	$\operatorname{err}\left(F_{var}\right)$
Fermi γ-ray	0.2601	0.0964

Ι	0.0120	8.2755E-05

**Table 2.** Fractional variability amplitude ( $F_{var}$ ) parameter for the blazar 1ES 1218+304 from optical to HE  $\gamma$ -rays using observations during January 1, 2018 - May 31, 2021 (MJD 58119-59365) with different instruments.

it's difficult to comment on the flux level. However, in UV (W1, M2, W2) bands (panel 6) high flux state is observed corresponding to TeV and X-ray activity. In panel 7, we show the archival optical data from ASAS-SN, and no short time scale variability is seen. We also have optical data from the ground-based observatory (panel 5), which covers the last part of the light curve showing a nice variation from a high flux state to a low flux state, suggesting a long-term variation in optical bands.

#### 3.3 Variability Study

To study the intrinsic property, we calculate the Fractional Variability Amplitude ( $F_{var}$ ) from the multi-wavelength light curve of the source. The relation given in (Vaughan et al. 2003) is used to determine the fractional variability ( $F_{var}$ )

$$F_{var} = \sqrt{\frac{S^2 - E^2}{F^2}} \tag{3}$$

$$err(F_{var}) = \sqrt{\left(\sqrt{\frac{1}{2N}}\frac{E^2}{F^2 F_{var}}\right)^2 + \left(\sqrt{\frac{E^2}{N}}\frac{1}{F}\right)^2} \tag{4}$$

where  $S^2$  is the variance of the light curve, F is the average flux,  $E^2$  is the mean of the squared error in the flux measurements, and N is the number of flux points in a light curve. We have estimated the  $F_{var}$ for all the light curves, and the corresponding values are tabulated in Table 2. We observe that variability is more significantly detected in UV than X-rays and  $\gamma$ -rays. We also plot the F<sub>var</sub> with respect to the corresponding frequency in Figure 5. A similar behavior is also seen for another TeV blazar 1ES 1727+502 for one of the states (Prince et al. 2022). In past studies, it has also been argued that the variability pattern resembles the shape of the broadband SED seen in blazar if the source is observed from radio to very high energy  $\gamma$ rays. One of the best examples is Mrk 421 which is also a TeV source, where the variability pattern during its two flaring states resembles the blazar SED (Aleksić et al. 2015a,b). A long-term study, using 10 yrs data, is done on 1ES 1218+304 by Singh et al. (2019) using the multi-wavelength data from radio to  $\gamma$ -rays and the F<sub>var</sub> estimated on long-term period is different from what we have found in our study. Singh et al. (2019) have found that source is more variable in radio at 15 GHz followed by X-ray band, optical-UV band, and  $\gamma$ -ray band.

The timescale of variability is yet another important parameter that

**Figure 4.** Multi-wavelength light curve of 1ES 1218+304 from January 2018 to May 2021. 7-day binned  $\gamma$ -ray flux are presented in units of  $10^{-8}$  ph cm<sup>-2</sup> s<sup>-1</sup>, and X-ray fluxes are in units of  $10^{-10}$  erg cm<sup>-2</sup> s<sup>-1</sup>. The vertical red line represents the Flare period from 5-7 January 2019 and the vertical green line represents the Flare period from 15-20 January 2019. This period also includes the data from AstroSat for the period 17-20 January 2019. We identify these periods as Flare A and Flare B.

sets the bound on the size of the emission region. Doubling/Halving timescales are calculated from MJD 58119 to 59365 for the 7-day binned  $\gamma$ -ray light curve for all time bins. The formula used is:

$$F(t_2) = F(t_1) \times 2^{(t_2 - t_1)/T_d}$$
(5)

Here  $F(t_1)$  and  $F(t_2)$  are the fluxes measured at time  $t_1$  and  $t_2$ , respectively.  $T_d$  is the flux doubling/halving time scale, and also known as the variability time scale. The fastest variability time  $(T_d)$  in  $\gamma$ -rays was found to be 0.396 days or 9.5 hr. The hour scale variability is very common in blazar, suggesting a compact emitting region close to the central supermassive black hole.

Using the same equation, we also calculate the time-scale variability for the 856 sec binned AstroSat SXT light curve shown in Figure 1. The flux fastest variability time is estimated as  $T_d = 1849$  sec. One can also assume that the fastest variability time can be linked with the exponential growth or decay time scale generally given by  $T_f = T_d/\ln 2$  which is estimated as 1281 sec (1.2 ksec) or ~21 minutes. A similar flux variability time of 1.1 ksec is also estimated for Mrk 421 in the SXT light curve by Chatterjee et al. (2021). Considering the fact that 1ES 1218+304 is a high synchrotron peaked blazar, the synchrotron process will produce the X-ray emission. We considered that the X-rays decay timescale corresponds to the radiation cooling

Figure 5. Fractional variability for various wavebands is plotted with respect to their frequency.

timescale due to synchrotron emission (Homan et al. 2001; Belloni et al. 2002; Uttley et al. 2014). Under this assumption, cooling time is equivalent to X-ray variability time, which is given by (Rybicki & Lightman 1979),

$$t_{cool} \simeq 7.74 \times 10^8 \frac{(1+z)}{\delta} B^{-2} \gamma^{-1} \text{ sec.}$$
 (6)

Where B is the strength of the magnetic field in Gauss and  $t_{cool}$  is the synchrotron cooling timescale in seconds. Following (Rybicki & Lightman 1979), we can also derive the characteristic frequency of the electron population, responsible for the synchrotron emission at the SED peak,

$$v_{ch,e} = 4.2 \times 10^6 \frac{\delta}{(1+z)} B \gamma^2 \text{ Hz.}$$
 (7)

Using the above two equations, we eliminate the  $\gamma$  since it changes with different states and derives a single equation given as,

$$B^{3}\delta \simeq 2.5(1+z)(\nu_{ch,e}/10^{18})^{-1}\tau_{d}^{-2}.$$
(8)

Using the above equation, we derive the magnetic field strength for the Doppler factor,  $\delta = 30$ , and variability time scale of 1.2 ksec, and it is found to be 0.1 G. The strength of the magnetic field derived from the broadband SED modeling is lower than the estimated value. This discrepancy could be because of the many assumptions made in deriving the equation (7) or due to the degeneracy in the SED modeling.

#### 3.4 Flux-Index Correlation

We computed flux-index correlation for the  $\gamma$ -rays and X-rays data to study index hardening/softening. Figure 6 shows the flux vs. index plot with  $\gamma$ -ray band on the upper panel and X-ray band on the lower panel. In the case of  $\gamma$ -rays, we have taken data points with TS  $\geq$  16. We also observe a positive correlation between the flux and index, with Pearson correlation coefficient, R = 0.644 and pvalue  $\approx$  0. The trend follows the linear function with slope = 0.184. In contrast to the above plot, X-rays data show an inverse trend, i.e., a negative correlation between flux and index, with Pearson correlation coefficient, R = -0.748 and p-value  $\approx$  0. It can also be fitted by a linear function with a slope = -0.274. This plot shows two contrasting trends, we can see the 'harder-when-brighter' trend in the X-ray energy range and the 'softer-when-brighter' trend in the  $\gamma$ -ray energy range. A similar trend is also observed for one of the

**Figure 6.** Scatter plot for the correlation between flux and index of the blazar 1ES 1218+304. The top plot represents the 7-day binned Fermi-Lat data. The slope is positive and the Person correlation coefficient is 0.644. The bottom plot represents Swift-XRT data for Flux (0.3-10 keV) vs Photon Index. The slope is negative and the Pearson correlation coefficient is -0.748, it follows an inverse trend as the  $\gamma$ -ray data. The orange line is a linear fit for reference.

TeV blazar 1ES 1727+502 (Prince et al. 2022). One of the possible explanations for having different trends in X-ray and  $\gamma$ -ray is that they are produced via two different processes. For BL Lac-type sources such as 1ES 1218+304, it is well-known that the synchrotron process produces the X-rays and  $\gamma$ -rays are produced via the inverse-Compton process.

A long-term study done by Singh et al. (2019) also found a mild harder-when-brighter trend in X-rays using almost 10 yrs of data. The average spectral index is estimated as  $1.99\pm0.16$ , which is consistent with our estimated value as ~2.0 where synchrotron peaks in X-ray band. These results are also consistent with the long-term study done by Wierzcholska & Wagner (2016) where they found the average photon spectral index as ~2.0±0.01 for different values of galactic absorption taken from different models. A recent study by Sahakyan (2020) estimated the average photon spectral index ≥2 for the period from 2008 to 2020. The spectra can be even harder during the bright state as 1.60±0.05, which is consistent with our result (see Figure 6).

#### 3.5 Fermi-LAT $\gamma$ -ray spectral fitting

The data extraction and fitting process is provided in subsection 2.1. We have used the fermipy to extract the  $\gamma$ -ray SED for the two periods (5-7 and 15-20 January 2019). The SEDs are then fitted with a simple power law spectral model. We noticed that the spectra are very hard and still increasing with energy suggesting the involvement of high-energy particles in their production. The fitted parameters are given in Table 3 and the spectral index for period A ( $\Gamma$ =1.55±0.23) and B ( $\Gamma$ =1.54±0.19) is much harder than the average power law index, ( $\Gamma$ =1.75±0.03) for the total period. The harder spectra suggest that the IC peak is even at higher energy which is clearly seen in broadband SED modeling. A study by Costamante et al. (2018) also shows a harder  $\gamma$ -ray spectrum for many TeV blazar. A harder  $\gamma$ -ray spectrum is also seen in another TeV extreme blazar. Including the TeV data in broadband SED Aguilar-Ruiz et al. (2022) modeled the

**Figure 7.** The  $\gamma$ -ray SED extracted for both the period and fitted with powerlaw using the Likelihood fit method. The fitting parameters are discussed in the corresponding Section 3.5.

SED for six such sources with a two-zone emission model. Few new EHBL types sources are also discovered with the MAGIC telescope, and the Fermi-LAT  $\gamma$ -ray spectra were found to be very hard for all the sources suggesting an extreme location of the second SED peak above 100 GeV energy range (Acciari et al. 2020). A long-term  $\gamma$ -ray spectral index was also estimated for 1ES 1218+304 by Singh et al. (2019), and they found it to be harder with 1.67±0.05, similar to our estimated value. Sahakyan (2020) also estimated the  $\gamma$ -ray spectra averaged over ~11.7 years which found to be 1.71±0.02 mostly consistent with above discussed results. These values are also consistent with the long-term average photon spectral index reported in the recent 4FGL catalog.

#### 3.6 Color-Magnitude Variations

The color-magnitude relation helps us understand the different variability scenarios of the blazar. Fluctuations in optical flux are often followed by spectral changes. Therefore studying the colormagnitude (CM) relationship can further shed light on the dominant emission mechanisms in the blazar. To obtain a better understanding of the CM relation for our source, we fit a linear plot (CI = mV + c) between the color indices (CI) and (B+V)/2 magnitude. We then estimate the fit values, i.e., slope (m), constant (c), along with the correlation coefficient (r) and the respective null hypothesis probability (p) using two methods, Pearson and Spearman, as listed in Table 4. The generated CM plots are shown in Figure 8. Offsets of 1.3 and 0.2 are used for (B-V) and (R-I). A positive slope with p < 0.05 implies a bluer-when-brighter (BWB) trend or a redder-when-fainter trend (Agarwal et al. 2021) while a negative slope indicates a redder-whenbrighter trend (RWB). As evident from Table 4, a significant BWB is dominant during our observation period for all possible color indices, namely; (B-V), (B-I), (R-I), and (V-R). Blazars, in general, display BWB from their quasi-simultaneous optical observations (Ghosh et al. 2000; Agarwal et al. 2015; Gupta et al. 2016a).

The BWB trend can be attributed to the electron acceleration process to higher energies at the shock front, followed by losing energy by radiative cooling while propagating away (Kirk et al. 1998). On the other hand, the opposite trend of redder when brighter is observed more commonly in FSRQs due to the contribution of bluer thermal emission from the accretion disc (Villata et al. 2006). In addition to BWB and RWB trends, other optical studies have revealed

Figure 8. Colour magnitude plot for 1ES 1218+304. The various color indices are plotted against (B+V)/2.

cycle or loop-like trends (Agarwal et al. 2021), a mixed trend where BWB is dominant during higher state while RWB during the fainter state, or a stable-when-brighter (SWB) which is no significant colormagnitude correlation in the data at any timescale (Gupta et al. 2016b; Isler et al. 2017; Negi et al. 2022; Agarwal et al. 2022). However, due to the lack of simultaneous observations for a larger sample of blazars, color-magnitude trends are still a topic of debate.

#### 3.7 Broadband SED modeling

Simultaneous multi-wavelength SEDs were generated for two time periods, which overlapped with the proposed flaring periods. The model fitting was done using a publicly available code JetSet<sup>10</sup> (Tramacere et al. 2009, 2011, 2020; Massaro, E. et al. 2006). Broadband emission of BL Lac sources like 1ES 1218+304 is better explained by the one-zone Synchrotron-Self Compton (SSC) model. Leptonic models assume that relativistic leptons (mostly electrons and positrons) interact with the magnetic field in the emission region and produce synchrotron photons in the frequency region of radio to soft X-rays or the first hump of the SED. The emission in the frequency region of X-rays to  $\gamma$ -rays or the second hump of the SED is produced by inverse Compton (IC) scattering of a photon population further classified into synchrotron-self Compton (SSC) or external Compton (EC) categories based on the source of the seed photons. In the case of SSC models (Ghisellini 1993; Maraschi et al. 1992), relativistic electrons up-scatter the same synchrotron photons which they have produced in the magnetic field. The model assumes a spherically symmetric blob of radius (R) in the emission region, surrounded by relativistic particles accelerated by the magnetic field (B). The blob makes an angle  $\theta$  with the observer and moves along the jet with the bulk Lorentz factor  $\Gamma$ , affecting emission region by the beaming factor  $\delta = 1/\Gamma(1 - \beta \cos \theta)$ . The blob is filled with a relativistic population of electrons following an empirical Lepton distribution relation, and the power law with an exponential cut-off (PLEC) distribution of particles is assumed:

$$N_e(\gamma) = N_0 \gamma^{-\alpha} exp(-\gamma/\gamma_{cut}) \tag{9}$$

where  $\gamma_{cut}$  is the highest energy cut-off in the electron spectrum. We see that the optical/UV measurements are higher than the non-

**Figure 9.** Broadband SED Modelling for (5-7) January 2019 (Flare A). Optical data is fitted with the host galaxy template available in JetSet. Archival NuSTAR data are plotted in cyan color, which does not match the current X-ray spectral shape. Due to the hard X-ray spectral index, the synchrotron peak is observed to be shifted to higher frequencies (above  $\sim 10^{18.5}$  Hz, possibly  $\sim 10^{20}$  Hz in our modeling) compared to the synchrotron peak location ( $\sim 10^{17.5}$  Hz) during (15-20) January as constrained by AstroSat observation in Figure 3 and also visible in Figure 10.

thermal emission from the jet predicted by the SSC model. We also see high flux points in UV/optical range from the long-term observation of 1ES 1218+304, from NASA/IPAC Extragalactic Database (NED)<sup>11</sup>. These observations suggest that the stellar emission from the host galaxy of the source is dominant at optical/UV frequencies. In order to accurately account for this emission due to the host galaxy, we have added the host galaxy component while modeling the SED using JetSet. Modeling of blazar 1ES 1218+304 is based on the SSC model in reference to equation (9). Results for the SSC model are shown in Figure 9 and Figure 10 for Flare A and Flare B. The model parameters are given in table 5.

<sup>11</sup> https://ned.ipac.caltech.edu/

**Figure 10.** The plot is the same as Figure 9 but for (15-20) January 2019 (Flare B). For this time period, the archival NuSTAR spectrum also does not match the current state X-ray spectral shape, suggesting that the NuSTAR spectrum was taken in low-flux states. The synchrotron peak is decided by the Swift-XRT and AstroSat-SXT spectra plotted on top of each other, which peaks at roughly ~1.6 keV or  $3.9 \times 10^{17}$  Hz as estimated in section 3.1 using AstroSat data.

#### 3.7.1 The constraint on Doppler factor

We can calculate the minimum value of the Doppler factor using the detection of high-energy photons from the source. This calculation assumes the optical depth,  $\tau_{\gamma\gamma}(E_h)$ , of the highest energy photon,  $E_h$ , to  $\gamma\gamma$  interaction is 1. The target photons for optical depth of GeV  $\gamma$ -rays, caused by photon-photon collisions, are in the X-ray band. The formula for calculating the minimum value of the Doppler factor is derived in Dondi & Ghisellini (1995) & Ackermann et al. (2010a,b) as

$$\delta_{min} \cong \left[ \frac{\sigma_t d_l^2 (1+z)^2 f_{\epsilon} E_h}{4 t_{var} m_e c^4} \right]^{1/6} \tag{10}$$

where  $\sigma_t$  is the Thomson scattering cross-section for the electron  $(6.65 \times 10^{-25} cm^2)$ ,  $d_l$  is the luminosity distance of the source,  $f_{\epsilon}$  is the X-ray flux in 0.3-10 keV energy range,  $E_h$  is the highest energy photon,  $t_{var}$  is the observed  $\gamma$ -rays variability time. For 1ES 1218+304, z=0.182,  $d_l$  is 924 Mpc and  $t_{var}$  is 0.396 days. Using the

value of highest energy photon  $E_h = 162.822$  GeV for Flare A and 278.132 GeV for Flare B, and  $f_{\epsilon} = 1.94 \times 10^{-10}$  for Flare A and  $1.55 \times 10^{-10}$  for Flare B, we get the  $\delta_{min}$  value to be 12.9 for Flare A and 13.6 for Flare B.

#### 3.7.2 The size of emission region

The variability time scale estimated from the  $\gamma$ -ray light curve is used to estimate the size of the emission region. The radius *R* can be estimated by using the equation,

$$R = c\delta t_{var}/(1+z),\tag{11}$$

The Doppler factor from the broadband SED modeling is derived in Singh et al. (2019) as  $\delta = 26$  and also assumed to be 25 in Sahakyan (2020) which is higher than the minimum value derived in this paper. We took  $\delta = 26$  and the *R* is estimated as  $2.3 \times 10^{16}$  cm, using the and  $t_{var} = 9.5$  hr. During the SED modeling, 'R' is kept as free parameters, which gives the values  $1.06 \times 10^{16}$  cm for Flare A and  $1.40 \times 10^{16}$  cm for Flare B, both are consistent with the estimated value. The location of the emission region along the jet axis from the supermassive black hole can also be estimated from the variability time assuming a spherical emission region by using the expression  $d \sim 2c\Gamma^2 t_{var}/(1+z)$  (Abdo et al. 2011). Using the conical jet geometry the Lorentz factor,  $\Gamma = \delta_{min}$ , where the jet opening angle,  $\theta_{iet} \ll 1/\delta_{min}$  and  $t_{var} = 0.396$  days and z = 0.182, the location is estimated to be,  $d \sim 2.9 \times 10^{17}$  cm. To optimize the broadband SED modeling, we have fixed the location of the emission region to  $1.0 \times 10^{17}$  cm from the SMBH along the jet axis.

## 3.7.3 Jet Power

We have estimated the power carried by individual components (leptons, protons, and magnetic fields) and the total jet power. The total power of the jet was estimated using

$$P_{jet} = \pi R^2 \Gamma^2 c (U'_e + U'_p + U'_B)$$
(12)

Here  $\Gamma$  is the bulk Lorentz factor and  $U'_e, U'_p, U'_B$  are the energy densities of electrons-positrons, cold protons, and the magnetic field respectively in the co-moving jet's frame (primed quantities are in the co-moving jet frame while unprimed quantities are in the observer frame). All energy densities and the 'R' are the best-fit parameters of the fit and taken from Table 5. The power in leptons is given by

$$P_e = \frac{3\Gamma^2 c}{4R} \int_{E_{max}}^{E_{min}} EQ(E) dE$$
(13)

where Q(E) is the injected particle spectrum. The integration limits,  $E_{min}$  and  $E_{max}$  are calculated by multiplying the minimum and maximum Lorentz factor ( $\gamma_{min}$  and  $\gamma_{max}$ ) of the electrons with the rest-mass energy of the electron respectively. The power in the magnetic field is calculated using

$$P_B = R^2 \Gamma^2 c \frac{B^2}{8} \tag{14}$$

where B is the magnetic field strength obtained from the SED modeling. Our model returned the energy densities for electron-positron and magnetic field for both Flare events. The energy density for the cold proton was not estimated as it was too small. We calculated  $P_e, P_B$ , which is the power carried by the leptons and the magnetic field respectively. The total power  $P_{jet} \approx P_e + P_B$  along with the power of the individual components is shown in Table 5. The jet is dominated by the lepton's power compared to the magnetic field and can be considered a pair-dominated jet. The luminosities have been computed for a pure electron/positron jet since the proton content is not well known and can be considered as the lower limit. The absolute jet power  $L_{jet} \approx 1 \times 10^{46} erg s^{-1}$  for Flare A and is below the Eddington luminosity for a  $5.6 \times 10^8 M_{\odot}$  black hole mass  $(L_{Edd} = 7.3 \times 10^{46} erg s^{-1})$  estimated from the properties of the host galaxy in the optical band (Rüger et al. 2010). For Flare B,  $L_{jet} \simeq 7.37 \times 10^{44} erg s^{-1}$  is significantly below the  $L_{Edd}$ .

#### 3.7.4 Broadband emission during flaring states

We choose two flaring periods during the month of January 2019, MJD 58488-58490 (5-7 January 2019, Fig 9) and MJD 58498-58503 (15-20 January 2019, Fig 10) were modeled with a one-zone leptonic scenario. The modeled parameters are mentioned in Table 5. The model parameters inferred from this fitting suggest that Flare A had more activity compared to Flare B. The  $\gamma_{max}$  and  $\alpha$  are almost the same for both the flares, we see from Table 5 that  $\gamma_{min}$ ,  $\gamma_{cut}$  have significantly higher values for Flare A compared to Flare B, which may be due to the flaring seen in the X-ray band. The magnetic field (B) for Flare A  $(2.74 \times 10^{-3})$  is also less than that of Flare B (1.30×10<sup>-2</sup>). During the fitting of SED, we kept  $R_H$  and  $\delta$  as free parameters. We find that the value of  $R_H$  is close to the value we calculate using equation (11). We also calculate the minimum doppler factor  $\delta_{min}$  between the range (12.9-13.6), but during the SED modeling, we find that for Flare A,  $\delta = 16$  and for Flare B, it is much higher  $\delta = 30$  then the calculated value. It suggests that variation in  $\delta$  could be one of the reasons for different flux states.

During these flares, the optical-UV emission is dominated by thermal emission from the host galaxy and hence has been modeled using the host galaxy model using JetSet. It is also seen that the X-ray data is better explained by synchrotron radiation of electrons. The SSC component of SED modeling dominates above  $10^{20}$  Hz (~ 1 MeV), and it is useful in describing the data up to the VHE  $\gamma$ -ray band.

#### **4 SUMMARY AND DISCUSSIONS**

In our work, we present the multi-wavelength study of HBL blazar 1ES 1218+304 from 1st January 2018 to 31st March 2021 (58119-59365), which also includes the high flux event in VHE  $\gamma$ -rays detected by both MAGIC and VERITAS observatories during January 2019. This high flux rate was also seen in Swift-XRT and UVOT instruments. Hence we divided our SED analysis into two flaring periods, 5-7 January 2019 and 15-20 January 2019, for simultaneous multi-wavelength observation of 1ES 1218+304. The fastest variability timescale was found to be 0.396 days from analyzing the  $\gamma$ -ray light curve, constraining the size of the emission region to  $\sim 2.3 \times 10^{16}$  cm, which came out to be higher than previous modeling results (Rüger et al. 2010, Sahakyan 2020, Singh et al. 2019) but consistent with our SED modeling results, see Table 5. The location of the emission region is estimated to be  $d \sim 2.9 \times 10^{17}$  cm, which is similar to that used for SED modeling. The highest energy photon detected was 278.132 GeV which arrived during Flare B. We can also see the 'harder-when-brighter' trend in the X-ray energy range and the 'softer-when-brighter' trend in the  $\gamma$ -ray energy range. We also observed variability of 20 minutes in the SXT light curve. The SXT spectrum is well-fitted with the log-parabola model. The joint fit of SXT along with the LAXPC spectrum helps to constrain the location of the synchrotron peak. The estimated location is 1.6 keV which is roughly matching with the synchrotron peak constrained by the broadband SED modeling (Figure 10).

The broadband SED modeling of the source was reproduced by a leptonic simple one-zone SSC model with the electron energy distribution described by a Power-law with an exponential cut-off (PLEC) function. Parameters like the magnetic field, injected electron spectrum, and minimum and maximum energy of injected electrons have been optimized to fit the SED's data points well. This study suggests that a single-zone model can also be good enough to explain the multi-waveband emissions from 1ES 1218+304 up to GeV energy range. The optical and UV emissions from the source are found to be dominated by the stellar thermal emissions from the host galaxy and can be modeled using the JetSet code by a simple blackbody approximation (Rüger et al. 2010).

Costamante et al. (2018) argued that the one-zone SSC model can explain the broadband SED modeling in hard-TeV blazar at the expense of extreme electron energies with very low radiative efficiency. The maximum electron Lorentz factor estimated in their modeling for all the six sources is orders of  $10^7$  which is consistent with our results for 1ES 1218+304. The other modeling parameters, such as the size of the emission region, magnetic field strength, and the magnetization parameters  $(U_B/U_e)$ , are very similar to our SED modeling result for 1ES 1218+304. In our case, the  $U_B/U_e = 10^{-4} - 10^{-6}$  and in Costamante et al. (2018) it is order of  $10^{-2} - 10^{-5}$ . Similar results were also obtained by Kaufmann et al. (2011) where they model the broadband SED of extreme TeV source 1ES 0229+200. The magnetic field and the magnetization parameter  $(10^{-5})$  are consistent with our results for 1ES 1218+304. However, their model requires a narrow electron energy distribution with  $\gamma_{min} \sim 10^5$  to  $\gamma_{max} \sim 10^7$  rather than the broad energy range obtained in our study, Costamante et al. (2018), and Acciari et al. (2020).

Acciari et al. (2020) have observed ten new TeV sources with MAGIC from 2010 to 2017 for a total period of 262 hours, and the simultaneous X-ray observations confirm that 8 out of 10 sources are of extreme nature. Their  $\gamma$ -SED was found to be very hard between 1.4 to 1.9. Blazar 1ES 1218+304 is also an extreme TeV blazar, and in our study, the  $\gamma$ -ray SED is found to be 1.5, consistent with the above TeV sources. They have modeled all the sources with a single zone conical-jet SSC model. Additionally, they also used the protonsynchrotron and a leptonic scenario with a structured jet. They also argue that all the model provides a good fit to the broadband SED, but the individual parameters in each model differ substantially. Comparing their SSC model results to our SSC modeling, the maximum electron energy is consistent. The electron spectral index, in our case, is harder than their results, and the magnetic field is much smaller. The estimated Lorentz factor is more or less consistent with the  $\Gamma$ used for all the sources in their study. In their recent work, Aguilar-Ruiz et al. (2022) have modeled the six well-known extreme BL Lac sources with a lepto-hadronic two-zone emission model to explain the broadband SED. In another study, Zech & Lemoine (2021) have shown that the broadband SED of extreme BL Lac sources can be explained by considering the co-acceleration of electrons and protons on internal or recollimation shocks inside the relativistic jet.

Sahakyan (2020) has modeled the average state of 1ES 1218+304 with one-zone SSC model. The parameter estimated in their study is mostly consistent with ours. However, our study focuses on the smaller period, including two flaring events. During the flaring event (15-20 Jan), the magnetic field and the magnetization parameters are estimated as  $1.30 \times 10^{-2}$  Gauss and  $\sim 10^{-4}$ , which is comparable to the value for the same parameters estimated by modeling the average state of the source in Sahakyan (2020). However, the Doppler factor required in Sahakyan (2020) is much higher than the Doppler factor needed to fit the flaring state in our case. Singh et al. (2019) also modeled the average broadband SED collected for almost 10 years with a one-zone SSC model. The required  $\gamma_{min}$ ,  $\gamma_{max}$ , and Doppler factor are consistent with our result, but the size of the emission region is one order of magnitude smaller than ours. Also, the magnetic field estimated in their model is much higher than what we found. The difference in some of the parameters could be because they modeled the average SED, and in our case, we are more focused on a short period of time. The optical-UV SED is mostly off to the general trend of broadband SED of blazar and hence in both cases, is fitted with a host-galaxy contribution. Singh et al. (2019) used a specific model to fit the host-galaxy and estimated the black hole mass of the source, however, in JetSet we can not include a specific model, and hence host-galaxy is fitted as a free parameter.

# **5** CONCLUSIONS

In this work, we present the long-term study of the blazar 1ES 1218+304 using 3.5 years of near-simultaneous multi-wavelength data from Fermi-LAT, SWIFT-XRT, SWIFT-UVOT, AstroSat, and TUBITAK observations taken between January 1, 2018, and March 31, 2021. This study explores the broadband temporal and spectral behavior of the source during flaring states. The main results of our study are provided below:

• The Astrosat SXT light curve reveals a variability of the order of 20 minutes and the X-ray spectrum is well fitted with both power-law and the log parabola models. However, the LP provides a better fit. A joint fit with the LAXPC spectrum provides a constraint on the location of synchrotron peak roughly around ~1.6 keV or  $3.9 \times 10^{17}$  Hz.

• The fast flux variability in  $\gamma$ -rays is calculated to be 0.39 days, the size of the emission region is estimated to be  $\sim 2.3 \times 10^{16}$  cm, and the emission region is located at a distance of  $\sim 2.9 \times 10^{17}$  cm. A "harder-when-brighter" trend was seen in X-rays whereas a "softer-when-brighter" trend was in  $\gamma$ -rays. The  $\gamma$ -ray emission from 1ES 1218+304 can also be described by a power law with a spectral index of  $\sim 1.75$ .

• As seen in many other TeV blazars, a shift in synchrotron peak is observed from one state to another state from  $\sim 10^{17.5}$  Hz to possibly  $\sim 10^{20}$  Hz (from  $\sim 1$  keV to above 10 keV, possibly  $\sim 500$  KeV from our modeling) suggesting an extreme state of the source.

• The broadband SED modeling from radio to GeV energies is reproduced by a one-zone leptonic SSC model with the electron energy distribution described by a Power-law with an exponential cut-off (PLEC) function. We also find that the Optical/UV emissions from the source are dominated by the stellar thermal emissions from the host galaxy which are modeled by a simple blackbody approximation (Rüger et al. 2010) using JetSet. The JetSet code uses an approximation of the host galaxy model to help fit the SED modeling. We need more precise and dedicated observation in the UV/Optical band for a better understanding of the host galaxy.

# ACKNOWLEDGEMENTS

We thank the referee for their insightful comments and suggestions which helped us to improve the draft. D. Bose acknowledges the support of Ramanujan Fellowship-SB/S2/RJN-038/2017. R. Prince is grateful for the support of the Polish Funding Agency National Science Centre, project 2017/26/A/ST9/-00756 (MAESTRO 9) and the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No. [951549]. This work made use of Fermi telescope data and the Fermitool package obtained through the Fermi Science Support Center (FSSC) provided by NASA. This work also made use of publicly available packages JetSet, Fermipy, and PSRESP. This publication uses the data from the AstroSat mission of the Indian Space Research Organisation (ISRO), archived at the Indian Space Science

Data Centre (ISSDC). This work has used the data from the Soft Xray Telescope (SXT) developed at TIFR, Mumbai, and the SXT POC at TIFR is thanked for verifying and releasing the data via the ISSDC data archive and providing the necessary software tools. We thank the LAXPC Payload Operation Center (POC) at TIFR, Mumbai for providing the necessary software tools. We have also made use of the software provided by the High Energy Astrophysics Science Archive Research Center (HEASARC), which is a service of the Astrophysics Science Division at NASA/GSFC.

## DATA AVAILABILITY

For this work, we have used data from the Fermi-LAT, Swift-XRT, Swift-UVOT, and AstroSat which are available in the public domain. We have also used optical data collected by the TUBITAK telescope. This optical data was given to us on request. Details are given in Section 2.
