Abstract. Core collapse supernovae are thought to be one of the main sources in the galaxy of elements heavier than iron. Understanding the origin of the elements is thus tightly linked to our understanding of the explosion mechanism of supernovae and supernova nucleosynthesis. X-ray and gamma-ray observations of young supernova remnants, combined with improved theoretical modeling, have resulted in enormous improvements in our knowledge of these events. The isotope ^{44}Ti is one of the most sensitive probes of the innermost regions of the core collapse engine, and its spatial and velocity distribution are key observables. Hard X-ray imaging spectroscopy with the Nuclear Spectroscopic Telescope Array (*NuSTAR*) has provided new insights into the structure of the supernova remnant Cassiopeia A (Cas A), establishing the convective nature of the supernova engine. However, many questions about the details of this engine remain. We present here the concept for a balloon-borne follow-up mission called *ASCENT* (A SuperConducting ENergetic x-ray Telescope). *ASCENT* uses transition edge sensor gamma-ray microcalorimeter detectors with a demonstrated 55 eV Full Width Half Maximum (FWHM) energy resolution at 97 keV. This 8–16-fold improvement in energy resolution over *NuSTAR* will allow high resolution imaging and spectroscopy of the ^{44}Ti emission. This will allow a detailed reconstruction of gamma-ray line redshifts, widths, and shapes, allowing us to address questions such as: What is the source of the neutron star “kicks”? What is the dominant production pathway for ^{44}Ti ? Is the engine of Cas A unique?

Keywords: X-ray, spectroscopy, instrumentation, Supernova remnants.

*Fabian Kislat, fabian.kislat@unh.edu

1 Introduction

Core-collapse supernovae (CCSNe) of prior generations of stars are thought to be a major source of elements heavier than iron in our Solar System.¹ Hence, understanding their explosion mechanism is key to understanding the evolution of our Galaxy eventually supporting life on Earth. In this paper, we describe a concept for a new balloon-borne high-energy X-ray telescope and potential future satellite mission that will, among other science goals, provide new experimental insights into the inner workings of the CCSN engine.

Supernovae as a source of heavy elements are supported both by theoretical considerations and experimental evidence. Since ^{56}Fe is the nucleus with the lowest mass per nucleon, fusion of

heavier elements cannot serve as a source of energy in stellar cores. Instead, heavier elements are formed via slow (*s*-process) or rapid neutron capture (*r*-process). Some of the earliest and strongest experimental evidence for nucleosynthesis in CCSNe comes from the detection of 847 keV and 1238 keV gamma-rays associated with the decay of ^{56}Co to ^{56}Fe in SN 1987A.² Direct evidence for the fact that our Solar System is indeed made of reprocessed stellar ejecta comes from the analysis of presolar grains in meteoritic material and interplanetary dust, whose isotopic composition is representative of the seed material of the Solar System.³ In fact, recent simulations show that $15M_{\odot}$ CCSNe are capable of producing many of the isotopic anomalies found in certain presolar SiC grains,⁴ which have long been argued to condense in supernovae.⁵

An important conclusion from the observations of high-energy X-ray and gamma-ray emission from SN 1987A soon after the explosion was that mixing of material from the different shells of the progenitor star must occur very early on in the explosion.⁶ This mixing moves radioactive nickel outward from the innermost parts of the ejecta, which then drives the X-ray emission. However, the details of this mixing and the underlying mechanism are still poorly understood and depend on the local conditions of the early shock, such as peak temperature and density. Due to these convective instabilities, anisotropies are expected in supernovae and their remnants.

The structure of young supernova remnants (SNR) reflects the conditions of the explosion. Since many galactic SNR are spatially resolvable in X-rays and gamma-rays, these remnants are an excellent site to study supernova explosion physics. Regions where explosive Si burning occurs can be observed via the K line emission from ^{56}Fe , which is a decay product of ^{56}Ni produced during Si burning with relatively little dependence on local conditions. The observations, however, come with the caveats that the X-ray emission depends on the heating of the material in the shock, and that some of the iron may actually be interstellar material swept up in the shock rather than supernova ejecta.

The production of ^{44}Ti in the same regions, on the other hand, is very sensitive to the local conditions. This isotope with a half-life of $(58.9 \pm 0.3) \text{ yr}$ ⁷ is in principle observable in galactic supernova remnants up to a few hundred years old. It decays via $^{44}\text{Ti} \rightarrow ^{44}\text{Sc} \rightarrow ^{44}\text{Ca}$, emitting gamma-rays with energies of 1157 keV, 78.32 keV and 67.87 keV with branching ratios between 93 % and 99.9 %.⁸ These gamma-rays directly trace the distribution of ^{44}Ti decays. Because of these properties, observations of ^{44}Ti are a particularly powerful tool to test supernova models, which has been noted as early as 1969.⁹

Here, we discuss a concept for a new balloon-borne high-energy X-ray telescope called *ASCENT* (A SuperConducting ENergetic x-ray Telescope), which had been proposed to NASA's Astrophysics Pioneers program, and which could form the basis of a future *NuSTAR* follow-up mission. *ASCENT* consists of a novel transition edge sensor (TES) microcalorimeter gamma-ray detector array in the focal plane of a multi-layer coated Wolter-type focusing X-ray mirror. Transition edge sensors utilize the rapid change in conductivity with temperature of a superconductor at its superconducting transition temperature T_c for calorimetric energy measurements.¹⁰ A gamma-ray spectrometer is constructed by coupling the TES to a thick absorbing structure, commonly made of Sn, which increases the quantum efficiency for the detection of 10–100 keV photons. Recently, an array consisting of 512 detectors with a spectral resolution of 55 eV FWHM at 97 keV has been demonstrated,¹¹ and individual detectors have achieved a resolution as precise as 22 eV. Using these detectors, *ASCENT*'s spectral resolution will be about 15 times better than *NuSTAR* in the 60–85 keV energy range (900 eV at 60 keV).¹²

Additionally, *ASCENT* will use a new Ni/C multilayer structure on its X-ray optics. The energy bandpass of *NuSTAR* was limited by the platinum K edge at 78.395 keV of its Pt/C multilayer, which prevents it from observing the blue-shifted 78 keV ^{44}Ti line. The use of a Ni/C multilayer will extend *ASCENT*'s bandpass to 85 keV and beyond. Furthermore, its multilayer structure will be optimized for the 55–85 keV range, in order to maximize its effective area for observations of ^{44}Ti . While the baseline angular resolution of the *ASCENT* optics of 2' will be slightly worse than *NuSTAR*, it will still allow resolution of the most prominent ^{44}Ti emission regions in Cas A.

Observations of the supernova remnant Cas A with *ASCENT* will test if asymmetries of the ejecta can completely account for compact remnant “kicks”. Furthermore, they will allow us to determine the dominant pathway for the production of ^{44}Ti .

So far, ^{44}Ti has only been firmly detected from two objects: SN 1987A^{13,14} and Cas A.^{15–17} Tentative detections from Vela Jr.¹⁸ and Tycho's SNR¹⁹ have so far not been confirmed.^{20,21} However, the Compton Spectrometer and Imager (*COSI*) will map the Galaxy with unprecedented spectral and spatial resolution and may find additional sources of ^{44}Ti emission.²² While *COSI* is an excellent tool to discover ^{44}Ti emission from additional SNR, its spatial and spectral resolution are not sufficient to map individual objects. A more sensitive space mission based on the *ASCENT* design could follow up on these detections and provide detailed maps of additional SNR. This would answer the question whether features observed in Cas A are universal or whether there is wide variation in the underlying engine depending on properties of the progenitor star. Furthermore, a detection of ^{44}Ti from a remnant associated with a type Ia supernova, such as Tycho's SNR, would be a major breakthrough. Ordinarily, SNIa are not expected to produce much ^{44}Ti . However, some models predict a potential detonation below the Chandrasekhar mass limit (see *e.g.*, Woosley and Weaver, 1994²³), in which case a large amount of ^{44}Ti may be produced. Such explosions are thought to be one of the candidates for the origin of Galactic positrons.²⁴ Thus, such an observation would not only constrain the SNIa explosion mechanism but also provide new insights into the origin of Galactic positrons.

Launched on a stratospheric balloon from Kiruna, Sweden, *ASCENT* will float westward at an altitude of about 125,000 ft to northern Canada. Typical flight times are 5–7 days, allowing for up to 560 ksec of observation time of Cas A. A Southern Hemisphere flight from McMurdo Station, Antarctica, will circle the South Pole at least once for a typical flight time of two weeks. Such a flight will allow deep observations of SN 1987A.

In Section 2 we discuss the scientific questions addressed by the *ASCENT* balloon mission, the technical aspects of which we describe in detail in Section 3. In Section 4, we present results of Geant4 Monte Carlo simulations of the expected performance of *ASCENT* and the resulting sensitivity of the instrument to address its science goals. Finally, in Section 5, we summarize the results and give an outlook towards a space-based mission based on the *ASCENT* technology.

2 Scientific objectives

ASCENT's improved spectral resolution will allow it to address some key questions brought up by the recent *NuSTAR* observations of Cas A: what is the source of compact remnant “kicks” and what are the conditions of ^{44}Ti production in the Cas A supernova remnant?

The high yield of ^{44}Ti detected in Cas A^{15–17,25,26} is seen as strong support for the expected anisotropies.²⁷ A 2.4 Ms observation with the *NuSTAR* satellite was used to obtain the first 3-D map of the ^{44}Ti ejecta,^{17,28} which confirmed these high yields and, furthermore, found that the ^{44}Ti

lies in clumpy structures. Because much of the ^{44}Ti was found to lie in unshocked regions, its observation provides a pristine measurement of the asymmetries in the supernova engine, and this *NuSTAR* data decisively showed that Cas A was produced from an explosion with multiple outflows (as expected from the convective engine) and not a jet. However, the *NuSTAR* observations left many questions unanswered and raised a series of new problems with our understanding of Cas A, which *ASCENT* will address.

Along with ^{56}Ni , ^{44}Ti is produced in the innermost supernova ejecta. In contrast to ^{56}Ni production, ^{44}Ti production is extremely sensitive to the temperature and density evolution of the ejecta²⁹ and, hence, the nature of the explosion. Within 1–2 years of a supernova explosion, ^{56}Ni decays to stable iron. This iron produces emission lines when heated by the reverse shock as the supernova ejecta plows through the circumstellar medium and depends on the distribution of the circumstellar medium as well as the explosion, making its interpretation complicated. The innermost iron in the remnant is also difficult to measure accurately, since it is inside of the reverse shock and therefore cold. Although attempts have been made at detecting this iron in the infrared in Cas A,³⁰ the unbiased nature of the ^{44}Ti observations and their sensitivity to the explosion characteristics have led to ^{44}Ti 's important role in shaping our understanding of the core-collapse explosion.

2.1 The core collapse engine of Cas A

A key to understanding the core collapse supernova engine is understanding the production and mixing of ^{44}Ti during the explosion, which will identify the dominant pathways of ^{44}Ti production in supernovae. The processes that produce Ti are quasi-statistical or statistical equilibrium processes. They produce an equilibrium distribution of nuclei based on the nuclear chemical potentials at a given temperature, density, and electron fraction.²⁹ The local ratio between ^{44}Ti and ^{56}Ni strongly constrains the thermodynamic initial conditions, allowing a fairly precise determination of the final distribution of all nuclei. The remaining uncertainty can then be attributed to the thermodynamic history, which determines the details of freezeout. Observations of additional nuclear species will provide additional constraints and reduce residual uncertainties.

Combining *ASCENT*'s ^{44}Ti observations with observations of Cas A's Si and Fe lines from JAXA's and NASA's *XRISM* mission (to be launched in 2023) will allow us to perform an improved reconstruction of the Si, Fe, and Ti configurations at the current time and at the time of the supernova explosion. *ASCENT* will improve the spectral resolution of the ^{44}Ti emission over *NuSTAR*, allowing us to construct a more detailed map of the clumpy structures in Cas A, enabling a more detailed comparison to numerical models and helping to disentangle multiple structures along a line of sight and the properties of these structures. These comparisons provide direct constraints on the engine.

NuSTAR's results indicate that most of the ejecta are moving away from us with a velocity of 1000–5000 km s^{−1} but that some ^{44}Ti regions (*Region 1* in Fig. 1, *i.e.*, Region 20 of Grefenstette et al., 2017²⁸) move towards us with 7500 km s^{−1}. The combination of *ASCENT*'s 67 eV energy resolution with its effective area extending to >85 keV will enable an analysis with much smaller systematic errors than that of the *NuSTAR* analysis. If confirmed, these high velocity ejecta would challenge current supernova theory and provide a strong constraint on models. Most current models that lead to a high yield of ^{44}Ti do not result in velocities >4500 km s^{−1},^{31,32} and the highest velocity found in the models by Vance et al.³³ is ~5500 km s^{−1}. The detailed velocity measurement can also be used to understand ^{44}Ti production. Nucleosynthesis calculations predict different ^{44}Ti

Fig 1: X-ray image of emission lines in Cassiopeia A: iron (red), silicon/magnesium (green), titanium (blue), and continuum emission (yellow).¹⁷ Two parts of the remnant of particular interest are highlighted. *Region 1* is the only region in which *NuSTAR* detected significantly blue-shifted ^{44}Ti ejecta. *Region 2* is of interest due to the highly blue-shifted almost pure iron ejecta. Composite Chandra/*NuSTAR* image credit NASA/JPL-Caltech/CXC/SAO.

yields depending on the ejecta velocity.³³ We can use the ejecta velocities to constrain the trajectories (temperature and density evolution) of the ejecta, allowing us to test both our explosion and nucleosynthesis models. These ejecta velocities can be tied to more fundamental properties like the electron fraction and nuclear cross sections.

Because we expect ^{44}Ti to be produced at some level whenever ^{56}Ni is produced, we expect to see ^{44}Ti lines wherever iron is observed. This raises the question why there are large iron ejecta with no evident detection of ^{44}Ti in Cas A. The *NuSTAR* observations could not detect ^{44}Ti in the iron-rich southeastern region of Cas A (*Region 2* in Fig. 1). Is it because that iron is produced directly (not the decay product of ^{56}Ni), or was there a large amount of ^{56}Ni produced with ^{44}Ti mass fractions below the *NuSTAR* detection limit? The *NuSTAR* upper limit in this region of the SNR is not very constraining,²⁸ and the iron-rich ejecta are blue-shifted with a velocity up to 3000 km s^{-1} .^{34,35} Therefore, *ASCENT* may be able to detect the ^{44}Ti in this region due to its sensitivity to the blue-shifted 78 keV line, or significantly improve on the *NuSTAR* upper limit.

2.2 Compact Remnant Kicks

Observations of pulsar proper motions and the existence of specific peculiar binary systems suggest that momentum is imparted onto compact remnants during their formation (for a review, see Fryer and Kusenko, 2006³⁶). A diverse set of models have been proposed to create these kicks, but these models can be separated into two categories: asymmetries in the ejecta and asymmetries in the neutrino emission. Under the convection-enhanced supernova engine paradigm,³⁷ low-mode convection produces asymmetric explosions with a nonzero net momentum in the ejecta.³⁸ These asymmetries impart a net momentum to the compact remnant, and a 1 % asymmetry in the ejecta produces the high observed kick velocities. Although simulations have struggled to produce some of the highest observed kicks, ejecta asymmetries remains one of the strongest candidate mechanisms for explaining pulsar proper motions. Alternatively, asymmetries in the neutrino emission

(typically requiring strong magnetic fields – albeit not necessarily strong bipolar magnetic fields) also carries away a net momentum, imparting an equally strong kick onto the compact remnant.³⁹

The different mechanisms proposed in the ejecta and neutrino mechanisms make a variety of predictions on the relation of the compact remnant kicks with relation to angular momentum, dipole magnetic-field strength, final remnant mass, and the formation of a black hole versus a neutron star. Many of these predictions are indirect, and it is difficult to place strong constraints on the mechanism with existing observations. However, *NuSTAR* observations opened up the potential for a more direct observational constraint with detailed maps of the ^{44}Ti to compare the asymmetries in the explosion to the remnant velocities. Because ^{44}Ti is produced in the innermost ejecta, it is an ideal probe of these explosion asymmetries. However, to truly compare the explosion asymmetries with the compact remnant kick, we need detailed 3-dimensional ejecta information. Although the current *NuSTAR* data hinted at a correlation between the explosion asymmetries and the compact remnant kick supporting the ejecta kick mechanism,²⁸ the higher-fidelity *ASCENT* observations will allow a more quantitative test of the ejecta kick mechanism.

2.3 Validating the convective SN engine

The convective nature of the supernova engine in Cas A has been established quite firmly. However, there are only two SNR with confirmed detections of ^{44}Ti , and Cas A is the only SNR in which ^{44}Ti emission has been spatially resolved. This raises the question whether the SN engine of Cas A is unique, which *ASCENT* can address through observations of SN 1987A.¹³ While *ASCENT* cannot spatially resolve SN 1987A, a precise measurement of the ^{44}Ti line shapes can be used to quantify asymmetries in the Ti distribution.

Figure 2 shows the velocity distributions along three lines of sight for two different supernova explosions. These velocity distributions are derived from 3-dimensional smooth particle hydrodynamics simulations of asymmetrically-driven supernova explosions.⁴⁰ One explosion is bimodal (either produced by a mild “jet” or low-mode convection model with rotation) and the other is more representative of a low-rotation, low-mode convectively-driven explosion (“Asym”). For the velocity distributions in this figure, we chose 3 different lines-of-sight and measured the velocities of the ejecta along these lines-of-sight (to determine the red- and blue-shifted features). The *ASCENT* observations will not only be able to easily differentiate between these models, but also enable us to further constrain the specific features of the convective engine.

3 Technical implementation

3.1 Overview

The *ASCENT* experiment (Figure 3) uses a 12 m optical bench with a 45 cm-diameter, $F = 12$ m multilayer X-ray mirror at the front end and a cryogenically cooled microcalorimeter detector assembly at the rear end. A balloon gondola holds a two-frame gimbal, pointing the optical bench in the direction of the observed astrophysical sources with the help of the Wallops Arc Second Pointer (WASP) system.⁴¹ The microcalorimetric detector array is cooled by an Adiabatic Demagnetization Refrigerator (ADR) inside a 65 L liquid He dewar. Table 1 summarizes key characteristics of the *ASCENT* observatory and its expected performance. In the remainder of this section, we describe the design of each of the main components.

The telescope will be carried by a $1.1 \times 10^6 \text{ m}^3$ He-filled balloon to an altitude of about 38 km. When launched from Esrange in Kiruna, Sweden, it will partially circle the North Pole, reaching

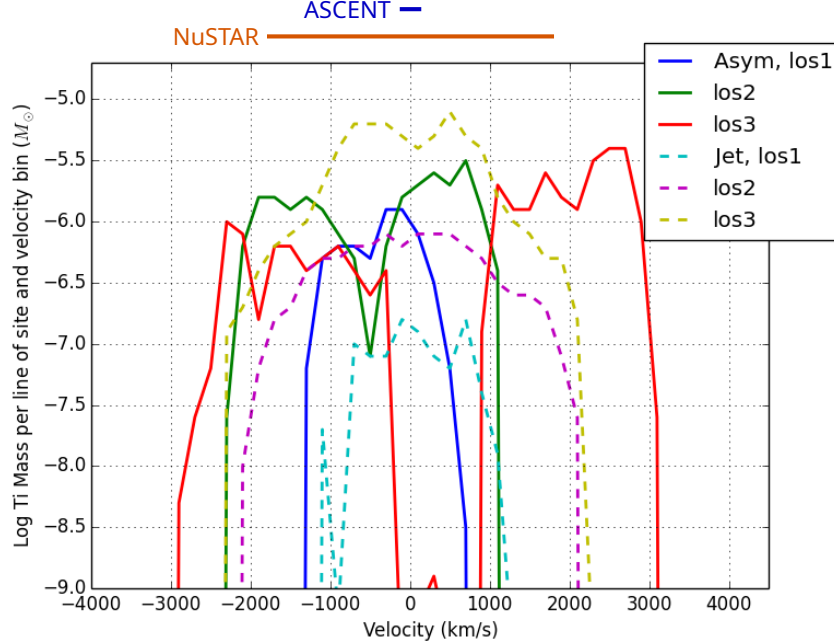

Fig 2: Velocity distribution of the ^{44}Ti ejecta for two different supernova explosions: a bipolar explosion where the ejecta is fastest along the axis (jet) and an explosion with multiple strong outflows mimicking the predictions of the convective supernova engine (asym).⁴⁰ The structure in the line of sight velocity distribution can be tied to the structure of the supernova engine (*i.e.*, the bipolar explosion has a very different profile than the asymmetric explosion). The bars at the top of the graph illustrate the line-of-sight velocity resolution of *NuSTAR* and *ASCENT*. Thanks to *ASCENT*'s energy resolution, we will be able to measure these differences.

Northern Canada after a typically 5–7-day flight. On this trajectory, the telescope will be able to continuously observe Cas A with an elevation angle of about $36 - 82^\circ$. Additional, longer, flights from McMurdo Station (Antarctica) will circle the South Pole, enabling deep observations SN 1987A.

3.2 Focal plane instrumentation

3.2.1 Transition Edge Sensor array

Microcalorimeter technology has shown great promise for transforming X-ray astrophysics. For example, the *Hitomi* mission used a 36-pixel Si thermistor microcalorimeter array for its Soft X-ray Spectrometer (SXS).⁴² The *Athena* mission (to be launched in 2032) will use a 4000-pixel microcalorimeter array for its X-ray Integrated Field Unit (X-IFU).^{43,44} Over the last 15 years, transition-edge sensor (TES) microcalorimeter spectrometers have been developed as cutting-edge tools in the fields of nuclear materials analysis^{11,45–47} and the X-ray sciences.^{48–54}

TES microcalorimeters are detectors that measure the energy of individual photons through the temperature change of a superconducting thin film thermometer (see Fig. 4). The TES thermometer is coupled to a photon absorber composed of a high-Z element such as bismuth or tin, enabling high quantum efficiency for x-rays up to 100 keV. The fundamental energy resolution of a calorimeter is

$$\Delta E \propto \sqrt{k_B T^2 C}, \quad (1)$$

Table 1: Key *ASCENT* payload characteristics and expected performance. Details of the performance estimates are provided in Section 4.

Component	Description	Performance
Truss	Carbon fiber tubes and aluminum joints	Focal spot movement <3 mm, alignment knowledge 0.5 mm ($9''$)
Pointing system	Pitch-yaw articulated	Pointing precision 1.0 – $3.6''$ (3σ) on source
Star camera	100 mm, $f/1.5$ short-wave infrared lens	Pointing knowledge $<15''$ (3σ)
X-ray mirror	Wolter I, 12 m focal length, diameter 40 cm, 110 Ni/C-coated and 100 Pt/C-coated shells	Effective area 190 cm ² at 70 keV, Angular resolution $2'$ HPD, Field of view $5'$ FWHM
Cryostat	LHe-backed adiabatic demagnetization refrigerator	Base temperature 70 mK
Detector	Two-layer gamma-ray TES array, 256 pixels each, $1.4 \times 1.4 \times 0.59$ mm ³ absorbers ($30'' \times 30''$ at 12 m), microwave multiplexed readout	Bandpass: 2 – 100 keV, energy resolution $\Delta E(80 \text{ keV}) = 67$ eV FWHM
Power	Detectors, cryostat, heaters	~ 350 W
Mass	Mass under balloon rotator	~ 1700 kg
Signal rate	1 Crab source at 45° elevation	0.5 Hz at 60 – 80 keV
Background rate	BGO shield veto applied	0.02 Hz at 60 – 80 keV

Fig 3: CAD rendering of the *ASCENT* telescope. Key components are labeled in the Figure and described in Section 3. The gondola and truss design are almost identical to *XL-Calibur*, maximizing flight heritage.

Fig 4: (a) Calorimetric spectroscopy of x-rays. An incident photon deposits its energy into a target with a weak thermal link to a cold isothermal bath. (b) A typical pulse-response curve with a decay time determined by the properties of the calorimeter element and its coupling to the isothermal bath. The filtered pulse height is an extremely precise measure of the photon’s energy. (c) Thermometry is performed with a thin-film superconducting transition-edge sensor. The extreme precision results from the sharp temperature dependence of the electrical resistance of the thin film operated close to its superconducting transition temperature.

where T and C are the sensor temperature and heat capacity,^{10,55} allowing these devices to achieve extraordinary energy resolution by operating at cryogenic temperatures of about ~ 100 mK.

A prototype detector array called “Spectrometer to Leverage Extensive Development of Gamma-ray TESs for Huge Arrays using Microwave Multiplexed Enabled Readout” (*SLEDGEHAMMER*, see Fig. 5 and Mates et al., 2017¹¹) has achieved a full-width at half maximum (FWHM) resolution of 55 eV at 97 keV. A resolution as low as 22 eV has been demonstrated with individual detectors.^{11,45,56} The 100 keV energy resolution of 55 eV FWHM of *SLEDGEHAMMER* is $10\times$ better than that of cryogenically cooled High Purity Germanium spectrometers (HPGe) and $\sim 20\times$ better than room-temperature CdZnTe detectors.

ASCENT will use detectors similar to those of the *SLEDGEHAMMER* hard X-ray/ γ -ray spectrometer.¹¹ A photograph of a *SLEDGEHAMMER* detector is shown in Fig. 6. These sensors use polycrystalline tin absorbers to absorb photons. Tin is chosen because it combines a relatively high stopping power for γ -rays in the energy range of interest with a low specific heat at cryogenic temperatures. In *SLEDGEHAMMER*, these absorbers are $1.45 \text{ mm} \times 1.45 \text{ mm}$ in area and 0.38 mm thick. For *ASCENT* we plan on using 0.59 mm thick absorbers to increase quantum efficiency to 87 % at 68 keV and 75 % at 78 keV. The 55 % increase in absorber volume results in a corresponding increase of the heat capacity, and a 25 % increased energy resolution based on Eq. (1). The expected energy resolution of the detectors, thus, increases to 68 eV. The absorbers are glued to epoxy posts, which are connected to the TES element by copper traces of equal length to ensure a uniform thermal path to the sensor (Fig. 6). The TES element is a $400 \mu\text{m} \times 400 \mu\text{m}$ bilayer of superconducting material and normal metal, lithographically deposited on a Si_3N_4 membrane. The transition temperature T_c is set to ~ 120 mK by the superconducting proximity effect in thin-film bilayers. This T_c includes enough margin above the base temperature of an Adiabatic Demagnetization Refrigerator (ADR) to allow for stable operation. Options for bilayer materials include MoCu, as in *SLEDGEHAMMER*, as well as MoAu TES using NIST’s patented hasTES process.⁵⁷

Current fabrication methods require manual placement of the absorbers on the TES array using mechanical tweezers. This constrains the minimum size and spacing of the absorbers to dimensions

Fig 5: *Left*: Photograph of the fully assembled *SLEDGEHAMMER* detector package. The package contains eight TES microcalorimeter chips with 32 sensors each (center), eight microwave multiplexer chips with 32 channel readout (outer vertical columns), and eight chips each for detector bias, Nyquist filtering, and signal routing. The TES signals are read out by two pairs of coaxial cables attached to the box by SMA connectors on the top and bottom of the box, each recording the signals for 128 sensors. *ASCENT* will use similar architecture to minimize risk, but with two monolithic detector chips stacked on top of each other, to minimize inter-pixel dead space and maximize collection efficiency. *Right*: A combined ^{153}Gd spectrum from 89 active TESs measured simultaneously using microwave SQUID multiplexing readout. The inset shows a zoomed region around the 97 keV γ -ray peak (blue) with a Gaussian fit FWHM resolution of 55 eV (red). The energy resolution achievable with TES microcalorimeters is 15 times better than that achieved by *NuSTAR*, achieving 270 km/s accuracy in measurements of the velocity of ^{44}Ti ejecta. Reprinted from Mates et al. (2017)¹¹ with the permission of AIP Publishing.

Fig 6: (a) Photograph of a TES gamma-ray microcalorimeter pixel before the Sn absorber is attached, showing the Si_3N_4 membrane (darker area), the Mo-Cu TES in the middle, and 20 SU8 epoxy posts connected to the TES by the Cu legs. (b) A portion of the detector chip with some of the Sn absorbers attached. The Sn absorbers are 1.45 mm \times 1.45 mm \times 0.38 mm thick, placed on a 1.75 mm pitch. (c) Each *ASCENT* detector die uses a central array of 256 of these γ -ray sensors (within the black inner circle) surrounded by an octagonal pattern of eight sets of 32-channel bias chips (blue), Nyquist filtering chips (red) and microwave SQUID multiplexer chips (purple). For scale, the outer black circle is 80 mm in diameter, and the overlay indicates a projection of the Cas A ^{44}Ti distribution measured by *NuSTAR*. Each die will be fabricated monolithically from a 75 mm Si wafer to minimize space between pixels. Figures (a) and (b) reprinted from Bennett et al. (2012)⁴⁵ with the permission of AIP Publishing.

close to those of *SLEDGEHAMMER*, resulting in a 1.75 mm pixel pitch and an array fill fraction of about 65 %. At 12 m focal length, this pixel pitch corresponds to an angular separation of 30''. The low array fill fraction correspondingly reduces the overall photon collection efficiency of the array.

To alleviate these issues, the instrument detector package will consist of 512 detectors, in the form of two dies each containing 256 detectors. The dies will be stacked on top of each other and offset so that the detectors in the lower die will lie directly underneath the gaps between detectors in the upper die. This will result in a total detection efficiency for photons striking the array of 80 % at 68 keV and 70 % at 80 keV. The layout and design of each die is conceptually similar to the proven design of the *SLEDGEHAMMER* microcalorimeter array. The central array of 256 TES detectors in each die (Fig. 6(c)) is fabricated from a single 75 mm Si wafer, with wiring to carry the TES signals to bond pads for connection to the rest of the readout circuitry arranged in an octagon around the outside of the TES array.

At 12 m focal length, a point spread function with the half power diameter (HPD) of *ASCENT* corresponds to 3.5 mm, which is Nyquist sampled by each of the two detector dies. Combining the two offset detector dies allows a sampling of the PSF with an effective detector pitch of ~ 1.2 mm. The distance between the two dies will be less than 1 cm. Assuming the focal plane of the X-ray optics is placed directly between the two dies, the HPD of the point spread function will increase by only ~ 2 %. The array diameter corresponds to an angular scale of about 8.8', significantly larger than the field of view of the X-ray optics, which eases the requirements on alignment stability as long as alignment knowledge can be maintained.

3.2.2 Sensor readout

TES arrays use multiplexing to minimize the thermal load and cryogenic complexity of wire connections to room temperature. The development of the Microwave SQUID Multiplexer, which reads out array of microcalorimeters using microwave techniques,^{11,58} increases the available measurement bandwidth from ~ 30 MHz (the intrinsic limit in previous multiplexing architectures) to the several GHz of bandwidth available on a single coaxial cable.

In the Microwave SQUID Multiplexer,⁵⁹ each sensor is coupled to a high-Q, thin-film resonant circuit by an rf-SQUID that transduces current changes at the sensor to changes in inductive load on the resonator (Fig. 7). Multiple resonators, each with a unique frequency, are coupled to a single microwave feedline. A sum of microwave tones (sine waves) is supplied to the feedline, each tone matched to the frequency of one resonator. Changes in the current through a sensor will shift the center frequency of its resonator and thus change the amplitude and phase of the tone that propagates through the feedline. All tones are amplified by a single shared cryogenic low-noise amplifier before returning to room temperature, where they are analyzed to extract the detector signals. Signals from different sensors can easily be separated because they appear in modulation sidebands of their respective tones. The first microcalorimeter array with microwave readout, *SLEDGEHAMMER*, demonstrated multiplexing factors of 128 with negligible resolution degradation, yielding a co-added resolution of 55 eV at the 97 keV gamma-ray peak (Figs. 5 and 6).

ASCENT will use the same 33-resonator microwave SQUID multiplexing chip designs used for *SLEDGEHAMMER*, shown in Fig. 7(b). Each resonator has a FWHM bandwidth of ~ 300 kHz, and the resonances are spaced 3 MHz apart. Variations to the design place 32 resonators into each of eight 125 MHz bands between 5 GHz and 6 GHz, yielding a total density of 256 detectors per

Fig 7: (a) Circuit schematic showing three channels of a microwave SQUID multiplexing circuit with TES microcalorimeters. (b) A photograph of a 33-channel microwave SQUID multiplexer chip used in the *SLEDGEHAMMER* instrument. (c) A close-up photograph showing quarter-wave microwave resonators capacitively coupled to a feedline. The resonators are terminated by inductively coupled rf-SQUIDs (left). The microwave SQUID multiplexer takes advantage of the large bandwidth provided by coaxial cables to significantly reduce the thermal load and design complexity of reading out large-format arrays of TES microcalorimeters, such as those used in *ASCENT*. Reprinted from Mates et al. (2017)¹¹ with the permission of AIP Publishing.

GHz of available bandwidth. To read out the 512 detectors used in *ASCENT*, we will use 2 parallel pairs of coaxial cables, each reading out a separate set of resonators in the 5–6 GHz range.

The signals will be analyzed by four commercially available *ROACH2* Field Programmable Gate Array (FPGA) systems designed by the *CASPER* radio astronomy consortium,⁶⁰ each covering a bandwidth of 512 MHz using commercially available DAC and ADC daughter boards.

3.2.3 Calibration

Achieving the best possible spectroscopic performance requires constant monitoring of the detector calibration, in order to be able to correct for calibration drift. *ASCENT* will carry a calibration source housed inside a tungsten enclosure outside a dedicated window in the cryostat, illuminating the detector array from behind. The calibration of gamma-ray TESs drifts on timescales of minutes to hours. Experience shows that the dominant contribution to short-term drift is correlated with the baseline and can be corrected for. Therefore, it is necessary to obtain calibration spectra about once per hour to keep the systematic uncertainty due to residual drift below 10 eV. By collecting about 100 photons per calibration line, we can keep the statistical uncertainty of the calibration negligible. Two approaches to calibration are still under consideration: continuous illumination with a weak source or use of a strong source behind a shutter periodically illuminating the array for a brief period of time.

The advantage of continuous illumination is that no shutter mechanism is required and that no artificial dead-time is introduced. This reduces mission complexity and, thus, risk. However, care must be taken in the selection of calibration isotope or combination of isotopes. Calibration lines should be close to the energy range of interest, but lines within the energy range of interest, including escape peaks, will cause unacceptable background. Furthermore, emission lines above the energy range of interest will cause a background continuum due to Compton scattering in the detectors. A preliminary Geant4^{61–63} simulation study of calibration spectra obtained with a selection of viable sources revealed ¹⁵⁵Eu with sufficiently strong lines at 60 keV and 86 keV as a candidate.

A sufficiently strong source behind a shutter will allow us to acquire calibration spectra at regular intervals over a short period of time. Because calibration data are acquired at known time intervals during which science data collection will be suspended, it is possible to use calibration lines in the energy range of interest. This has the advantage of mitigating the impact of non-linearities in the detector response. The approach also reduces the continuum background due to high-energy lines from the calibration source, assuming sufficient shielding is possible. The downside of this approach is that a mechanical shutter is required, adding complexity. While details still need to be optimized, a preliminary estimate shows that a 1 min calibration window every hour will be sufficient. A possible calibration isotope is ^{227}Ac which emits a large number of X-ray and gamma-ray lines in the energy range of interest. This calibration method would result in an additional dead-time of $<2\%$.

3.2.4 Anti-coincidence detector

In order to reduce the background, the cryostat section containing the focal plane instrumentation will almost entirely be enclosed in a $\sim 2\text{--}3\text{ cm}$ -thick active bismuth-germanate (BGO) anti-coincidence shield. Scintillation light due to particles interacting in the anti-coincidence shield will be detected by photomultiplier tubes (PMTs) or Silicon Photomultipliers (SiPMs). Signals in these PMTs or SiPMs will produce a flag vetoing any triggers in the TES detector readout, significantly reducing the residual background, in addition to the passive shielding provided by the absorption of particles in the BGO. The design will maximize the solid angle covered by the active shield. The conservative solution is to place the active shield components at the outside of the cryostat, avoiding the difficulties associated with bringing the scintillator crystal and detectors from ambient temperatures and pressure to liquid helium temperatures and near vacuum. In this case, passive tungsten shielding will be used inside the cryostat for the small solid angle portions not covered by the active shield outside the cryostat. We are evaluating solutions with active shielding inside the cryostat which would result in a smaller shield and thus reduced cross sections for interactions with the background, and a reduced shield mass. In both cases, the veto flag will be fed to the data acquisition and will be digitized along with the TES signals.

3.3 X-ray optics

ASCENT achieves a large effective area in the 65–85 keV energy range using a dedicated multilayer-coated grazing incidence X-ray mirror. The mirror consists of 213 nested shells in two reflection stages with a diameter of 40 cm. The innermost 110 shells will be coated with approximately 500 Ni/C layer pairs, while the remaining shells will be coated with roughly 200 Pt/C layer pairs. Given the focal length of 12 m, the design will limit incidence angles to $< 0.23^\circ$. Reflectivity over a broad bandwidth at high X-ray energies is achieved by coating the shells with alternating layers of high-Z and low-Z material. The *ASCENT* optics are expected to achieve an angular resolution of $2'$ half-power diameter (HPD). The field of view of $5'$ FWHM exceeds the angular size of Cas A of $4'$.

Most X-ray telescopes are designed to achieve a high collection area over a broad energy range. The broadband design necessitates the deposition of a multilayer stack for soft X-rays on top of the stack for hard X-rays. However, the thick soft X-ray layers absorb some of the higher-energy photons. For *ASCENT*, the multilayer design will be optimized for energies above 60 keV, achieving there substantially higher reflectivities than a broadband X-ray multilayer coating. Figure 8

Fig 8: Comparison of the effective areas of mirror designs for *ASCENT* and the two *NuSTAR* mirrors combined.¹² The *ASCENT* design uses a combination of Ni/C multilayer coatings on the inner 110 shells and Pt/C on the outer shells. An alternative design using Pt/C layers on all shells is shown for comparison. The shaded region indicates the expected range of the surface roughness between $\sigma = 6 \text{ \AA}$ (worst case) and 4 \AA (best case). The dashed and dotted red lines indicate the contribution of the Pt/C and Ni/C shells in the $\sigma = 4 \text{ \AA}$ case, respectively.

shows the comparison of the collection areas of the *ASCENT* and the two *NuSTAR* mirrors. The platinum K absorption edge at 78.395 keV limits the effective area at higher energies, preventing a purely Pt/C multilayer mirror from properly observing the ^{44}Ti line at 78.36 keV, especially when that line is blueshifted. Therefore, in addition to an optimized multilayer structure, the *ASCENT* optics will use Ni/C coatings on the innermost 110 out of 213 nested shells. The Ni/C design requires about 500 layer pairs, while the Pt/C design requires about 200 layer pairs, which limits the number of foils that can be fabricated with this method within the project timeline. A surface roughness of 4–6 \AA of the multilayer coatings is expected. The *ASCENT* mirror achieves collection areas of $>100 \text{ cm}^2$ in the 65–80 keV band. Due to the optimization of the layer structure for ^{44}Ti observations, the effective area between $\sim 30 \text{ keV}$ and 55 keV is very small. The low-energy reflectivity is not due to Bragg reflection on the multilayer, but due to total external reflection on the surface. The Ni/C multilayer combination has been studied by several groups in the past (*e.g.*, Spiga et al., 2004⁶⁴) and is considered a top candidate material for future missions, such as *HEX-P*, to extend their energy band out to 200 keV.⁶⁵

3.4 Cryostat

The *ASCENT* cryogenic system cools the detector assembly to a nominal base temperature of 70 mK. Our baseline design foresees to use the cryostat architecture of Fig. 9 that uses a commercial adiabatic demagnetization refrigerator (ADR) coupled to a closed-cycle 300 mK refrigerator and a liquid helium bath. The 65 L tank is designed to cool the detectors for up to 14 days, more than sufficient for the expect duration of the balloon flights from Sweden to Northern Canada. An

Fig 9: Conceptual design of the *ASCENT* cryostat, which provides a 70 mK base temperature for the detectors. The detectors are housed in a protruding snout to minimize the mass of the shielding.

absolute pressure regulator maintains the tank near atmospheric pressure to provide a 4 K thermal bath, and internal baffles minimize sloshing to prevent resonances with the pointing system. Counterweights on the pointing system maintain payload balance as the motion of the liquid during elevation changes and cryogen boil-off shift the center of mass.

The main liquid helium tank is insulated by two vapor-cooled shields. As cold gas boils away from the liquid helium reservoir, it flows through stainless steel pipes connected to the shields through low-impedance heat exchangers. Since the helium boil off rate is proportional to the thermal load, negative feedback enforces temperature stability within the cryostat. G-10 trusses mechanically support each stage while maintaining sufficient thermal insulation. Liquid nitrogen cooling was considered as an alternative for the vapor-cooled shields, but would have led to a heavier and more complex design due to the additional cryogen tank.

A 300 mK temperature stage is provided by a multi-stage closed-cycle He-4/He-3 sorption refrigerator coupled to the cryostat's liquid helium tank. This serves as the launching point for the ADR, allowing a lower magnetic field strength and thus lower power consumption than launching directly from 4 K. The 300 mK stage also intercepts the parasitic load from the wiring and mechanical support structures to reduce the cooling power requirement on the lowest temperature stage. Similar refrigerators have been successfully used by many different balloon-borne cryogenic systems (*e.g.*, SPIDER,⁶⁶ EBEX,⁶⁷ BLAST-Pol,⁶⁸ and BOOMERANG⁶⁹).

The detector assembly is maintained at a base temperature of 70 mK by a commercially available ADR using a single ferric ammonium alum (FAA) salt pill⁷⁰ launched from the 300 mK stage to provide 1 μ W of cooling power with 120 mJ cooling capacity. A 3-hour regeneration cycle will be performed once every 24 hours, providing roughly 90 % observing efficiency. For optimal operation, the TES detectors and SQUID multiplexer chips must be protected from external magnetic

fields. The entire detector package assembly containing both detector dies and all SQUID multiplexer chips will therefore be enclosed in a two-layer magnetic shield, incorporated within the cryostat and maintained at cryogenic temperatures. These reduce the magnetic flux in the SQUIDS due to Earth’s magnetic field by about two orders of magnitude.

As an alternative cooling option, we are currently evaluating the performance of a mini Dilution Refrigerator.⁷¹ First measurements in the lab indicate that the mini Dilution Refrigerator is well suited for this application, offering continuous cooling to 80 mK temperatures. The cooling power does not change significantly for elevation changes of $\pm 30^\circ$, enabling its use for *ASCENT*.

3.5 Optical bench and gondola

X-ray optics and cryostat will be supported by a 12 m-long optical bench pointed by NASA’s Wallops Arc-Second Pointer (WASP) system. The optical bench consists of three sections made of carbon fiber tubes glued to Aluminum joints. The design results in an extremely stiff truss and is similar to previous balloon-borne telescopes *X-Calibur* and *XL-Calibur*.^{72,73} For example, the 8 m long truss of *X-Calibur* achieved a stability of <1.5 mm of the focal point during most of the flight.⁷⁴ The X-ray mirror, star tracker, and fiber-optic gyro of the WASP will be mounted to an Al honeycomb panel at the front end of the truss, and the focal plane instrumentation will be attached to an Al honeycomb panel at the rear end of the truss.

The stiffness of the optical bench fulfills two requirements. First, the WASP pointing system requires that the lowest-frequency vibration mode of the pointed body exceeds 10 Hz. Second, we require a motion of the focal spot <3 mm in order to ensure the entire image is always contained in the detector array. A focal spot motion of 3 mm corresponds to $50''$ pointing error. In order to reduce the resulting degradation of the point spread function, *ASCENT* will use an alignment monitoring system similar to *X-Calibur*.⁷⁴ The system uses an optical camera mounted in the central bore of the X-ray optics observing a pattern of LEDs mounted to the entrance window of the detector. On a 12 m truss, it measures the alignment with a precision of 0.15 mm or $2.5''$, negligible compared to the point spread function of the optics.

An aluminum gondola suspended from the balloon supports the truss pointed by the WASP. The WASP points the truss in pitch and within a limited yaw range with respect to the gondola. Coarse pointing in yaw is achieved using a standard NASA balloon rotator coupling the gondola to the balloon. Absolute pointing information is provided by a star tracker system specially developed for balloon flight applications. This system achieves a pointing stability of $<1''$ and an absolute pointing accuracy of $\sim 15''$.

4 Expected performance

During a balloon flight from Kiruna, Sweden, *ASCENT* will observe Cas A for approximately 500 ksec at an elevation of about $36\text{--}82^\circ$. We envision multiple northern hemisphere flights in order to attain longer total observation times.

In order to estimate *ASCENT*’s sensitivity, we simulated the detector in Geant4 as two stacked arrays of Sn absorbers with the layout as shown in Fig. 6c and a thickness of 0.59 mm. Input spectra were folded with the mirror effective area based on the Ni/C multilayer mirror shown in Fig. 8 and energy-dependent atmospheric absorption at a balloon altitude of 125,000 ft corresponding to an overburden of 2.9 g cm^{-2} . Photons were distributed according to the mirror point spread function (PSF) of ASTRO-H HXT,⁷⁵ which is similar to the expected *ASCENT* PSF.

Fig 10: *ASCENT* narrow line sensitivity as a function of energy, demonstrating *ASCENT*'s ability to detect ^{44}Ti in various regions of Cas A with a single 500 ksec flight. The vertical yellow bands indicate energy ranges of interest and the horizontal black bars are the flux levels measured by *NuSTAR*.²⁸

We estimate the background using measurements made during the Antarctic flight of *X-Calibur*⁷⁴ and taking into account improvements to the anticoincidence shield, which will reduce this background by a factor of ~ 10 .⁷³ To account for the difference in detector size we scale with area and square root of thickness. This results in a background rate of $\sim 1.7 \times 10^{-6} \text{ s}^{-1} \text{ keV}^{-1}$ per TES detector at 68 keV. In the future, this estimate can be refined using data from an upcoming test flight of a small TES array scheduled for the fall of 2023, as well as with the help of detailed Monte Carlo simulations.⁷⁶

In the sensitivity calculation, we weighted events in each detector by the expected signal-to-background ratio for a point-like source according to Ref.⁷⁷ Figure 10 shows the expected narrow line sensitivity of *ASCENT*. *NuSTAR* detected lines with fluxes ranging from $6 \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ to $1.7 \times 10^{-6} \text{ cm}^{-2} \text{ s}^{-1}$. *ASCENT*'s energy resolution of 67 eV FWHM will allow us to determine the velocity of ^{44}Ti ejecta with a FWHM accuracy of 270 km s^{-1} , compared to *NuSTAR*'s FWHM accuracy of 3600 km s^{-1} .

From each flight we expect highly significant detections of the ^{44}Ti emission from Cas A of 11σ and 6.5σ of the 67.9 keV and 78.4 keV lines, respectively, when summing over all bright spots. Particularly interesting will be the energy spectrum from *Region 1* in Fig. 1, which we expect to detect with 5σ at 67.9 keV and with 3σ at 78.4 keV. The advantage of *ASCENT* is greatest in regions where the width of the ^{44}Ti lines is small compared to *NuSTAR*'s energy resolution. A single 500 ksec observation with *ASCENT* will improve measurements in all regions where *NuSTAR* detected ^{44}Ti , except two where the lines are broadened and very weak. We estimate that *ASCENT* will improve the line centroid and width measurements compared to previous results by a factor of 2–20 and 2–10, respectively (Fig. 11). These measurements will significantly improve the 3D localization of the ^{44}Ti ejecta and result in much tighter constraints on the local $^{56}\text{Ni}/^{44}\text{Ti}$ ratio. These improvements in constraining the local ratio will greatly increase our knowledge of the nuclear production pathways in the supernova explosion.

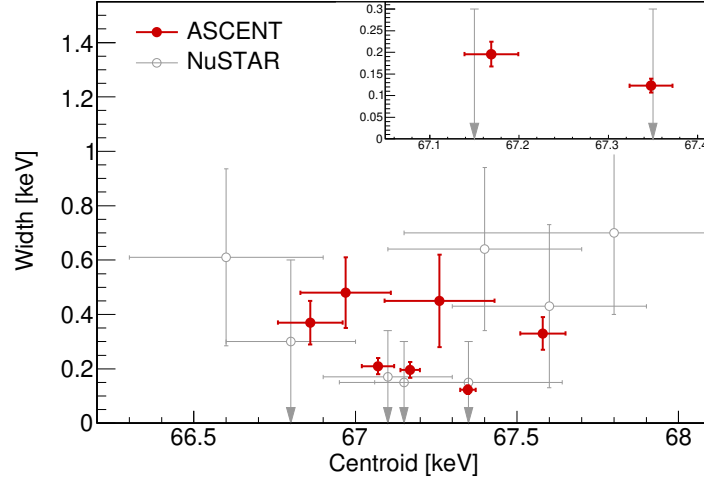

Fig 11: Expected *ASCENT* results for the measurements of ^{44}Ti emission lines in the 8 ^{44}Ti -bright regions analyzed in Ref.²⁸ compared to the *NuSTAR* results. Simulations assume the Gaussian line parameters measured by *NuSTAR*. In regions where *NuSTAR* only set an upper limit on the line width, a smaller value is assumed. The inset shows two lines with assumed widths of 150 eV and 100 eV, respectively. The *ASCENT* centroid and line width uncertainties are a factor 2–10 smaller than *NuSTAR*'s.

5 Summary and Outlook

Core collapse supernovae are considered to be a significant source of mid-Z elements in the Galaxy. Despite significant theoretical and observational progress in the last few decades, many details of the explosion are still poorly understood. One observational approach to gaining new insights is to study the distribution of elements in supernova remnants. The isotope ^{44}Ti is of particular interest because it is produced in the innermost regions of the supernova engine, and it is radioactive with a half-life long enough to be observable in historic supernova remnants.

In this paper we present a concept for a balloon-borne hard X-ray telescope called *ASCENT* designed to study the nuclear emission lines from Cas A and SN 1987A, as well as potentially other remnants that may be discovered by *COSI*. *ASCENT* uses an array of transition edge sensor (TES) microcalorimeter detectors as its focal plane instrument, improving spectral resolution by more than an order of magnitude over existing semiconductor detectors at gamma-ray energies. Observations with *ASCENT* will significantly improve 3D maps of ^{44}Ti in Cas A, and can deliver detailed spectra of ^{44}Ti from SN 1987A.

ASCENT will also demonstrate the viability of hard X-ray TES technology for a future space mission. The energy resolution of an *ASCENT*-type mission would benefit all spectral studies of a *NuSTAR* follow-up, *e.g.*, broadband observations of Active Galactic Nuclei (AGN) covering the lines of the soft excess emission, the Fe $K\alpha$ emission, and the Compton hump emission. The broadband results obtained for a sample of ~ 100 of AGNs can be used to calibrate the spin measurements of ESA's *ATHENA* mission^{43,44} and the proposed NASA *Lynx* mission.^{78–80} The *ASCENT* detector technology could be used for example as the focal plane detector of the *HEX-P* mission.⁶⁵ While *ASCENT* has not been selected when first proposed, the team continues to pursue the project and is planning to repropose the mission after maturing detector, cryostat, and X-ray optics technologies.
