Abstract

Molecular simulations are an important tool for research in physics, chemistry, and biology. The capabilities of simulations can be greatly expanded by providing access to advanced sampling methods and techniques that permit calculation of the relevant underlying free energy landscapes. In this sense, software that can be seamlessly adapted to a broad range of complex systems is essential. Building on past efforts to provide open-source community supported software for advanced sampling, we introduce PySAGES, a Python implementation of the Software Suite for Advanced General Ensemble Simulations (SSAGES) that provides full GPU support for massively parallel applications of enhanced sampling methods such as adaptive biasing forces, harmonic bias, or forward flux sampling in the context of molecular dynamics simulations. By providing an intuitive interface that facilitates the management of a system's configuration, the inclusion of new collective variables, and the implementation of sophisticated free energy-based sampling methods, the PySAGES library serves as a general platform for the development and implementation of emerging simulation techniques. The capabilities, core features, and computational performance of this new tool are demonstrated with clear and concise examples pertaining to different classes of molecular systems. We anticipate that PySAGES will provide the scientific community with a robust and easily accessible platform to accelerate simulations, improve sampling, and enable facile estimation of free energies for a wide range of materials and processes.

Keywords: Enhanced sampling methods, GPU acceleration

1. Introduction

Molecular simulations are extensively used in a wide range of science and engineering disciplines [1]. As their use has grown for the discovery of new phenomena and the interpretation of sophisticated experimental measurements, so has the complexity of the systems that are considered. Classical atomistic molecular dynamics (MD) simulations are generally limited to microsecond time scales and length scales of tens of nanometers. For systems that are characterized by rugged free energy landscapes, such time scales can be inadequate to ensure sufficient sampling of the relevant phase space, and advanced methods must therefore be adopted to overcome free energy barriers. In that regard, it is useful and increasingly common to identify properly chosen collective variables (CVs), which are generally differentiable functions of the atomic coordinates of the system; then, biases can be applied to explore the space defined by such CVs, thereby overcoming barriers and enhancing sampling of the thermally accessible phase space.

The rapid growth of hardware accelerators such as GPUs or TPUs, or specialized hardware designed for fast MD computations [2, 3], has provided researchers with increased opportunities to perform longer simulations of larger systems. GPUs, in particular, provide a widely accessible option for fast simulations, and several software packages, such as HOOMD-blue [4], OpenMM [5], JAX MD [6, 7], LAMMPS [8], and Gromacs [9], are now available for MD simulations on such devices.

As mentioned above, enhanced sampling methods seek to surmount the high energy barriers that separate multiple metastable states in a system, while facilitating the calculation of relevant thermodynamic quantities as functions of different CVs such as free energy surfaces (FES). Several libraries, such as PLUMED [10], Colvars [11], and our own SSAGES package [12], provide out-of-the-box solutions for performing enhanced sampling MD simulations.

Among the various enhanced sampling methods available in the literature, some of the most recently devised schemes rely on machine learning (ML) strategies to approximate free energy surfaces and their gradients (generalized forces) [13, 14, 15, 16]. Similarly, algorithms for identifying meaningful CVs that correlate with high variance or slow degrees of freedom (DOFs) are based on deep neural networks [17, 18, 19, 20, 21, 22]. These

advances serve to highlight the need for seamless integration of ML frameworks with existing MD software libraries.

To date, there are no solutions that combine enhanced sampling techniques, hardware acceleration, and ML frameworks to facilitate enhanced-sampling MD simulations on GPUs. While some MD libraries that support GPUs provide access to a limited set of enhanced sampling methods [5, 9, 23, 24, 25], there are currently no packages that enable users to take advantage of all of these features within the same platform and in the same backend-agnostic fashion that tools such as PLUMED and SSAGES have provided for CPU-based MD simulations.

Here we present PYSAGES, a Python Suite for Advanced General Ensemble Simulations. It is a free, open-source software package written in Python and based on JAX that follows the design ideas of SSAGES and enables users to easily perform enhanced-sampling MD simulations on CPUs, GPUs, and TPUs. PYSAGES can currently be coupled with HOOMD-blue, OpenMM, JAX MD and ASE – and by extension from the latter to CP2K, Quantum ESPRESSO, VASP and Gaussian, among others. At this time, PYSAGES offers the following enhanced sampling methods: Umbrella Sampling, Metadynamics, Well-tempered Metadynamics, Forward Flux Sampling, String Method, Adaptive Biasing Force, Artificial neural network sampling, Adaptive Biasing Force using neural networks, Combined Force Frequency, and Spectral Adaptive Biasing Force. PYSAGES also includes some of the most commonly used CVs and, importantly, defining new ones is relatively simple, as long as they can be expressed in terms of the NumPy [26] interface provided by JAX. All CVs can be automatically differentiated through JAX functional transforms. PYSAGES is highly modular, thereby allowing for the easy implementation of new methods as they emerge, even as part of a user-facing script.

In the following sections, we provide a general overview of the design and implementation of PYSAGES, and present a series of examples to showcase its flexibility for addressing research problems in different application areas. We also discuss its performance in GPUs and present a few perspectives on how to grow and improve the package to cover more research use cases through future development, as well as community involvement and contributions.

2. Implementation

We begin by briefly outlining the core components of PYSAGES, how they function together, and how communication with each backend allows PYSAGES

to bias a simulation during runtime. A summary of the execution workflow of PYSAGES along with a mapping of the user interface with the main stages of the simulation and the interaction with the backends, is illustrated in [Figure 1](#).

To provide a uniform user interface while minimizing disruption to pre-existing workflows, PYSAGES only requires the user to wrap their traditional backend scripting code into *simulation generator* functions. This approach accommodates the heterogeneity of Python interfaces across the different simulation backends supported by PYSAGES. An example of a simulation generator function and how a traditional OpenMM script can be modified to perform an enhanced-sampling MD simulation is depicted in [Figure 2](#).

At the start of a simulation, the simulation generator function is called to instantiate as many replicas of the simulation as needed. Then, for each replica, PYSAGES queries the particle information and the device that the backend will be using. In addition, during this initial stage PYSAGES also performs automatic differentiation of the collective variables via JAX’s grad transform – required to estimate the biasing forces, and generates specialized initialization and updating routines for the user-declared sampling method.

Like SSAGES, PYSAGES wraps the simulation information into an object called a Snapshot. This object exposes the most important simulation information, such as particle positions, velocities, and forces in a backend- and device-agnostic format. To achieve this, PYSAGES uses DLPack [27] – for C++ based MD libraries – to directly access the contents of the backend-allocated buffers for the different particle properties without creating data copies whenever possible.

Once the setup of both the simulation and sampling method is completed, PYSAGES hands control back to the backend, which will run for a given number of time steps or until some other stopping criteria is reached. In order to exchange information back and forth, PYSAGES adds a force-like object or function to the backend which gets called as part of the time integration routine. Here, the sampling method state gets updated and the computed biasing forces are added to the backend net forces.

Finally, the information collected by the sampling method is returned and can be used for calculating the free energy as function of the selected CVs. Unlike SSAGES, PYSAGES offers a user-friendly analyze interface that simplifies the process of performing post simulation analysis, including the automatic calculation of free energies based the chosen sampling method. This feature can greatly reduce the time and effort required to gain valuable insights from simulations.

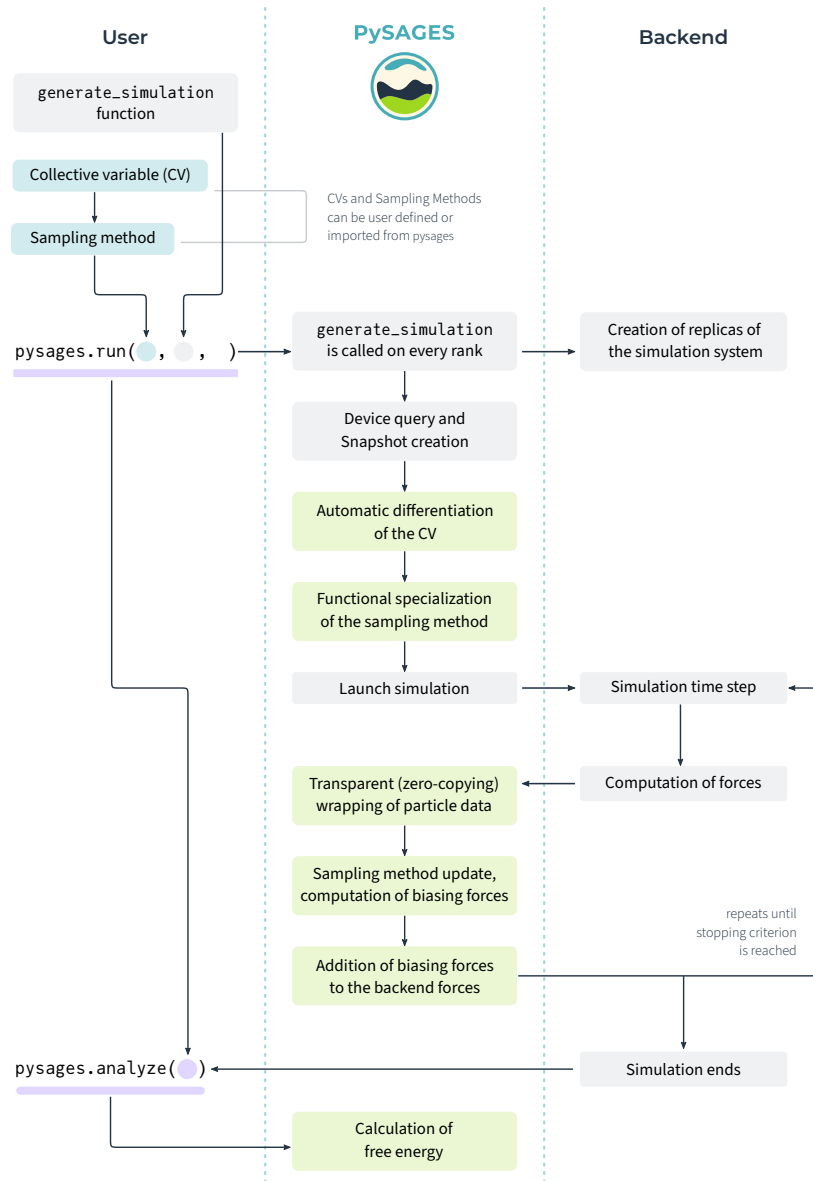

Figure 1: The PySAGES simulation flowchart. For a simulation, a user sets up a script that declares the CV and sampling methods to be used.

Figure 2: Example of how to use the Python interface for PYSAGES. It is easy to extend existing MD scripts with PYSAGES to perform enhanced-sampling MD, with minimal changes to the code. In general, the only requirement is for the user to wrap the code that defines the simulation system into a *simulation generator* function.

PYSAGES offers an easy way to leverage different parallelism frameworks including MPI with the same uniform fronted available to run enhanced sampling simulations. This is achieved via Python’s `concurrent.futures` interface. In particular, for MPI parallelism, the user only needs to pass an additional `MPIPoolExecutor` (from `mpi4py`) to PYSAGES’ `run` method. If the user selects a method such as `UmbrellaSampling`, the workload for each image will be distributed across available MPI nodes. On the other hand, for most of the sampling methods, the parallelization interface allows the user to run multiple replicas of the same system to enable, for instance, analysis of the uncertainties associated to computing the free energy of a given system.

To ensure the reproducibility and correctness of our implementation and to follow software engineering best practices, we have implemented a comprehensive unit tests suite, and leverage GitHub’s continuous integration services. In addition, we use trunk.io [28] to adhere to quality standards as well as to ease the collaboration of developers.

2.1. Enhanced Sampling Methods

While we assume the reader has some basic understanding of enhanced sampling methods, here we provide an overview of these techniques. We direct readers interested in learning more about the fundamentals of enhanced sampling to a number of excellent recent review articles [29, 30, 31, 32, 33, 34, 35, 36, 37, 38]. In addition, we discuss the general structure of how

enhanced sampling methods are implemented within PYSAGES, and also present a summary of the various methods already available in the library.

Enhanced sampling methods are a class of simulation techniques that manipulate regular MD simulations in order to more effectively sample the configuration space. In MD a collective variable, ξ , is typically a function of the positions of all particles, $\hat{\xi}(\{r_i\})$.

For a given statistical ensemble (such as the canonical, NVT), the corresponding free energy can be written as $A = -k_B T \ln(Z)$, where A is the Helmholtz free energy and Z is the canonical partition function. To make explicit the dependency of the free energy on ξ , let us write down the partition function:

$$Z(\xi) \propto \int d^N r_i \delta(\hat{\xi}(\{r_i\}) - \xi) e^{-U(\{r_i\})/k_B T} \quad (1)$$

Normalizing this partition function gives us the probability of occurrence, $p(\xi) = Z(\xi)/(\int d\xi Z(\xi))$, for configurations in the CV subspace. Substituting this probability into the expression for the free energy, we get:

$$A(\xi) = -k_B T \ln(p(\xi)) + C \quad (2)$$

where C is a constant.

If we take the derivative of the free energy with respect to ξ we get

$$\frac{dA(\xi)}{d\xi} = \frac{\int d^N r_i \frac{dU}{d\xi} \delta(\hat{\xi}(\{r_i\}) - \xi) e^{-U(\{r_i\})/k_B T}}{\int d^N r_i \delta(\hat{\xi}(\{r_i\}) - \xi) e^{-U(\{r_i\})/k_B T}} = \left\langle \frac{dU}{d\xi} \right\rangle_\xi, \quad (3)$$

where $\langle . . . \rangle_\xi$ denotes the conditional average.

The goal of CV-based enhanced sampling methods is to accurately determine either $p(\xi)$ or $dA(\xi)/d\xi$ – from which $A(\xi)$ can be recovered – in a computationally tractable manner.

In PYSAGES, the implementation of sampling methods follows the JAX functional style programming model. New methods are implemented as subclasses of the `SamplingMethod` class, and are required to define a `build` method. This method returns two methods, `initialize` and `update`, used as part of the process of biasing the simulation. For readers familiar with JAX MD, these could be thought of as analogues to the higher level functions returned by JAX MD’s `simulate` integration methods. The `initialize` method allocates all the necessary helper objects and stores them in a `State` data structure, while the `update` method uses the information from the simulation at any given time to update the `State`.

While PYSAGES allows new methods to be written seamlessly as part of Python scripts used to set up molecular dynamics simulations, it also provides out-of-the-box implementations of several of the most important known sampling methods. We list and briefly detail them next.

2.1.1. Harmonic Biasing

One simple way to sample a specific region of the phase space is to bias the simulation around a point ξ_0 with harmonic bias. This adds a quadratic potential energy term to the Hamiltonian that increases the potential energy as a system moves away from the target point: $\mathcal{H}_b = \mathcal{H} + k/2(\xi - \xi_0)^2$, where $k > 0$ is the spring constant. The unbiased probability distribution $p(\xi)$ can be recovered by dividing the biased distribution by the known weight of the bias $p(\xi) = p_b(\xi)/e^{-k/2(\xi - \xi_0)^2/k_B T}$.

The disadvantage of this approach is that it can only be used to explore the free energy landscape near a well-known point in phase space. This may not be sufficient for many systems, where the free energy landscape is complex.

2.1.2. Umbrella Sampling

Umbrella sampling is a technique that traditionally builds on harmonic biasing by combining multiple harmonically-biased simulations. It is a well-known method for exploring a known path in phase space to obtain a free energy profile along that path [39, 40]. Typically, a path between two points of interest is described by N points in phase space, ξ_i . At each of these points, a harmonically biased simulation is performed, and the resulting occurrence histograms are combined to obtain a single free energy profile.

In PYSAGES, we implement umbrella integration for multi-dimensional CVs. This method approximates the forces acting on the biasing points and integrates these forces to find the free energy profile $A(\xi)$, and allows to explore complex high-dimensional free energy landscapes.

2.1.3. Improved String Method

When only the endpoints are known, but not the path itself, the improved (spline-based) string method can be used to find the mean free energy pathway (MFEP) between these two endpoints [41]. The spline-based string method improves upon the original string method by interpolating the MFEP using cubic-splines. In this method, the intermediate points of the path are moved according to the recorded mean forces acting on them, but only in the direction perpendicular to the contour of the path. This ensures that distances between the points along the path remain constant.

This method has been widely used and has been shown to be an effective way to find the MFEP between two points in the phase space [41].

2.1.4. Adaptive Biasing Force sampling

The adaptive biasing force (ABF) sampling method is a technique used to map complex free-energy landscapes. It can be applied without prior knowledge of the potential energy of the system, as it generates on-the-fly estimates of the derivative of the free energy at each point along the integration pathway. ABF works by introducing an additional force to the system that biases the motion of the atoms, with the strength and direction of the bias continuously updated during the simulation. In the long-time limit, this yields a Hamiltonian with no average force acting along the transition coordinate of interest, resulting in a flat free-energy surface and allowing the system to display accelerated dynamics, thus providing reliable free-energy estimates [42, 43]. Similarly to SSAGES, PYSAGES implementation of ABF is based on the algorithm described in [43].

2.1.5. Metadynamics

Metadynamics is another popular approach for enhancing sampling of complex systems. In metadynamics [44], a bias potential is applied along one or more CVs in the form of Gaussian functions. The height and width (σ) of these Gaussians are controlled by the user. The Gaussian bias potentials are cumulatively deposited at user-defined intervals during the simulation. In standard metadynamics, the height of the Gaussian bias potentials is fixed.

In contrast, for well-tempered metadynamics (WTMD) [45] simulations, the height of the Gaussian bias potentials is adjusted at each timestep using a preset temperature based bias factor. This scaling of Gaussian heights in WTMD leads to faster convergence compared to standard metadynamics, as it restricts the range of free energy explored to a range defined by the bias factor.

In PYSAGES, we have implemented both standard metadynamics and WTMD. The well-tempered variant is activated when a user sets a value for the bias factor. To improve the computational performance, we have added optional support for storing the bias potentials in both on a pre-defined grid. This allows users to trade-off accuracy for faster simulations, depending on their needs.

2.1.6. *Forward Flux Sampling*

Forward flux sampling (FFS) belongs to a different family of enhanced sampling methods than the ones described above. In the previously described methods, the free energy change from a region in the phase space (A) to the region of interest (B) is calculated by applying a bias to the system. In FFS no bias is added and instead an efficient selection of trajectories that crosses the phase space from A to B is performed. Since no bias is used, the intrinsic dynamics of the system is conserved and therefore kinetic and microscopic information of the transition path can be studied [46]. In PySAGES we have implemented the direct version of FFS [47, 48].

2.1.7. *Artificial neural networks sampling*

Artificial neural networks sampling (ANN) [13] employs regularized neural networks to directly approximate the free energy from the histogram of visits to each region of the CV space, and generates a biasing force that avoids ringing and boundary artifacts [13], which are commonly observed in methods such as metadynamics or basis functions sampling [49]. This approach is effective at quickly adapting to diverse free energy landscapes by interpolating undersampled regions and extrapolating bias into new, unexplored areas.

The implementation on PySAGES offers more flexible approaches to network regularization than SSAGES, which uses Bayesian regularization.

2.1.8. *Force-biasing using neural networks*

Force-biasing using neural networks (FUNN) [14] is based upon the same idea as ANN, that is, relying on artificial neural networks to provide continuous functions to bias a simulation, but instead of using the histogram to visits to CV space it updates its network parameters by training on the ABF estimates for the mean forces as the simulation advances. This method shares all of the features of ABF, but the smooth approximation of the generalized mean force it produces enables much faster convergence to the free energy of a system compared to ABF.

2.1.9. *Combined Force Frequency sampling*

The combined force frequency sampling (CFF) method [15] combines the speed of generalized-force based techniques such as ABF or FUNN with the advantages of frequency-based methods like metadynamics or ANN. Notable improvements over earlier force-based methods include eliminating the need for hyperparameters to dampen early-time estimates, automating

the integration of forces to generate the free energy, and providing an explicit expression for the free energy at all times, enabling the use of replica exchange or reweighing.

In principle, by using sparse storage of histograms, it should be possible to scale the method to higher dimensions without encountering memory limitations, such optimization is however not yet implemented in PYSAGES.

2.1.10. Spectral Adaptive Biasing Force

Spectral ABF [50] is a method that follows the same principle as neural-network-based sampling methods, in that it builds a continuous approximation to the free energy. However, in contrast to methods like FUNN it does so by fitting exponentially convergent basis functions expansions, and could be thought as a generalization of the Basis Functions Sampling Method. In contrast to the latter, and similar to CFF, it allows for the recovery of an explicit expression for the free energy of a system. It is an extremely fast method in terms of both runtime and convergence.

2.2. Collective variables

As previously mentioned, enhanced sampling calculations commonly involve the selection of a CV. An appropriate CV for a given system could simply be the distance between the centers of mass of two groups of atoms, but could be a complex specialized quantity.

Below, we list a set of CVs predefined in PYSAGES, sorted by the number of groups of atom coordinates necessary for their use:

1. TwoPointCV. This subclass is for CVs that need two groups for their definition. This includes Distance and Displacement (vector).
2. ThreePointCV. Subclass of CVs with three groups of atoms, such as Angle.
3. FourPointCV. Subclass of CVs with four groups of atoms, such as DihedralAngle.
4. AxisCV. Subclass of CVs that are projected on a determinate axis. This includes Component and PrincipalMoment.
5. CollectiveVariable General base class for all CVs. In PYSAGES, CVs that directly derive from this class, and do not belong to the previous groups, include: RingPhaseAngle, RingAmplitude, RadiusofGyration, Asphericity, Acylindricity, ShapeAnisotropy, RingPuckeringCoordinates [51] (vector).

In PYSAGES we provide users with a simple framework for defining CVs, which are automatically differentiated with JAX. To illustrate this, we

compare how to write the calculation of a CV that measures the projection of the vector between two groups of atoms over the axis that passes by other two groups, in both SSAGES and PYSAGES (see Figure 3). In PYSAGES the gradient calculation is done automatically whereas in SSAGES it has to be coded explicitly.

Data-driven and differentiable CVs discovered using artificial neural networks (e.g. autoencoders) [29, 21, 18, 52, 53] with arbitrary featurizations of atoms can in principle be implemented in PYSAGES based on the above general abstract classes of CVs.

The following second example shows the power of differential programming for CV declaration in PYSAGES.

2.2.1. Case study: A collective variable for interfaces

When the two immiscible liquids are in contact with each other, the density of one liquid experiences a gradual change. This transition region is the liquid-liquid interface and its position has high importance in many studies (see section 3.1.3). However, the location of such interface is not a trivial task since it generally fluctuates as the simulation progresses. As a representative CV for the interface, we can utilize the position of the point where the gradient of the density is maximized. More formally, let $\rho(x)$ denote the density of a liquid of interest at a coordinate x on the perpendicular axis. We would like to find the location of the interface:

$$I = \arg \max_x |\rho'(x)| \quad (4)$$

However, the density function $\rho(x)$ is not directly measurable in a molecular simulation, as the coordinates of atoms are discrete. To obtain an approximation of $\rho(x)$, we divide the coordinates into multiple bins, each with a width of δ , and create a histogram $p(x)$ that records the number of atoms falling into the bin around position x . In other words,

$$p(x) = \sum_{i=1 \dots n} [|x_i - x| < \delta/2] \quad (5)$$

in which x_i denotes the coordinate of atom i . As written above, $p(x)$ is non-differentiable. Therefore, as in other works [54], we utilize the kernel density trick with a Gaussian kernel to modify $p(x)$. The modified $\tilde{p}(x)$, is defined as:

$$\tilde{p}(x) = \sum_{i=1 \dots n} \exp \left(-\frac{(x_i - x)^2}{2\sigma^2} \right) \quad (6)$$

Figure 3: Example of how to write a CV in PYSAGES. On the left is the same CVs written in SSAGES and on the right the PYSAGES version. In general, the only requirement is for the user to write the CV as a differentiable function in JAX.

in which σ is a hyperparameter that decides the width of the Gaussian kernel. Then, the gradient of the density can be approximated as:

$$\tilde{p}'(x) = \frac{\tilde{p}(x + \delta/2) - \tilde{p}(x - \delta/2)}{\delta} \quad (7)$$

and we calculate the location of the interface as $I = \arg \max_x |\tilde{p}'(x)|$. The $\arg \max$ operator is also non-differentiable. As a result, we replace it with a softmax function that transforms the raw input into a probability. Denote the m bins as $j = 1 \dots m$, and finally we calculate the location of the interface as:

$$I = \frac{\sum_j x_j \exp |\tilde{p}'(x_j)|}{\sum_j \exp |\tilde{p}'(x_j)|} \quad (8)$$

As demonstrated in the code snippet for this CV, provided in [Appendix A](#), PYSAGES allows for the concise and straightforward implementation of complex CVs such as this one.

3. Results and Discussion

To evaluate a software package like PYSAGES, we must consider at least two factors: physical correctness and computational performance.

First, to assess the correctness of the enhanced sampling methods implemented in PYSAGES, we present in [Appendix B.1](#) the free-energy landscape for the dihedral angles ϕ and ψ of alanine dipeptide (ADP). This example is commonly used to benchmark new enhanced sampling algorithms. Similarly, we also show in [Appendix B.2](#) the free-energy as a function of the dihedral angle of butane. Our results show that PYSAGES reproduces the expected free-energy landscapes using different methods and backends. In [section 3.1](#), we further investigate the applicability and correctness of PYSAGES beyond these simple model systems.

Second, we demonstrate the performance of PYSAGES on GPUs with two different backends in [section 3.2](#). In particular, we compare the performance of enhanced sampling simulations to the performance of pure MD simulations, as well as other enhanced sampling implementations.

3.1. Example applications of enhanced sampling with PYSAGES

To demonstrate the versatility and effectiveness of PYSAGES in different contexts, we present several examples of how enhanced sampling methods can be used to gain valuable insights in various fields including biology, drug design, materials engineering, polymer physics, and ab-initio simulations.

These examples showcase how PYSAGES can be used in diverse research areas and the utility of different enhanced sampling methods and backends.

Overall, these examples confirm that the enhanced sampling methods implemented in PYSAGES work as intended and provide results consistent with existing literature.

3.1.1. Structural Stability of Protein-Ligand Complexes for Drug Discovery

High-throughput docking techniques are a widely-used computational technique in drug lead discovery. However, these techniques are limited by the lack of information about protein conformations and the stability of ligands in the docked region [55]. To address this issue, the Dynamical Undocking (DuCK) method was developed to evaluate the stability of the ligand binding by calculating the work required to break the most important native contact (hydrogen bond interactions) in the protein-ligand complex [56]. This method has been shown to be complementary and orthogonal to classical docking, making both techniques work parallel in drug discovering [57, 58]. However, DuCK can be slow to converge when combined with traditional enhanced sampling techniques [56], making it unsuitable for high-throughput drug discovery protocols.

Here, we demonstrate how PYSAGES with OpenMM can be used efficiently in drug discovery applications, where the user-friendly interface, native parallel capabilities, and new enhanced sampling methods with fast convergence are synergistically combined to accelerate the virtual screening of ligand databases. In this example, we study the main protease (Mpro) of Sars-CoV-2 virus (PDB: 7JU7 [59]), where the ligands were removed and the monomer A was selected as the docking receptor. A ligand with SMILES string CCCCOCC(=O)c1ccc(C)cc1N[C@H]1N[C@@H](c2cccn2)CS1 was docked using RDock [60]. The best scoring pose was used to initialize the system, which was simulated using the ff14SB [61], TIP3P [62], and GAFF [63] force fields. A 10 ns equilibration procedure was carried out to find the most stable hydrogen bond between the ligand and the protein. The last frame of this equilibration was then used to initialize the enhanced sampling calculations in PYSAGES with ABF, metadynamics, FUNN, ANN, and Spectral ABF. These methods were compared against the same system simulated using Amber20 [64] with Steered Molecular Dynamics (see Figure 4b). Our results suggest that we can reduce the simulation time by an order of magnitude using new enhanced sampling methods like Spectral ABF or FUNN. This can greatly accelerate the drug discovery process and help identify potential drug leads more quickly.

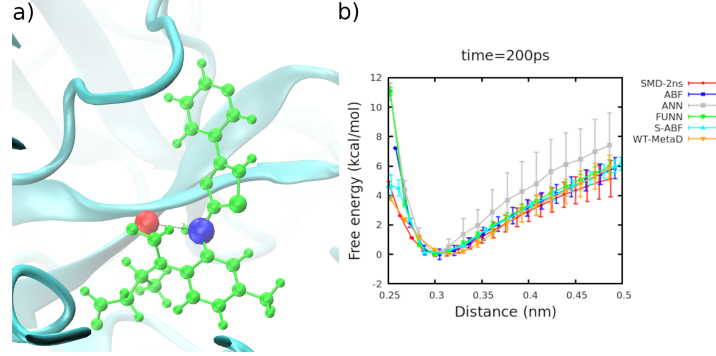

Figure 4: Dynamical Undocking (DuCK) method in detail. For a proposed binding mode obtained from classical docking, a short run using MD simulations is carried out and the most stable receptor-ligand native contact is selected from that run. In this case, it is the hydrogen bond between the red and blue atoms highlighted in panel a). b) Comparison between different methods in PYSAGES for DuCK calculations averaged over 5 different replicas for each method. The reference, a Steered MD simulations simulations of 2 ns is in red. In comparison, different methods in PYSAGES are used considering simulation period 10 times shorter: only ANN [13] provides inferior performance against the reference; Spectral ABF [50] or FUNN [14] give the best performance.

3.1.2. Fission of a Diblock Copolymer Spherical Domain

We now investigate the fission of a single spherical domain of a diblock copolymer using a coarse-grained model. We use a soft, coarse-grained dissipative particle dynamics (DPD) model published in previous studies [65, 66, 67]. The model consists of $n = 200$ chains with $N = 256$ beads each, representing a liquid polymer melt. The first $N_A = 16$ beads in each chain are type A, while the remaining $N_B = 240$ are type B.

A standard DPD potential is used to enforce incompressibility with a repulsion parameter of $A_{ii} = 5k_B T / \sigma^2$. However, a higher interaction of $A_{AB} = A_{ii} + \Delta A k_B T / \sigma^2$, with $\Delta A \in [0.1, 0.4]$ is applied between unlike particles to create a repulsion that leads to a microphase separation. A Flory-Huggins parameter $\Delta A \propto \chi N > 0$ can characterize this phase separation. The interaction range of this non-bonded potential is 1σ , as well as the range of the DPD thermostat that keeps the temperature at $T = 1k_B T = 1\epsilon$.

In addition, a harmonic spring force with zero resting length is used to connect the beads to polymer chains with a spring constant of $k = 16/3k_B / \sigma^2$, resulting in an average bond length of $b_0 = 0.75\sigma$. The equilibrium phase for this polymer melt is a body-centered cubic (BCC) phase of spherical A droplets inside a B melt. [68] However, we confine the polymer to a tight cubic simulation box of length $L_0 = 10\sigma$, which results in a single

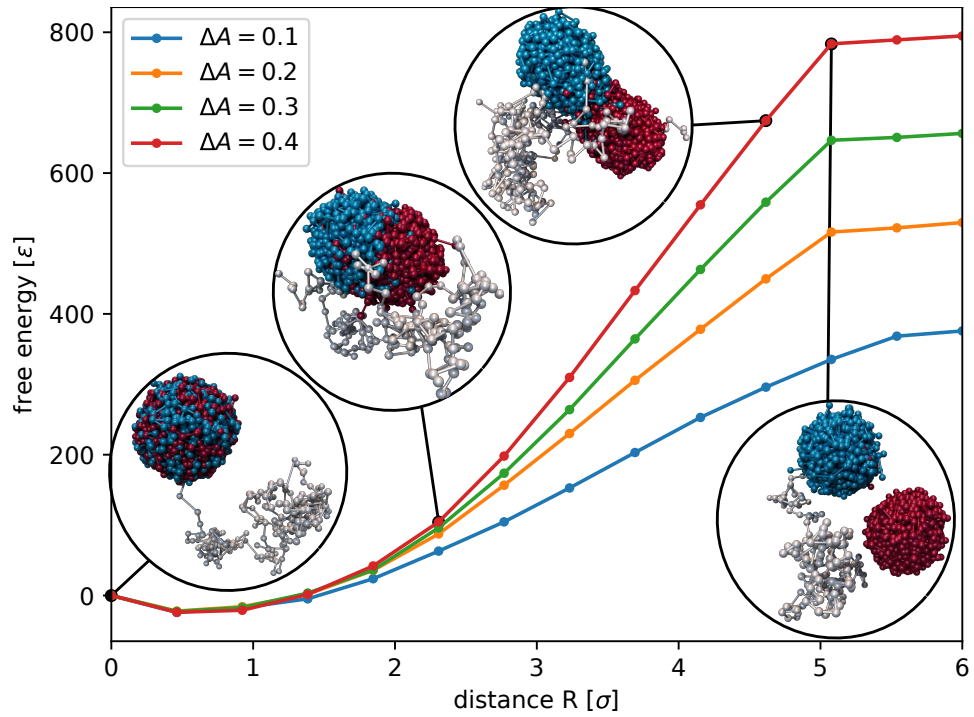

Figure 5: Free energy landscape of the fission of a spherical diblock-copolymer domain. The chain ends forming the spherical domain are split into two groups (blue) and (red), the other chain ends not visible for clarity except for a single chain (grey). Initially, a single spherical domain is formed, but as we constraint the center of mass between the blue and red groups further, the domain first elongates and then separates completely. During this separation, the free energy continuously increases and the increase is steeper for high repulsion between unlike type ΔA . As soon as the domain is separated, the free energy plateaus.

A spherical domain in the B matrix. We integrate the simulation with a time step of $\Delta t = 10^{-3}\tau$ and each simulation is equilibrated for $t = 1000\tau$, followed by a production run of $t = 1000\tau$ as well. A discussion of the GPU performance of this system with and without PYSAGES can be found in [section 3.2.1](#).

After defining the diblock copolymer system, the next step is to define a CV within the system. In this case, we are interested in the fission of the single spherical A domain into two equally sized smaller A domains. To achieve this, we divide the polymer chains into two groups: the first $n = 100$ chains are going to form the first small domain (blue in [Figure 5](#)) and the second $n = 100$ chains form the second spherical domain (red in [Figure 5](#)). To define and enforce the separation of the two groups, we define our CV as the distance, R , between the center of mass of the blue A-tails and the center of mass of the red A-tails. Initially, without biasing, the two groups form a single spherical domain and blue and red polymer tails are well mixed, as shown at small $R < 1\sigma$ in [Figure 5](#).

To study the separation of the spherical domain, we use harmonic biasing (see [section 2.1.1](#)) to enforce a separation distance R_0 between the two groups. The high density in the system $\sqrt{N} = \frac{\rho_0}{N} R_{e0}^3 \approx 344$, leads to low fluctuations and suppression of unfavorable conformations. Therefore, we use a high spring force constant of $k_{CV} = 1500\epsilon/\sigma^2$ to facilitate the separation.

We investigate a separation of $R \in [0, 6]\sigma$ with 14 replicas and use umbrella integration (see [section 2.1.2](#)) to determine the free energy profile, as shown in [Figure 5](#). As we increase the external separation distance R_0 , we observe how the single domain splits into two. At a low separation distance $R < 2\sigma$, the single domain is mostly undeformed, but the two groups separate inside the single spherical domain. Increasing the separation distance further goes beyond the dimensions of the spherical domain, leading to the deformation of the domain into an elongated rod-like shape. The two groups still maintain a connection to minimize the AB interface.

At a separation between 4σ and 5σ the deformation becomes so strong, that the penalty of forming another AB interface between the two groups, and hence forming two spherical domains, is lower than the entropic penalty of the domain deformation and elongated AB interface of the droplet. After the separation, the free energy landscape remains indifferent to the separation, since there is no interaction between the two domains left.

The free energy profile of separation is controlled by the repulsion of unlike types $\chi N \propto \Delta A$. The stronger the repulsion, the more energy is necessary to enlarge the AB surface area for the fission. For the strongest

interaction $\Delta A = 0.4\epsilon$, the total free energy barrier reaches about 800ϵ , while for the lowest $\Delta A = 0.1\epsilon$ it remains below 400ϵ . Both barriers are orders of magnitude larger than thermal fluctuations $1k_B T = 1\epsilon$, so a spontaneous separation is not expected and the fission can only be studied via enhanced sampling.

It is interesting to note that at the lowest separation distance $R_0 = 0$ it is not the lowest free energy state. Enforcing perfect mixing is not favorable, as the two groups naturally want to separate slightly optimizing the entropy of the chain end-tails.

3.1.3. Liquid Crystal Anchoring in Aqueous Interfaces

Liquid crystals (LCs), materials that flow like liquids but have anisotropic properties as crystals, have been used lately as prototypes for molecular sensors at interfaces given the high sensitivity in their anchoring behavior relative to small concentration of molecules at aqueous interfaces [69]. The presence of molecules at the interface changes drastically the free energy surface of LC molecules relative to their orientation and distance to such interface. In this example, we are revisiting some canonical interfaces for LC; 4-cyano-4'-pentylbiphenyl (5CB) at the interface of pure water and sodium lauryl sulfate (SDS). For 5CB and water, previous work has focused on obtaining the free energy surface of a 5CB at the water interface [70]. In our case, hybrid anchoring conditions have been imposed on a 16 nm slab of 1000 5CB molecules in the nematic phase (300 K) interacting with a 3 nm slab of water with 62 molecules of SDS at one of the interfaces. The force fields used are: *united atom* for 5CB [71], TIP3P [62] for water, GAFF [63] and Lipid 17 for SDS. The CVs chosen to study this system are the distance of the center of mass of one molecule of 5CB at each one of the interfaces (see Appendix A), and the tilt orientation of the same molecule with respect to the z axis of the box. The free energy surfaces for the pure water and with SDS at the interface are both displayed in Figure 6. We can observe that the free energy surface of pure water shows a minimum corresponding to a parallel orientation to the surface with a similar shape that one calculated in [70]. On the contrary, the presence of SDS transforms the minimum to a maximum in the same relative position and orientation to the interface (Figure 6 top left), moving now the minima to a perpendicular orientation of 5CB to the interface, in agreement to the experimental observation of change from planar to homeotropic anchoring in the presence of SDS in water.

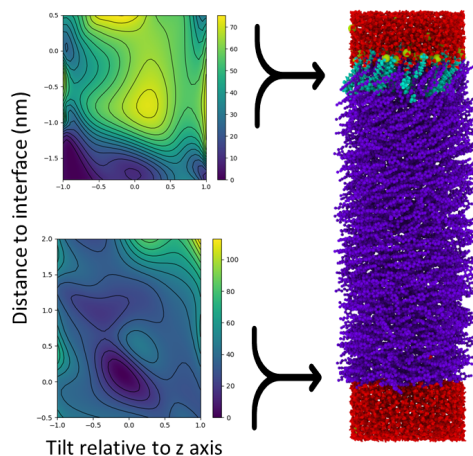

Figure 6: Free energy surface of 5CB in a hybrid anchoring slab with SDS and water. Right: Snapshot of the system with water molecules in red, 5CB in purple, SDS in green and sodium ions in yellow. Top Left: FES of 5CB molecule near the water-SDS interface. Bottom Left: FES of 5CB near a pure water interface. Both FES were obtained with PYSAGES and OpenMM using the FUNN method.

3.1.4. *Ab Initio* Enhanced Sampling Simulations

In the field of *ab initio* simulations of heterogeneous catalysis, capturing the dynamic and entropic effects is crucial for an accurate description of the phenomena [38]. Classical force fields are inadequate for capturing the essential bond breaking events involved in catalysis, so MD simulations based on first-principles calculations are necessary. Given that reactive events are often limited by large free energy barriers, enhanced sampling techniques are a crucial part of these simulations. Coupling PYSAGES to ASE, provides access to a wide range of first-principle calculators.

As an example, we have used VASP as a calculator for a simple *ab initio* enhanced sampling simulation. The CV is the separation distance between a sodium and chlorine atom using the PBE functional [72], and Spectral ABF as the enhanced sampling method (see section 2.1.10). The results are shown in Figure 7, where the minimum in the free energy profile along the Na-Cl distance corresponds to the equilibrium distance between Na and Cl atoms in vacuum.

3.1.5. Enhanced Sampling with Machine Learning Force Fields

Deep neural network (NN) force fields can retain the accuracy of *ab initio* MD while allowing for computational costs similar to those of classical MD.

Figure 7: Free energy ($T = 300$ K) and potential energy calculations of Na-Cl distance with ASE + VASP using Spectral ABF in PYSAGES.

Through ASE it is possible to access NN potentials such as DeepMD [73], and the Gaussian Approximation Potential (GAP). Additionally, JAX MD allows to leverage more general NN potentials that can be used in enhanced sampling calculations. Coupling of PYSAGES with ASE or JAX MD can be used in active learning of NN force fields by efficiently sampling rare events using any of the enhanced sampling methods provided by PYSAGES as described in Ref. [74] where parallel tempering metadynamics was used to generate accurate NN force field in urea decomposition in water.

To test the capabilities of PYSAGES to handle different NN force fields, we have selected three different systems trained with the methods mentioned above. For DeepMD, we use a pre-trained model for water, where the enhanced sampling system is one single water molecule in vacuum, the collective variable is the internal angle of the molecule and the sampling method is ABF (section 2.1.4). The results in Figure 8 show that the minimum for this free energy profile is around 105 degrees, which is within the range of the experimental value.

Next, in Figure 8b, a GAP potential was used for Si-H amorphous mixtures [75]. In this case, a system of 244 atoms was used, and the collective variable is the bond angle between a triad of Si-Si-H atoms in the mixture. The global minimum in free energy agrees with the histogram taken from

unbiased simulations reported in [75].

Lastly, we studied a Graph neural network (GNN) model of a Si crystal [76] with PYSAGES and JAX MD. In this case, a crystalline Si system of 64 atoms was used, and the CV was the Si-Si distance for the the crystal. The results of Figure 8c show that for this model, the minimum in the free energy corresponds almost exactly to the experimental value for the Si-Si nearest distance of 2.35 Å.

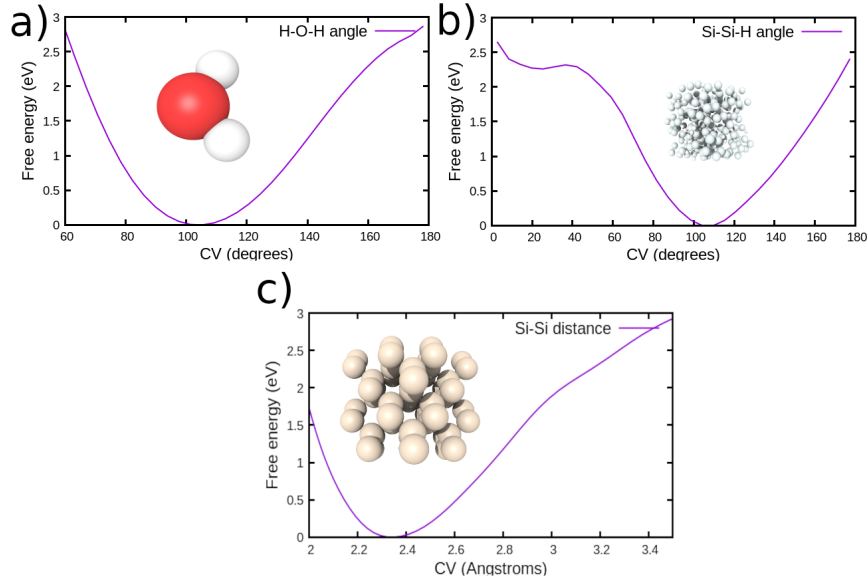

Figure 8: Free energy calculation of: a) Water internal angle from a DeepMD model with ASE, b) Si-Si-H angle of GAP model with ASE and c) Si-Si distance of a GNN model with JAX MD.

3.2. Performance

Our analysis revealed that PYSAGES is at least ~ 14 – 15 times faster than SSAGES on an Nvidia V100 GPU machine. To obtain this estimate, we ran enhanced sampling using umbrella sampling along the center of mass distance between two spherical polymer domains to measure the free energy landscape of the fission of a spherical diblock-copolymer blend (Figure 5) described in section 3.1.2. For support and compatibility across libraries and MD engine versions, we estimated the performance with SSAGES v0.9.2-alpha and PYSAGES v0.3.0 using HOOMD-blue v2.6.0 and HOOMD-blue v2.9.7, respectively.

Figure 9: The figure shows a 1.8ms section of profiled timeline recorded with Nvidia Nsight systems on an Nvidia V100 GPU. The top row shows a vanilla HOOMD-blue simulation step, while the bottom row shows a PYSAGES/HOOMD-blue simulation with harmonic biasing of a center of mass CV. Light-blue represents the GPU activity while dark-blue represents individual CUDA compute kernels. The maroon letters show case the same compute steps in both simulations: a) First half-step of integration, b) compute of bond forces, c) pair-forces, d) calculation of the CV, e) addition of the harmonic biasing force to the HOOMD-blue simulation, and f) the second integration step. Sections d) and e) are PYSAGES only and are executed on the GPU. We observe GPU idle time during the PYSAGES Python coordination with GPU-JAX/CuPy (green bar), but note that there is no memory copies even within the GPU memory. The additional time for CV biasing per time step is 247 μ s (teal bar).

3.2.1. GPU utilization analysis

PYSAGES is designed to execute every compute-intensive step of a simulation on the GPU and have zero copy instruction between GPU device and host CPU memory for its explicit backends for HOOMD-blue [4] and OpenMM [5], while still providing Python code for the user through JAX [77]. In this section, we investigate the calculation efficiency of PYSAGES by examining two example systems, one for each backend.

For HOOMD-blue, we are investigating a system of highly coarse-grained DPD diblock-copolymers as discussed in section 3.1.2. The simulation box contains a total of $nN = 51\,200$ particles at a density of $\rho = 51.2/\sigma^3$, which we use for benchmarking purposes with an Nvidia V100 GPU hosted on an Intel Xeon Gold 6248R CPU @ 3.00GHz. Running only with HOOMD-blue v2.9.7 we achieve an average time steps per second (TPS) of 754, which is the expected high performance of HOOMD-blue on GPUs.

Figure 9 shows a detailed profiled timeline during the execution of a single time step. During 1.8 ms, HOOMD-blue spends the most computational effort on the calculation of pairwise DPD forces. It can be noted that HOOMD-blue is designed to have almost no idle time of the GPU during a time step. As soon as PYSAGES is added computation part, we observe that an additional part is added to calculate the CV and add the forces to every particle. This causes a small period of idle of the GPU, since the execution also requires action of the Python runtime interface with JAX. In the future, we plan to launch the calculation of CV asynchronously with the regular

Figure 10: 1.6ms profiled time line of an OpenMM OPLS simulation of 40,981 particles as polymers with particle mesh Ewald (PME) summation for long-range Coulomb forces. The colors and labels are identical to Figure 9. OpenMM works with asynchronous GPU kernel execution, which leads to less linearly sorted timelines, compared with HOOMD-blue, but we can still identify the CV calculation d) and force biasing e) and the synchronization idle of the GPU (green). Overall, the performance degradation is more pronounced with OpenMM compared to HOOMD-blue.

force calculation, which would hide this small CPU-intensive GPU idle time. However, we measure that the total delay due to the extra computation is only about 247 μ s only. We regard this to be an acceptable overhead for the user-friendly definition of CVs.

In order to connect multiple points in CV space we can use enhanced sampling methods such as umbrella sampling (see section 2.1.2) or the improved string method (see section 2.1.3) to calculate the MFEP. Common for these advanced sampling methods that multiple replica of the system are simulations. With PYSAGES we easily parallelize their execution using the Python module mpi4py and its MPIPoolExecutor. This enables us to execute replica of the simulations on multiple GPUs even as they span different host machines. In our example, we used 14 replicas for umbrella integration with 7 Nvidia V100 GPUs. The use of a single V100 GPU to execute the simulations with $5 \cdot 10^5$ time steps for all replicas takes 2 hours and 59 minutes. Ideal scaling with 7 GPUs reduces the time to solution to about 26 minutes. With our MPI-parallel implementation, we achieve a time-to-solution of 28 minutes. Synchronization overhead and nonparallel aspects like final analysis sum up to 2 minutes or about 9% overhead. This multi-GPU implementation via MPI enables automatically efficient enhanced sampling in high performance computing (HPC) environments.

For enhanced sampling methods that are designed for single replica simulations, we offer an implementation that allows multiple replicas to run in parallel, known as embarrassingly parallel computing. In this situation, the build-in analysis averages the results from multiple replicas and estimates uncertainties.

In the previous section, we have demonstrated the fast GPU interoperability between PYSAGES and HOOMD-blue via JAX. However, the concept of PYSAGES is to develop enhanced sampling methods independently of the simulation backend, so here we demonstrate that similar performance can be achieved with OpenMM. Since OpenMM focuses on all-atom simulations, we simulate an all-atom model of a polymer with the BigSMILES [78] notation {[\$]CC([\$])(C)C(OCC(O)CSC1=CC=C(F)C(F)=C1)=O} with an OPLS-AA force field [79, 80] including long-range Coulomb forces via particle mesh Ewald (PME). We simulate a bulk system of 40mers with 31 macromolecules present, adding up to 40 981 atoms. As a proof of concept, we calculated the center of mass for every polymer chain and biased it harmonically via PYSAGES. As a performance metric, we evaluate the nano-seconds per day (NS/DAY) executed on the same hardware configuration as the HOOMD-blue example above. For the unbiased, pure OpenMM simulation we achieve a performance of ≈ 136 NS/DAY. For the PYSAGES biased simulation, we achieve a performance of ≈ 75 NS/DAY, equating to a biasing overhead of approximately 50%. Figure 10 shows a similar time series analysis as for HOOMD-blue.

It is notable that OpenMM’s execution model makes more use of parallel execution of independent kernels, which also changes the order of execution compared to HOOMD-blue. As a result, the same CPU synchronization changes the execution more drastically than in HOOMD-blue. Additionally, a single time step for this system is faster executed compared to HOOMD-blue, making the synchronization overhead more noticeable. In this case, parallelization of PYSAGES and OpenMM is projected to have a bigger performance advantage. Furthermore, we notice that the calculation of the center of mass and the biasing of all 31 polymer chains is more costly than the single CV in the previous example. The combination of these factors explain the higher PYSAGES overhead for this OpenMM simulation, but overall performance is good and significantly better for alternative implementations that require CV calculations on the CPU.

4. Conclusion

We have introduced PYSAGES, a library for enhanced sampling in molecular dynamics simulations, which allows users to utilize a variety of enhanced sampling methods and collective variables, as well as to implement new ones via a simple Python and JAX-based interface.

We showed how PYSAGES can be used through a number of example applications in different fields such as drug design, materials engineering,

polymer physics, and ab-initio MD simulations. We hope that these convey for the reader the flexibility and potential of the library for addressing a diverse set of problems in a high-performance manner.

As our analysis showcased, for large problems, PySAGES can perform biased simulation well over one order of magnitude faster than a library such as SSAGES even when the backend already performs computations on a GPU.

Nevertheless, as with any newly developed software, PySAGES is still under development and we are continually working to improve it. In the near term, we plan to add the ability for users to perform restarts, which will provide greater flexibility running long simulations. Moreover, we plan to optimize PySAGES-side computations to run fully asynchronously with the computation of the forces of the backend, which will further enhance its current performance. We also invite the community to contribute to the development of PySAGES, whether by suggesting new features, reporting bugs, or contributing code.

Overall, we believe that PySAGES provides a useful tool for researchers interested in performing molecular and ab-initio simulations in multiple fields, due to its user-friendly framework for defining and using sampling methods and collective variables, as well as its high performance on GPU devices.

Looking further ahead, we are excited about the potential for PySAGES to enable fully end-to-end differentiable free energy calculations. This will provide new possibilities for force-field and materials design, which would drive significant advances in these areas.

Code availability

The code for PySAGES is available in the GitHub repository: <https://github.com/SSAGESLabs/PySAGES>.

    probability = nn.softmax(mass_diff * coeff)
    interface = np.sum(probability * centers_mean)
    return mobile_axis - interface
```

Appendix B. Benchmark test systems

In the following sections, we present the results of the free energy calculation for the benchmark test systems of alanine dipeptide and butane. The details of all the parameters chosen to perform the enhanced sampling simulation of these are summarized in [Appendix B.3](#).

Appendix B.1. Alanine Dipeptide

The first test system involves alanine dipeptide in vacuum ([Figure B.11](#)), a benchmark system for enhanced sampling methods that is frequently used in the literature.

Figure B.11: Free energy landscape of alanine dipeptide (Amber ff99SB [\[81\]](#)) in vacuum as a function of the dihedral angles ϕ and ψ obtained with PYSAGES and OpenMM via different enhanced sampling methods: ABF, Metadynamics, Spectral ABF, ANN, FUNN, CFF. Each panel also indicates the length of the simulation necessary for the free energy to converge. The long ABF simulations represent the ground truth.

Appendix B.2. Butane

As a second test system, we compute the free energy profile along the C-C-C-C dihedral angle, ϕ_{CCCC} , of a butane molecule (in vacuum), [Figure B.12](#).

Appendix B.3. Example System Details

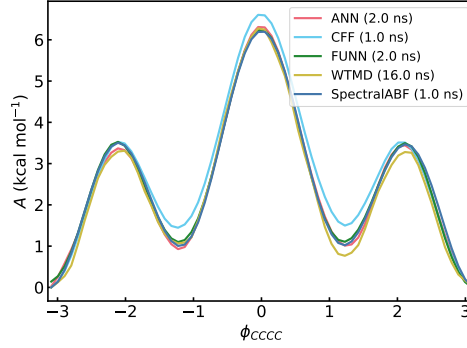

Figure B.12: Free energy profile along the dihedral angle of a butane molecule (using an OPLS-based force field [79]) obtained via different enhanced sampling methods with PySAGES and HOOMD-blue: ANN, CFF, FUNN, Spectral ABF, WTMD. The legend also indicates the length of the simulation. The long ABF simulations represent the ground truth.

Table B.1: Parameters and methods details for the various examples. For all methods but Metadynamics, we used a grid with 50 points along each CV for ADP and with 64 points along the CV for butane.

N (ABF) = Threshold parameter before accounting for the full average of the adaptive biasing force.

ADP = alanine dipeptide

System	Backend	CV	Method	Settings	Fig.
