(Dated: March 8, 2023)

We present a minimal model of charge transport in hybrid perovskites, which provides an intuitive explanation for the recently proposed formation of ferroelectric large polarons. We demonstrate that short-ranged charge–rotor interactions lead to long-range ferroelectic ordering of rotors, which strongly affects the carrier mobility. In the nonperturbative regime, where our theory cannot be reduced to any of the earlier models, we predict polaron properties in good agreement with experiment. This shows the potential of simple models to reveal electronic properties of molecular materials.

Hybrid organic-inorganic perovskites (HOIP) are praised for their outstanding performance in photovoltaic applications due to their long carrier lifetimes and diffusion lengths [1–3]. After the initial reports on spectacular optoelectronic properties of HOIP solar cells [4–7], the field has expanded at an unprecedented pace [8, 9]. It turned out that the physical properties of HOIP are quite complex, *inter alia* due to their soft structure [10], ionic mobility [11, 12], and the interplay between rotational dynamics of the molecular cations and their structural and (photo)electric properties [13–16]. Despite their complexity, a considerable progress in understanding of HOIP has been achieved through density functional theory [17–20], molecular dynamics [21] and machine learning [22–24] approaches. Based on such atomistic simulations it is, however, challenging to obtain a simple intuitive picture independent of microscopic details, motivating the development of minimal models that capture the key physical properties of HOIP.

Perhaps the most pressing issue to be addressed in HOIP concerns their charge transport properties. Although the carrier recombination lifetimes and diffusion lengths in HOIP are comparable to that of conventional semiconductors such as GaAs, the charge mobilities are orders of magnitude smaller [25]. Earlier theories tried to explain this through screening of excitons by collective orientation of organic cations [26] and modification of the band edges due to spin-orbit coupling resulting from cation-induced structural variability [17, 27, 28]. In contrast, recent theories emphasize the role of the large polarons screening the carriers from charged defects, other carriers, and phonons [29–39]. Still, the detailed origin of large polaron formation remains debated. A promising approach [38, 39] suggests ferroelectric large polarons, consisting of ferroelectrically ordered nanodomains, which are postulated to provide substantially increased screening compared to Fröhlich polarons [40, 41]. However, the involved properties of HOIP make quantitative predictions for such quasiparticles difficult [38], hindering their unambiguous experimental identification.

In this Letter we show that the formation of ferroelectric large polarons takes place already in a mini-

FIG. 1. (a) The tight binding model. Blue empty (filled) circles label empty (occupied) electron sites. Red circles show the dipole positions modeled by planar rotors. The distances between the sites and the orientations of the rotors/dipoles are also shown, where α is the lattice constant. (b) Illustration of the Gross-Hartree ansatz. The electron possesses quasimomentum, q, while the rotor states relative to it are described by the single-rotor states, $\varphi_j(\phi)$. Arrows show the orientations of the rotors.

mal model, where charge carriers interact with an onedimensional array of planar rotors, see Fig. 1(a). The dipolar rotors model the reorientation dynamics of organic molecular cations, A^+ in the ABX₃ perovskite structure. Molecules interact with charge carriers hopping on the inorganic sublattice made of octahedral $BX_6^$ cages, which we represent by discrete sites. Due to screening [42], we assume charge–dipole interactions to be short-ranged and dipole-dipole interactions to be absent. As we demonstrate, this model captures the formation of local ~ 10 nm-sized ferroelectric order [37, 43, 44] and the crossover between a large light polaron (associated with ferroelectrically polarized dipoles) and a small heavy polaron regime characterized by charge carrier localization at the boundary of two misaligned ferroelectrically ordered domains [39, 45].

This ferroelectric order significantly increases the effective mass of the carriers even within the light polaron regime, in agreement with the modest but not negligible mobilities observed in HOIP [25], but in contrast to other polaron models, e.g. the Holstein polaron, which predict much larger renormalization [46, 47]. When the domain wall forms, the effective mass grows exponen-

tially, suggesting high anisotropy of the mobilities and diffusion constants of large ferroelectric polarons in two and three dimensions. Anisotropies along different crystalographic directions have been recently experimentally identified [48–50], confirming the relevance of our model for HOIP.

The Hamiltonian of our model, cf. Fig. (1)(a), reads

$$\hat{H} = -t \sum_{i=1}^{M} (\hat{a}_{i+1}^{\dagger} \hat{a}_i + \text{h.c.}) - B \sum_{i=1}^{M} \frac{\partial^2}{\partial \phi_i^2}$$
$$- V_0 \sum_{i=1}^{M} \hat{a}_i^{\dagger} \hat{a}_i \left[\cos\left(\phi_i + \frac{\pi}{4}\right) + \cos\left(\phi_{i-1} - \frac{\pi}{4}\right) \right], \quad (1)$$

where \hat{a}_i (\hat{a}_i^{\dagger}) are the electron annihilation (creation) operators, angles ϕ_i define the dipole orientations and B their rotational constants (in what follows we use the terms dipoles and rotors interchangeably), t is the tunneling rate of the electron, V_0 is the electron–dipole interaction strength and M is the number of rotors in the lattice. For simplicity we neglect the activation energy of molecular rotations, $E_{\rm act}$, as its presence effectively inhibits rotor–electron interactions for $E_{\rm act} \gtrsim V_0$ [15, 51]. Note that we employ periodic boundary conditions, i.e. $\hat{a}_{M+j}^{\dagger} = \hat{a}_j^{\dagger}$ and $\phi_{M+j} = \phi_j$, for all $j = 1, \ldots, M$. Although the model can be trivially extended to hole carriers by assuming $V_0 < 0$, here we focus on electrons, $V_0 > 0$.

In HOIP the molecular rotational energy $B \sim 1 \text{ meV}$ is the lowest energy scale since $V_0, t \sim 0.1 - 1 \text{ eV}$ [51, 52]. To generate an appropriate rotor basis for $B \ll t$, we variationally optimize the state of the rotors relative to the electron, $\varphi_j(\phi)$, cf. Fig. 1(b), based on the following ansatz:

$$|\Psi_q(\phi_1,\ldots,\phi_M)\rangle = \sum_{j=1}^M \frac{e^{i\frac{2\pi q}{M}j}}{\sqrt{M}} \prod_{k=1}^M \varphi_{I(k,j)}(\phi_k)\hat{a}_j^{\dagger}|0\rangle, \quad (2)$$

where $|0\rangle$ and \hat{a}_j are the electron vacuum and creation operators and $q = 0, \ldots, M-1$ gives the quasimomentum of the polaron state. We will refer to this approach as the variational Gross-Hartree method (vGH). The indices of $\varphi_j(\phi)$ appearing in Eq. (2) read $I(k, j) = 1 + [(M + k - j) \mod M]$ and are selected such that the rotor state depends only on the relative distance between the rotor and the electron. For instance, $\varphi_1(\phi)$ and $\varphi_M(\phi)$ refer to the state of the rotor on the right and left of the electron, respectively, independently of the position of the latter, cf. Fig. 1(b).

Note that while the ansatz of Eq. (2) generalizes the basis generated via the Lang-Firsov transformation [41, 53] as it allows for t-dependent modifications of the rotor state, it neglects dipole–dipole correlations. These are not expected to limit the applicability of vGH, since no direct interaction between dipoles appears in Eq. (1). Thus, only dipole–dipole correlations mediated by the

FIG. 2. (a) Rotor-electron correlation function, $C_j(\phi)$, for j = 1 and j = M = 4, as a function of the electron-rotor interaction, V_0 . The electron is fixed at the first site. (b) Average rotor orientation, $\langle \phi_j \rangle$, depending on the electron-rotor distance and V_0 for M = 1024. In both cases $B = 10^{-3}t$. (c) Schematic illustration of the ferroelectric orders involved.

electron can take place, which result in small corrections in related polaron models (except for strong coupling) [54]. The applicability of the vGH approximation has been justified through comparison with exact diagonalization for small M [55].

The order emerging in the rotor lattice can be elucidated by considering the rotor–electron correlation function at distance j, $C_j(\phi) = |\varphi_j(\phi)|^2$, as shown in Fig. 2(a) for a small system with M = 4. In Fig. 2(b) we provide the average polarization of the rotors, $\langle \phi_j \rangle = \int_{-\pi}^{\pi} d\phi \ \phi C_j(\phi)$ for M = 1024, which is large enough to achieve convergence towards the $M \to \infty$ limit.

In the case of small $B = 10^{-3}t$, relevant for HOIP, we observe the emergence of two distinct interaction regimes. For $V_0 < 2t$ the rotors become strongly polarized towards the electronic lattice, $\phi \approx 0$, and an almost perfect ferroelectric order emerges (see Fig. 2(a) and the left panel of Fig. 2(c)). Similarly, Fig. 2(b) shows $\langle \phi_j \rangle \approx 0$, for all j within this V_0 range. For $V_0 > 2t$, on the other hand, we observe domain formation in the rotor system, see Fig. 2(a) and the right panel of Fig. 2(c). The rotors to the left of the electron, $M/2 < j \leq M$, polarize with $\phi \approx \pi/4$, while the rotors at $1 \leq j \leq M/2$ polarize towards $\phi \approx -\pi/4$. Thus, the electron acts as a ferroelectric domain wall, with rotors on each side of the electron pointing towards it. From Fig. 2(b) we can see that although this rotor ordering is local, it is quite extensive involving ~ 50 rotors in each side of the electron. Note that this change in ferroelectric order with varying V_0 is gradual, of typical crossover character [56, 57], as the rotors neighbouring the electron from either side possess slightly different average orientations even for $V_0 < 2t$, see Fig. 2(b).

The interaction dependence of the local ferroelectric

FIG. 3. (a, b) Polaron energy, E_0 , for different values of B as a function of V_0 . (a) compares the vGH results (solid lines) with perturbation theory (dashed lines). The dashed line in (b) is an eye-guide to estimate E_0 (see the text). In all cases M = 1024.

order, Fig. 2, provides an intuitive picture for the role of molecular dipole moments in the formation of polarons at ferroelectric domain boundaries, proposed in Ref. [39]. That work suggests that the carriers are confined to and move along a two-dimensional ferroelectric domain-wall, whereas the hopping perpendicular to it is much slower due to the distortion of the inorganic lattice. In our model this distortion corresponds to a reduced t along the distortion direction, resulting in an effectively higher V_0/t that can exceed the threshold for formation of ferroelectric domain walls, $V_0 \approx 2t$ in one dimension. In contrast, along the directions where no distortion takes place, V_0/t remains smaller than the threshold, which stabilizes an almost perfectly polarized rotor state.

The origin of the emerging order can be elucidated by examining the polaron energy, E_0 . First, let us analyze its scaling with V_0 , Fig. 3(a). For small V_0 , the polaron energy follows the pertubative result, $E_0 = -2t - V_0^2/\sqrt{B(B+4t)}$, independently of B [55]. With increasing V_0 , however, the energy of the polaron diverges from this scaling, with the strongest deviations observed for smaller B's. This behavior stems from the breakdown of perturbation theory for $V_0 > 2\sqrt{Bt}$, where the rotor–electron interaction creates a large number of rotor excitations.

The fact that the ferroelectric dressing of the electron observed in Fig. 2 takes place beyond the regime of validity of perturbation theory, implies that it originates from the collective excitations of the rotor array and their coupling to the electron. Since the spectrum of rotors is different from that of harmonic oscillators, the nonperturbative physics of the ferroelectric polaron given by Eq. (1) is fundamentally different from the traditional models such as the Holstein polaron [41, 58, 59].

The fundamental difference between the $B < 10^{-2}t$ and $B \approx t$ regimes is directly observable by comparing the polaron energies for different B's near the crossover point, $V_0 \sim 2t$, see Fig. 3(b). For $B < 10^{-2}t$ and $V_0 < 2t$, the polaron energy features an almost linear decrease, $E_0 \approx -2t - \sqrt{2}V_0$, stemming from strong polarization of the rotors ($\phi \approx 0$) in the vicinity of the electron. This results in the potential energy contribution $\sim V_0[\cos(\pi/4) + \cos(-\pi/4)] = -\sqrt{2}V_0$. For stronger interactions, $V_0 > 2t$, the polaron energy decreases faster than $\propto -\sqrt{2}V_0$ due to the domain-wall formation at the electron positions, which increases the rotor-electron attraction. For $B \sim t$, the behaviour of the system changes and the polaron energy decreases quadratically. This is due to the large amount of energy required to create rotor excitations which hinders their polarization and the associated potential energy benefit, thereby precluding the formation of ferroelectric order.

Having discussed the basic properties of the polaronic states based on energetic arguments, let us focus on their coherence and transport properties and their relation to HOIP experiments. The polaron size, or, equivalently, the polaron coherence length, is associated with the extent of the ferroelectric order in the vicinity of the electron, see also Fig. 2(b). This property can be expressed through the variance of the rotor angle, $\sigma_{\phi}(j) = \left[\int_{-\pi}^{\pi} d\phi \ (\phi - \langle \phi_j \rangle)^2 C_j(\phi)\right]^{1/2}$, over the variance of the uniform distribution, $\sigma_0 = 2\pi/\sqrt{12}$. The value of $\sigma_{\phi}(j)/\sigma_0 = 1$ corresponds to a uniform density profile, where the dipoles are unaffected by the electron motion. The values $0 \leq \sigma_{\phi}(j)/\sigma_0 < 1$ correspond to the polarization of the *j*-th rotor typical for ferroelectric order.

The localization of ferroelectric order is demonstrated by the exponential trend of $\sigma_{\phi}(j)/\sigma_0$ which rapidly saturates to unity as rotors far away from the electron remain not oriented, see Fig. 4(a). For fixed V_0 , a larger number of rotors can be excited at smaller B, giving rise to a more extensive dressing cloud around the electron. Inversely, for t = B, the polaron is strongly localized in the vicinity of the electron, $j \to 0$, and thus cannot be called a large polaron. This is fully consistent with the energetic arguments presented above, cf. Fig. 3(b), and is further illustrated in Fig. 4(b). Here we use an exponential fit, $\sigma_{\phi}(j)/\sigma_0 = 1 + (\sigma_{\phi}(1)/\sigma_0 - 1)e^{-(j-1)/M_p}$ for j < M/2, to extract the polaron size M_p . We find that almost independently of V_0 , the polaron size grows as $\propto B^{-1/2}$ with decreasing B.

In contrast, for a constant B, the spatial extent of the polaron depends weakly on V_0 , see the inset of Fig. 4(a), especially within the polarized regime, $V_0 < 2t$. This observation is confirmed by Fig. 4(c), which shows that M_p is independent of V_0 even for very small V_0 's. This can be explained along the lines of perturbation theory: electron-rotor interactions result in virtual rotor excitations localized in the vicinity of the electron, whose momentum shifts from q to q'. These excitations are characterized by an energy B and thus a lifetime $\sim \hbar/B$. Consequently, the maximum distance between the electron and an excitation depends solely on the distribution of available q' and the excitation lifetime, both of which are independent of V_0 controlling the excitation probability. For $V_0 > 2t$, where the ferroelectric domain wall forms, the spatial extent of the polaron decreases by a factor of ~ 2 ,

FIG. 4. (a) Variance of the rotor orientations, $\sigma_{\phi}(j)/\sigma_0$, for different *B* and $V_0/t = 0.5$. Inset: V_0 dependence of $\sigma_{\phi}(j)/\sigma_0$ for $B = 10^{-3}t$. (b, c) Polaron size, M_p , derived from exponential fits of $\sigma_{\phi}(j)/\sigma_0$ as a function of (b) *B* and (c) V_0 . (d, e) The ratio of the polaron and free electron effective masses, m_p^*/m_0^* for different values of *B*, as a function of V_0 . (e) Comparison of vGH results (solid lines) to perturbation theory (dashed lines). (f) The ratio m_p^*/m_0^* as a function of *B*. The dashed line in (b) and (f) serves as an eye-guide to estimate the scaling with *B*. In all cases M = 1024.

see the inset of Fig. 4(a). In this regime, the perturbative argumentation is invalid, since, as argued below, the electron becomes rigidly attached to its dressing cloud of rotor excitations. In summary, although the ferroelectric dressing is found to be large at the level of the unit cell, its spatial extent, $M_p \times \alpha \approx 30 \times 5 \text{\AA} \approx 15$ nm, is much smaller than the observed diffusion lengths of > 1 μ m [60–62]. This implies that the semiclassical treatment of diffusion lengths, frequently used in the literature [25], is well justified within our model.

The ferroelectric order crucially affects the polaron mass, Fig. 4(d). Note that the mass scale for $V_0 = 0$ is $m_0^* = \hbar^2/(2t\alpha^2) \approx 0.15 \ m_e$ (for $\alpha \approx 5$ Å and $t \approx 1 \ \text{eV}$ relevant for HOIP). For smaller B, the effective mass features a strong overall increase. For $B < 10^{-2}t$ the initial growth of $m_p^* = (\hbar^2/\alpha^2)(\partial^2 E_p/\partial q^2)^{-1}$ at smaller V_0 is followed by a plateau at $V_0 \sim t$. This can be rationalized by considering how m_p^* , scales with B and V_0 . From Fig. 4(e) we see that for small V_0 the effective mass increases following the perturbative result, $m_p^*/m_0^* = 1 + V_0^2(B+2t)/[B(B+4t)]^{3/2}$ [55], and saturates at larger V_0 . The saturation of m_p^* can be thought of as an almost rigid attachment of the ferroelectric polarization cloud to the electron at strong interactions. For $B \sim t$ the attachment is precluded by rapid rotation of the rotors, resulting in no saturation of m_p^* . The scaling of m_p^* with B, Fig. 4(f), demonstrates significant deviations from the perturbative result, $m_p^*/m_0^* - 1 \propto B^{-3/2}$, in the region where the ferroelectric polaron forms, $V_0 \sim t \gg B$. The *B*-scaling is found to be significantly less steep, $m_p^*/m_0^* - 1 \propto B^{-0.6}$ for $V_0 = 0.5t, 4t$, and $m_p^*/m_0^* - 1 \propto B^{-0.5}$ in the crossover region $V_0 = 2t$. Importantly, m_p^* is a decreasing function of B in all of the considered cases.

Thus, although the polaron for $V_0 < 2t$ is large, it features low but non-negligible mobility, $\mu \propto \tau/m_p^*$, which is consistent with HOIP experiments [25]. Here, τ corresponds to the mean scattering time which is large in HOIP [63] and is expected to increase due to polaron screening. Also, we would like to emphasize that the simultaneous power-law increase of the polaron size, M_p , and of its effective mass, m_p^* , with decreasing B, see Fig. 4(b, f), is the behaviour that sets our model apart from the well-known Holstein and Fröhlich polarons, where larger effective masses are associated with smaller polaron sizes [41, 58, 59, 64] or extremely heavy polarons with negligible mobilities [46, 47]. This indicates that the framework of rotor lattices introduced here has the potential to explain the apparently contradicting features of carrier dynamics in HOIP.

For $V_0 > 2t$, m_p^* grows exponentially with V_0 , Fig. 4(d), as a consequence of the reduced mobility due to the domain wall co-moving with the electron. This is consistent with strong anisotropy of the effective mass along vs. perpendicular to the ferroelectric domain wall once it forms [48–50]. Our results further suggest that the anisotropy in coherence length is much less pronounced, see the inset of Fig. 4(a). Thus the study of the relation between the coherence and mobility anisotropies might be important for the experimental detections of ferroelectric polarons.

In conclusion, we proposed a minimal, tractable, and extendable rotor lattice model describing the formation of ferroelectric polarons in HOIP [37–39]. The model captures several observed features of polarons such as their modest mobility but large coherence length. Furthermore, it provides intuition for the mechanism behind large polaron formation at ferroelectric domain boundaries, proposed in Ref. [39]. Our model lays the groundwork for realizing a top-down approach to the carrier dynamics in HOIP, complementary to the existing density functional theory studies [17–20]. Possible extensions include studying the phase diagram of the two-dimensional lattice system where signatures of carrier localization along different directions can be identified. The study of electron-hole interactions mediated by the rotors can elucidate the impact of the molecules on the observed long carrier lifetimes. Moreover, our study suggests an interesting interplay of mobility inhomogeneity and exciton lifetime which might provide quantitative predictions for the diffusion length. Different forms of rotor-phonon coupling Hamiltonians can be accounted for in order to fully capture the ferroelectric properties of HOIP materials. In addition, studies that connect the abstract model parameters with realistic material properties will be crucial. The possibility of angulon formation affecting molecular mobility [65–69] and of the halogen-metal hybridization which can introduce polarization of the $BX_6^$ cages [70, 71] might also be relevant for reliable modeling of HOIP properties with rotor lattice setups.

We thank Zhanybek Alpichshev, Artem Volosniev and Alexandra V. Zampetaki for fruitful discussions and comments. Supplementary Material Rotor Lattice Model of Ferroelectric Large Polarons

LANG-FIRSOV TRANSFORMATION

The Lang-Firsov transformation has been successfully used to describe polarons in the Holstein model [S1–S4]. Within the Lang-Firsov transformation one diagonalizes the Hamiltonian, $\hat{H}_{V_0\to\infty}$ for t = 0, and then uses the unitary matrix \hat{U} obtained by the diagonalization to obtain the hopping term in the transformed frame. Since in the case of the Holstein polaron the phonon–electron interaction has the simple form of a potential gradient, the operator \hat{U} corresponds to a displacement operator for the phonons and therefore the transformation can be performed analytically.

In our case, however, $\hat{H}_{V_0\to\infty}$ yields the Mathieu equation [S5] and therefore the operator \hat{U} has no simple analytic form. To describe how a pseudo-Lang-Firsov transformation can be performed in our case, let us assume that that the electron is localized at position j. This allows us to diagonalize the rotor sector of the strong-coupling Hamiltonian by solving the corresponding Mathieu and free-rotor equations. Notice that within its eigenbasis the strong-coupling Hamiltonian reads

$$\hat{H}_{V_0 \to \infty} = \sum_{j=1}^{M} \sum_{k=1}^{\infty} \epsilon_k |j\rangle \langle j| \otimes |\Psi_{j,k}^{\text{rotors}}\rangle \langle \Psi_{j,k}^{\text{rotors}}|, \quad (S1)$$

where, ϵ_k , $|\Psi_{j,k}^{\text{rotors}}\rangle$ are the eigenenergies and eigenstates of the rotor system respectively. Here we have used the fact that due to translational invariance ϵ_k is independent of the position of the electron. Furthermore, the electronic and rotor wavefunctions are in a product state but $|\Psi_{j,k}^{\text{rotors}}\rangle$ depends on the electron position, j, since only the dipoles next to the electron interact with it. The eigenstates of $\hat{H}_{V_0 \to \infty}$ form a complete basis and thus the identity operator can be expanded as $\hat{\mathbb{I}} = \sum_{j,k} |j\rangle \langle j| \otimes |\Psi_{j,k}^{\text{rotors}} \rangle \langle \Psi_{j,k}^{\text{rotors}}|$. This allows us to express the dipole–electron Hamiltonian of Eq. (1) as

$$\hat{H} = -t \sum_{j=1}^{\infty} \sum_{k,l} \left(\langle \Psi_{j,k}^{\text{rotors}} | \Psi_{j+1,l}^{\text{rotors}} \rangle | j \rangle \langle j+1 | \\ \otimes | \Psi_{j,k}^{\text{rotors}} \rangle \langle \Psi_{j+1,l}^{\text{rotors}} | + \text{h.c.} \right) \qquad (S2)$$
$$+ \sum_{j=1}^{\infty} \sum_{k} \epsilon_{k} | j \rangle \langle j | \otimes | \Psi_{j,k}^{\text{rotors}} \rangle \langle \Psi_{j,k}^{\text{rotors}} |.$$

By appropriately selecting the many-rotor state indices k and l and by making use of the translational invariance we can simplify Eq. (S2) further, see Fig. S1. Here, the indices $n_{\pm 1}^k = 0, 1, \ldots$ parametrize the single particle eigenstate of the dipoles neighbouring the electron,

 $|\psi_{n_{\pm 1}^k}^{\mathrm{M}}\rangle$, which solves the corresponding Mathieu equation. Furthermore, $\ell_j^k = 0, \pm 1, \ldots$, with $j = \pm 2, \pm 3, \ldots$, are the indices of the angular momentum eigenstates, $\hat{L}_z |\psi_{\ell_j^k}^{\mathrm{AM}}\rangle = \ell_j^k |\psi_{\ell_j^k}^{\mathrm{AM}}\rangle$, for the dipoles further that the neighbouring ones. Note that within this framework each different many-rotor state k corresponds to a unique configuration $\{n_{\pm 1}^k, \ell_{\pm 2}^k, \ell_{\pm 3}^k, \ldots\}$ of the above mentioned single-rotor states. With these definitions the overlaps of the many-rotor states contributing to tunneling read

which are independent of j and thus translationally invariant. Also, $O_{kl}^L = \langle \Psi_{j+1,k}^{\text{rotors}} | \Psi_{j,l}^{\text{rotors}} \rangle = (O_{lk}^R)^*$ holds. By transforming to the momentum basis for the electron, $|q\rangle = \frac{1}{\sqrt{M}} \sum_{j=1}^{M} e^{i\frac{2\pi q}{M}j} |j\rangle$, Eq. (S2) reduces to $\hat{H} = \sum_{q=0}^{M-1} \hat{H}_q \otimes |q\rangle \langle q|$, with

$$\hat{H}_{q} = -t \sum_{k,l} \left(O_{k,l}^{R} e^{i\frac{2\pi q}{M}} |\Psi_{k}^{\text{rotors}}\rangle \langle \Psi_{l}^{\text{rotors}}| + \text{h.c.} \right) + \sum_{k} \epsilon_{k} |\Psi_{k}^{\text{rotors}}\rangle \langle \Psi_{k}^{\text{rotors}}|, \qquad (S4)$$

describing the *t*-dependent effective interactions among the rotors when the electron lies in a particular $|q\rangle$ state.

FIG. S1. Schematic illustration of the dipole-state-dependent correlated tunneling process described within the pseudo-Lang-Firsov transformation formalism. Blue empty (filled) circles label empty (occupied) electron sites. Red circles show the dipole positions modeled by planar rotors. The arrows and notation n_s , ℓ_s , show the employed basis type (see legend) and state for the particular rotor site, $s = \pm 1, \ldots, \pm M/2$. The tunneling of the electron from site j to j + 1 couples the states of the rotors within the dashed rectangle while for the remaining sites $\ell'_{s-1} = \ell_s$ holds.

The energy of the k-th many-rotor state is the sum of the energies of the constituent single-rotor states, namely

$$\epsilon_{k} = \frac{B}{4} \left[f_{n_{+1}^{k}} \left(\frac{2V_{0}}{B} \right) + f_{n_{-1}^{k}} \left(\frac{2V_{0}}{B} \right) \right] + B \sum_{j=2}^{M/2} \left[\left(\ell_{j}^{k} \right)^{2} + \left(\ell_{-j}^{k} \right)^{2} \right],$$
(S5)

with $f_n(q)$ given in terms of the Mathieu characteristic numbers, namely $f_n(q) = a_n(q)$ for even n and $f_n(q) = b_n(q)$ for odd n.

For $B \gg t$ and $V_0 \sim B$ it follows that $t \ll \epsilon_k - \epsilon_{k'}$, for any k, k', and the t-mediated interaction does not affect the state of the rotors to a large degree. Thus the different tunnelling channels $|\Psi_k^{\text{rotors}}\rangle$ do not interfere with one another and define different bands of the polaron with energies $\varepsilon_k(q) = \epsilon_k - 2t|O_{kk}^R|\cos(\frac{2\pi q}{M} + \arg(O_{k,k}^R)))$. For small $V_0 < B$, states with $n_{\pm 1}^k \neq n_{\pm 1}^{k'}$ but $\ell_j^k = \ell_j^{k'}$ for all $j = \pm 2, \pm 3, \ldots$ are coupled, implying local fluctuations of the rotor state in the vicinity of the electron, leading to interference of the above mentioned tunnelling channels. However, the number of such coupled states is independent of M, and the pseudo-Lang-Firsov approach can efficiently describe the polaron state.

In contrast, for $B \ll t$, which is the relevant case for applications in perovskites, $t \gg \epsilon_k - \epsilon_{k'}$ holds independently of V_0 at least in the cases where $n_{\pm 1}^k = n_{\pm 1}^{k'}$ and

$$\sum_{j=2}^{M} \left[(\ell_j^k)^2 - (\ell_j^{k'})^2 \right] + \sum_{j=2}^{M} \left[(\ell_{-j}^k)^2 - (\ell_{-j}^{k'})^2 \right] \ll \frac{t}{B}.$$
 (S6)

Therefore, in this case an extensive number of different $|\Psi_k^{\text{rotors}}\rangle$ states are strongly coupled by *t*-dependent effective interactions, provided that $V_0 \neq 0$ and thus $O_{kl}^R \neq \delta_{kl}$ hold. Consequently, the description of the system in this pseudo-Lang-Firsov basis becomes complicated. That is the main reason for the development of the vGH ansatz approach allowing for the construction of a Lang-Firsov-type basis that takes into account the effect of *t*-mediated interactions in a variational optimal manner.

PERTURBATIVE TREATMENT OF THE ROTOR-LATTICE HAMILTONIAN

In order to get an insight into the polaron state let us now consider the case where V_0 is much smaller than the rest of the system parameters and can thus be treated perturbatively. To this end, within this section we apply the Brillouin-Wigner (BW) perturbation theory [S6], which treatment as we will see below can be used to infer the results of other commonly used theoretical approaches in polaron physics.

Note that for $V_0 = 0$ the rotational and translational degrees of freedom decouple and as such we can define their eigenstates as $|\mathbf{m} = (m_1, m_2, ..., m_M)\rangle$ and

 $|k\rangle$, respectively. Here, k denotes the quasimomentum of the electron. The corresponding eigenenergies are $\epsilon_{\mathbf{m}}^{\mathrm{rot}} = B \sum_{i=1}^{M} m_i^2$ and $\epsilon_k^{\mathrm{tr}} = -2t \cos(k)$. The interaction Hamiltonian acting here as the perturbation, see also Eq. (1), reads

$$\hat{H}_{I} = -V_{0} \sum_{j=1}^{M} \hat{a}_{j}^{\dagger} \hat{a}_{j} \cos\left(\phi_{j} + \frac{\pi}{4}\right) -V_{0} \sum_{j=1}^{M} \hat{a}_{j}^{\dagger} \hat{a}_{j} \cos\left(\phi_{j-1} - \frac{\pi}{4}\right).$$
(S7)

Given that all interaction terms appearing in the rotor-electron interaction Hamiltonian are of the form $\hat{a}_n^{\dagger}\hat{a}_n e^{\pm i\phi_j}$ this implies that only the states $|k; \mathbf{m}\rangle$ and $|k; \mathbf{m} \pm \hat{\mathbf{e}}_j\rangle$, where $\hat{\mathbf{e}}_j$ is the unit vector of the *j*-th axis, are directly coupled by the interaction. Therefore, within the second-order BW perturbation theory the wavefunction expansion reads

$$\Psi(k,\mathbf{m})\rangle = \alpha_{k,\mathbf{m}}|k;\mathbf{m}\rangle + \sum_{\mathbf{k}'} \sum_{j=1}^{M} \left(\beta_{k,k',\mathbf{m},j}|k';\mathbf{m} + \hat{\mathbf{e}}_{j} \right) + \gamma_{k,k',\mathbf{m},j}|k';\mathbf{m} - \hat{\mathbf{e}}_{j} \rangle \right),$$
(S8)

where the wavefunction coefficients $a_{k,\mathbf{m}}$, $\beta_{k,k',\mathbf{m},j}$ and $\gamma_{k,k',\mathbf{m},j}$ are expressed in terms of the total energy of the system, E, as

$$\alpha_{k,\mathbf{m}} = \sqrt{Z},$$

$$\beta_{k,k',\mathbf{m},j} = -\sqrt{Z} \frac{\langle k'; \mathbf{m} + \hat{\mathbf{e}}_j | \hat{H}_I | k; \mathbf{m} \rangle}{\epsilon_{k'}^{\mathrm{tr}} + \epsilon_{\mathbf{m} + \hat{\mathbf{e}}_j}^{\mathrm{rot}} - E},$$
 (S9)

$$\gamma_{k,k',\mathbf{m},j} = -\sqrt{Z} \frac{\langle k'; \mathbf{m} - \hat{\mathbf{e}}_j | \hat{H}_I | k; \mathbf{m} \rangle}{\epsilon_{k'}^{\mathrm{tr}} + \epsilon_{\mathbf{m} - \hat{\mathbf{e}}_j}^{\mathrm{rot}} - E}.$$

Note that the wavefunction renormalization of the perturbative state is performed via the insertion of the of the polaron residue, Z. This factor is calculated by demanding that $\langle \Psi(k, \mathbf{m}) | \Psi(k, \mathbf{m}) \rangle = 1$. The above lead to the following equation for the polaron energy

$$E = \epsilon_k^{\rm tr} + \epsilon_{\rm m}^{\rm rot} - \Sigma_{k,{\rm m}}(E), \qquad (S10)$$

where $\Sigma_{k,\mathbf{m}}(E)$ denotes the so-called self energy of the system

$$\Sigma_{k,\mathbf{m}}(E) = \sum_{k'} \sum_{j=1}^{M} \left(\frac{|\langle k; \mathbf{m} | \hat{H}_{I} | k'; \mathbf{m} + \hat{\mathbf{e}}_{j} \rangle|^{2}}{\epsilon_{k'}^{\mathrm{tr}} + \epsilon_{\mathbf{m} + \hat{\mathbf{e}}_{j}}^{\mathrm{rot}} - E} + \frac{|\langle k; \mathbf{m} | \hat{H}_{I} | k'; \mathbf{m} - \hat{\mathbf{e}}_{j} \rangle|^{2}}{\epsilon_{k'}^{\mathrm{tr}} + \epsilon_{\mathbf{m} - \hat{\mathbf{e}}_{j}}^{\mathrm{rot}} - E} \right).$$
(S11)

Importantly, Eq. (S10) can also be derived by using Eq. (S8) as a variational ansatz and minimizing the energy functional $E = \langle \Psi(k, \mathbf{m}) | \hat{H} | \Psi(k, \mathbf{m}) \rangle$, under the constraint of normalized $|\Psi(k, \mathbf{m})\rangle$. This approach is commonly referred to as the Chevy ansatz approach [S7] and has applications in Fermi-polarons emerging in ultracold atomic Fermi gases [S8–S11]. Since Eq. (S10) is derived within BW perturbation theory, it features, in principle, multiple solutions corresponding to the analytic continuation of each of the participating $V_0 = 0$ eigenstates, $|k; \mathbf{m}\rangle$. In addition, since it can be derived within the Chevy ansatz, the lowest in energy solution of Eq. (S10) is an upper bound to the true ground state energy of the system, corresponding to the polaron. Within this framework we can identify several polaronic properties such as the above mentioned residue Z, the polaron energy $E_p = E - \epsilon_k^{\text{tr}} = -\Sigma_{k,0}(E_p + \epsilon_k^{\text{tr}})$ and the polaronic effective mass $m^* = (\frac{\partial^2 E}{\partial k^2})^{-1}$.

To proceed note that the matrix elements of \hat{H}_I read

$$\langle k'; \mathbf{m} + \hat{\mathbf{e}}_j | H_I | k; \mathbf{m} \rangle = - \frac{V_0 e^{i(k-k')\left(j-\frac{1}{2}\right)}}{M} \cos\left(\frac{k-k'}{2} + \frac{\pi}{4}\right) \langle k'; \mathbf{m} - \hat{\mathbf{e}}_j | \hat{H}_I | k; \mathbf{m} \rangle = - \frac{V_0 e^{i(k-k')\left(j-\frac{1}{2}\right)}}{M} \cos\left(\frac{k-k'}{2} - \frac{\pi}{4}\right),$$
(S12)

and consequently, the self energy for $\mathbf{m} = \mathbf{0}$ reads

$$\Sigma_{k,\mathbf{0}}(E) = \frac{V_0^2}{M} \sum_{k'} \frac{1}{B - E - 2t \cos k'}$$
$$= \begin{cases} -\frac{V_0^2}{\sqrt{(B - E)^2 - 4t^2}} & \text{for } E > B + 2t, \\ \frac{V_0^2}{\sqrt{(B - E)^2 - 4t^2}} & \text{for } E < B - 2t. \end{cases}$$
(S13)

In the intermediate range B - 2t < E < B + 2t the selfenergy becomes imaginary, indicating that no polaron exists in this regime. This stems from the extrapolation to the thermodynamic limit by substituting $\sum_k \rightarrow \frac{M}{2\pi} \int dk$. In this limit, the bands corresponding to the rotor excitations become a continuum of states in the energy interval B-2t < E < B+2t. Thus any discrete state that couples to this continuum of excitations becomes exponentially damped in time explaining its imaginary self-energy.

Having an exact expression for $\Sigma_{k,\mathbf{m}}(E)$ we can identify the minimum of the polaron band. To find the minimum of the energy we differentiate E with respect to kfor E < B - 2t, yielding

$$\left(1 + \frac{\partial \Sigma_{k,\mathbf{0}}}{\partial E}\right) \frac{\mathrm{d}E}{\mathrm{d}k} = \frac{\mathrm{d}\epsilon_k^{\mathrm{tr}}}{\mathrm{d}k} - \frac{\partial \Sigma_{k,\mathbf{0}}}{\partial k}.$$
 (S14)

Therefore, k = 0 is an extremal point since $\partial \Sigma_{k,0} / \partial k = 0$, $d\epsilon_k^{\text{tr}} / dk = 0$ and $\partial \Sigma_{k,0} / \partial E > 0$. Using the above and by differentiating once more with k we find

$$\left(1 + \frac{\partial \Sigma_{k,\mathbf{0}}}{\partial E}\right) \frac{\mathrm{d}^2 E}{\mathrm{d}k^2} = \frac{\mathrm{d}^2 \epsilon_k^{\mathrm{tr}}}{\mathrm{d}k^2}.$$
 (S15)

FIG. S2. (a, b) Comparison of the polaron energy, E_0 , obtained by the vGH approach and Brillouin-Wigner and Reileigh-Schrödinger perturbation theory for different values of B as a function of V_0 . The vGH results correspond to M = 1024, while perturbation theory refers to $M \to \infty$.

Thus, we conclude that k = 0 is the minimum of the polaron band for all values of B, V_0 and t > 0.

The above allows us to evaluate the polaron characteristics by focussing on k = 0. First, the polaron energy is the lowest in energy solution of the algebraic equation

$$E_p = -\frac{V_0^2}{\sqrt{(B+2t-E_p)^2 - 4t^2}}.$$
 (S16)

Which up to fourth order in V_0 yields

$$E_p = -\frac{V_0^2}{\sqrt{B(B+4t)}} + \frac{B+2t}{B^2(B+4t)^2}V_0^4 + \mathcal{O}(V_0^6).$$
(S17)

By substituting $E = \epsilon_k^{\rm tr}$ in the right hand size of Eq. (S10) it can be shown that the above expansion up to order $\propto V_0^2$ agrees with the second-order Reileigh-Schrödinger perturbation theory. For this reason we employ $E_p = -V_0^2/\sqrt{B(B+4t)}$ as a proxy of the perturbative result in the main text. Note that here by employing Eq. (S16) it can be proven that within the Chevy ansatz $E_p + V_0^2/\sqrt{B(B+4t)} > 0$ holds for all values of the parameters B, V_0 and t. In addition, explicit numerical solutions of Eq. (S16), see Fig. S2, show that the vGH value of E_p is always significantly smaller than the Chevy ansatz result demonstrating that the vGH approach is a significant improvement to the Chevy ansatz.

Nevertheless, Eq. (S17) indicates that the characteristic interaction scale obtained via BW perturbation theory is $V_0/\sqrt{B(B+4t)}$. Indeed, it can be seen that the vGH results presented in the main text begin to deviate when this dimensionless scale becomes of order ~ 1. Finally, let us derive the value of the effective mass within the above-mentioned perturbation theories. Within BW perturbation theory/Chevy ansatz the effective mass is a function of the polaron energy, E_p

$$\frac{m_p^*}{m^*} = 1 - \frac{B + 2t - E_p}{V_0^4} E_p^3.$$
 (S18)

And thus a substitution of Eq. (S17) to Eq. (S18) yields up to fourth order in V_0

$$\frac{m_p^*}{m_p} = 1 + \frac{B + 2t}{[B(B+4t)]^{3/2}} V_0^2
- \frac{2(B^2 + 4Bt + 6t^2)}{B^3(B+4t)^3} V_0^4 + \mathcal{O}(V_0^6).$$
(S19)

The same evaluation within the Reileigh-Schrödinger perturbation theory results to

$$\frac{m_p^*}{m_p} = 1 + \frac{2t}{[B(B+4t)]^{3/2}} V_0^2 + \mathcal{O}(V_0^4).$$
 (S20)

Therefore, the results for the effective mass agree up to quadratic order for $B \ll t$. In the main text, though, we employ $m_p^*/m_p = 1 + (B+2t)V_0^2/[B(B+4t)]^{3/2}$ as the perturbative result we compare with with vGH since it provides improved agreement even in the case of B = t.

DETAILS ON THE VGH APPROACH

The vGH equations of motion

To variationally evaluate the polaron ground-state and to get insight into the linear-response dynamics of the rotor lattice model described by Eq. (1)we resort to the Dirac-Frenkel variational formalism, $E[\varphi_1(\phi;\tau),\ldots,\varphi_M(\phi;\tau)] = \langle \Psi(\tau)|\hat{H} - \frac{\partial}{\partial\tau}|\Psi(\tau)\rangle$ [S12, S13]. The Dirac-Frenkel variational principle is a timedependent variational technique, widely employed in quantum chemistry (see e.g. [S14]), that allows the dynamical explorations of complex systems in a variationally optimal manner in addition to their ground state properties. Note that we have chosen the Dirac-Frenkel variational principle solely based on the fact that our analysis becomes more transparent. Indeed, it can be shown that our variationally obtained equations of motion can be obtained by the Langrangian [S15, S16] or McLachlan [S17] variational principles. This is a consequence of the fact that the Gross-Hartree ansatz of Eq. (2) is a linear combination of Hartree products and therefore it defines an analytic function, namely a linear combination of exponentials, due to the Thouless theorem [S18, S19].

The energy functional stemming from the Gross-

Hartree ansatz reads

$$\begin{split} E[\varphi_{1}(\phi;\tau),\ldots,\varphi_{M}(\phi;\tau)] &= \\ -t \left(e^{i\frac{2\pi q}{M}} \prod_{j=1}^{M} \int \mathrm{d}\phi \; \varphi_{j+1}^{*}(\phi;\tau)\varphi_{j}(\phi;\tau) \right. \\ &+ e^{-i\frac{2\pi q}{M}} \prod_{j=1}^{M} \int \mathrm{d}\phi \; \varphi_{j}^{*}(\phi;\tau)\varphi_{j+1}(\phi;\tau) \right) \\ &- B \sum_{j=1}^{M} \int \mathrm{d}\phi \; \varphi_{j}^{*}(\phi;\tau) \frac{\partial^{2}}{\partial \phi^{2}} \varphi_{j}(\phi;\tau) \\ &- i\hbar \sum_{j=1}^{M} \int \mathrm{d}\phi \; \varphi_{j}^{*}(\phi;\tau) \frac{\partial}{\partial \tau} \varphi_{j}(\phi;\tau) \\ &+ V_{0} \left[\int \mathrm{d}\phi \; \cos\left(\phi + \frac{\pi}{4}\right) |\varphi_{1}(\phi;\tau)|^{2} \right. \\ &+ \int \mathrm{d}\phi \; \cos\left(\phi - \frac{\pi}{4}\right) |\varphi_{M}(\phi;\tau)|^{2} \right] \\ &+ \sum_{j=1}^{M} \lambda_{j}(\tau) \left(1 - \int \mathrm{d}\phi \; |\varphi_{j}(\phi;\tau)|^{2} \right), \end{split}$$

with λ_j referring to the Lagrange multipliers ensuring the normalization of $\varphi_j(\phi; \tau)$.

The equations of motion are obtained via varying $E[\varphi_1(\phi;\tau),\ldots,\varphi_M(\phi;\tau)]$ with respect to $\varphi_j^*(\phi;\tau)$ and read

$$i\hbar \frac{\partial}{\partial \tau} \varphi_j(\phi;\tau) = (\hat{H}_j - \lambda_j(\tau))\varphi_j(\phi;\tau) - te^{i\frac{2\pi q}{M}} \mathcal{T}_{jL}(\tau)\varphi_{j-1}(\phi;\tau) - te^{-i\frac{2\pi q}{M}} \mathcal{T}_{jR}(\tau)\varphi_{j+1}(\phi;\tau),$$
(S22)

where $\hat{H}_j = -B\frac{\partial^2}{\partial\phi^2} + \delta_{j1}V_0\cos\left(\phi + \frac{\pi}{4}\right) + \delta_{jM}V_0\cos\left(\phi - \frac{\pi}{4}\right)$ and the non-linearity of the above-equations stems from the mean-field tunneling couplings $\mathcal{T}_{jL}(\tau) = \prod_{k\neq j} \int \mathrm{d}\phi \ \varphi_k^*(\phi;\tau)\varphi_{k-1}(\phi;\tau),$ $\mathcal{T}_{jR}(\tau) = \prod_{k\neq j} \int \mathrm{d}\phi \ \varphi_k^*(\phi;\tau)\varphi_{k+1}(\phi;\tau)$ which are analogous to the $O_{k,l}^R$ appearing in the Lang-Firsov formalism, see Eq. (S3). Finally, in order to calculate the Langrange coefficients we demand that the $\varphi_j(\phi;t)$ functions remain normalized and employ the fact that the Hamiltonian is Hermitian to obtain

$$\lambda_j(\tau) = \int \mathrm{d}\phi \; \varphi_j^*(\phi;\tau) \hat{H}_j \varphi_j(\phi;\tau) - t \left(e^{i\frac{2\pi q}{M}} \mathcal{T}_L(\tau) + e^{-i\frac{2\pi q}{M}} \mathcal{T}_R(\tau) \right),$$
(S23)

where $\mathcal{T}_L(\tau) = \prod_{k=1}^M \int d\phi \ \varphi_k^*(\phi;\tau)\varphi_{k-1}(\phi;\tau)$ and $\mathcal{T}_R(\tau) = \prod_{k=1}^M \int d\phi \ \varphi_k^*(\phi;\tau)\varphi_{k+1}(\phi;\tau)$. The above expression implies that $\lambda_j(t)$ is always real, and thus even if the $\lambda_j(\tau)\varphi_j(\phi;\tau)$ term of Eq. (S22) is neglected, the magnitude of the single rotors states is conserved, since

$$\frac{\mathrm{d}}{\mathrm{d}\tau} \left[\int \mathrm{d}\phi \, |\varphi_j(\phi;\tau)|^2 \right] = \frac{2}{\hbar} \mathcal{I}(\lambda_j(\tau)) = 0.$$
 (S24)

Therefore the Lagrange multipliers are not *per se* needed for dynamical investigations, e.g. to study polaron dynamics.

However, herewith we are mainly interested in the ground state properties of the system, which can be calculated by imaginary time propagation. Within this approach we perform the transformation $\tau \rightarrow -i\tau$ in Eq. (S22) resulting in a diffusion equation. This equation has an important property that the energy of the propagated state monotonically decreases in time according to $\sim e^{-(E(\tau)-E_0)\tau}$, where E_0 is the true ground state energy, and therefore the ground state is obtained in the limit of $\tau \rightarrow \infty$. In our implementation we perform finite imaginary time propagation up to the point that the right-hand side of Eq. (S22) is smaller than a tolerance of $10^{-12}B$, thus ensuring that the final state is stationary with a confidence comparable to the machine error.

Comparison with exact diagonalization for small systems

As discussed in the main text, the vGH ansatz of Eq. (2), neglects dipole-dipole correlations stemming from the effective rotor-rotor interactions due to electron tunnelling. We expect that these corrections are small and such they do not significantly affect the behavior of the system. Accounting for such correlations is a non-trivial task, as they involve multiple configurations of rotor states. In the absence of approximations, i.e. within exact diagonalization (ED), there are \mathcal{M}^M such different configurations, where \mathcal{M} is the number of singlerotor states considered. To ensure the convergence of the ED, \mathcal{M} should be large enough so that the observables of interest become independent of its increase. This implies an exponential increase of the numerical complexity with the system size, and consequently the ED treatment is computationally prohibitive for large M. Therefore, to obtain a numerical estimate of the error in the vGH results due to neglecting these correlations, we have to rely on small systems where ED is feasible.

In particular, for our ED calculations we used $\mathcal{M} = 21$ resulting in 194481 and 85776121 rotor configurations for M = 4 and M = 6 respectively. The individual singlerotor states correspond to the eigenstates of the \hat{L}_z operator, with eigenvalues $|\ell_z| < (\mathcal{M} - 1)/2$. This choice of the many-rotor basis is sufficient for the ED energies to converge at the 10^{-5} level.

The percentile deviation of the vGH and ED ground state energies, $(E_{\rm vGH} - E_{\rm ED})/|E_{\rm ED}|$ is shown in Fig. S3. Here it is verified that the energy contribution of the rotor-rotor correlations is indeed small, lying in the few % range. In particular, we observe that the deviation is the largest in the interaction regime where the ferroelectric domain-wall forms, $V_0 > 2t$. In this regime $(E_{\rm vGH} - E_{\rm ED})/|E_{\rm ED}|$ additionally exhibits an increas-

FIG. S3. Percentage deviation of the ground state energy within the ED and vGH approaches, $(E_{vGH} - E_{ED})/|E_{ED}|$, as a function of V_0 for (a) M = 4 and (b) M = 6 for different B/t (see legend).

FIG. S4. Rotor-electron correlation functions, $C_j(\phi)$, with $j = 1, \ldots, M$ (see row labels) as a function of V_0 within the exact diagonalization (left column) and vGH (right column) approaches. In both cases a small system with M = 4 and $B = 10^{-3}t$ is considered.

ing tendency with decreasing B. In contrast, the rotorrotor correlations seem to become less significant as Bdecreases for interactions supporting the polarized state, $V_0 < 2t$. Our results further suggest that the correlation corrections become less pronounced for increasing M, compare Fig. S3(a) and Fig. S3(b), provided that $B < 10^{-2}$.

To demonstrate that our results are robust to the inclusion of rotor-rotor correlations Fig. S4 compares $C_j(\phi)$ within ED and vGH. The behavior of $C_j(\phi)$ for the different approaches is nearly identical qualitatively, but there are a few notable quantitative differences. In particular, while both approaches capture the crossover from the almost perfectly ferroelectrically polarized to the domainwall state, the threshold shifts to a lower V_0 value within ED. In addition, within the $V_0 > 2t$ where the domainwall forms, vGH shows significantly larger values of $C_2(\phi)$ and $C_3(\phi)$ than ED for $\phi = \pi/4$ and $\phi = -\pi/4$ respectively. The above indicates that the overlap of adjacent rotors decreases when accounting for rotor-rotor correlations, which can be associated with a reduction of the mean-field tunneling integrals \mathcal{T}_{jL} and \mathcal{T}_{jR} . Therefore, rotor-rotor correlations might induce further increase of the polaron effective mass when the domain wall forms.

In conclusion, rotor-rotor interactions do not substantially alter the polaron state, however, properly accounting for them might be beneficial for obtaining highaccuracy predictions for the polaronic properties.
