January 10, 2023

Abstract

Linearizability has been the long standing gold standard for consistency in concurrent data structures. However, proofs of linearizability can be long and intricate, hard to produce, and extremely time consuming even to verify. In this work, we address this issue by introducing simple *universal*, *sound*, and *complete* proof methods for producing machine-verifiable proofs of linearizability and its close cousin, strong linearizability. Universality means that our method works for any object type; soundness means that an algorithm can be proved correct by our method only if it is linearizable (resp. strong linearizable); and completeness means that any linearizable (resp. strong linearizable) implementation can be proved so using our method. We demonstrate the simplicity and power of our method by producing proofs of linearizability for the Herlihy-Wing queue and Jayanti's single-scanner snapshot, as well as a proof of strong linearizability of the Jayanti-Tarjan union-find object. All three of these proofs are machine-verified by TLAPS (the Temporal Logic of Actions Proof System).

1 Introduction

Data structures that organize, store, and quickly recall important pieces of information are the fundamental building blocks behind fast algorithms. Thus, efficient and rigorously proved data structures are fundamental to reliable algorithm design. The task of designing such data structures for shared-memory multiprocessors, however, is notoriously difficult. Due to asynchrony, a *t* step algorithm for even just two processes has 2^t , i.e. exponentially many, possible executions depending on how the steps of the processes interleave. In fact, even deterministic concurrent algorithms have uncountably many possible infinite executions, as opposed to the single possible execution of a deterministic sequential algorithm. Designing algorithms that are correct in all of these executions is a grueling task, and thus, even mission-critical concurrent code often suffers from elusive races. For example, a subtle priority inversion bug in its concurrent code crashed the Pathfinder Rover days after its deployment on Mars and jeopardized the entire multimillion dollar NASA space mission [27]. Examples of errors in published concurrent data structures are also not left wanting [8, 11].

1.1 Understanding the Problem

Rigorously proving the correctness of a data structure implementation \mathcal{O} consists of two steps:

- 1. A prover, often the algorithm designer, deeply studies the implementation \mathcal{O} and produces a proposed proof P.
- 2. A *verifier* evaluates the proposed proof P by confirming that each claim made in the proof is mathematically justified, and that the resultant chain of reasoning constitutes a legitimate proof of O's correctness.

^{*}This paper contains material presented in Siddhartha Jayanti's Ph.D. thesis [24], Ugur Yavuz's bachelor's and master's theses [35, 36], and Lizzie Hernandez's bachelor's thesis [19].

In general, proving any type of correctness of any algorithm can be inherently intellectually difficult and time consuming, since it requires the prover to contemplate the algorithm deeply, understand why it is correct, and express this understanding in the methodical language of mathematics. Verifying many types of proofs can be rather easier, since it is in its essence a mechanical check.

In this work, we focus on concurrent data structures for asynchronous shared-memory multiprocessors. In particular, *linearizability* [18], which states that data structure operations must appear to take place atomically even in the face of tremendous concurrency, has been the longstanding gold standard for concurrent data structure correctness. Its close cousin *strong linearizability* [16], which ensures that even the hyper-properties of the data structure match those of an atomic object has also garnered a lot of recent interest [5].

When the correctness condition being proved is linearizability, we observe, in practice, that even the verification step can be taxing and time-consuming. Firstly, the proposed proof P can often run for several tens of pages of a dense research paper. For example, the original paper on linearizability [18] contains a short seven line implementation of a queue. To prove its linearizability, the authors propose an eighteen line invariant. The proof of correctness of this invariant and its entailment of the queue's linearizability are presented in a 14 page technical report. Those familiar with this queue implementation know that it, like many linearizable algorithms, is inherently "very tricky" to prove correct, and thus it is commendable that the authors, Herlihy and Wing, were able to design this algorithm and give a proof of it. Nevertheless, the subtlety and sheer length of the proof P, makes the job of a conscientious verifier quite hard.

Depending on the complexity of an algorithm and its proof, the mere process of verifying the mathematical validity of the linearizability proof can take hours, days, or even weeks. In some cases, due to the difficulty inherent to writing such long and intricate proofs, provers resort to making high-level "hand-wavy" arguments, or omit proofs altogether. This makes the verifier's job more difficult to impossible. In other cases, the verifier may be a conference reviewer who does not have the time to verify a long proof and thus must skim the details of the proof which may contain errors; or the end-user of the algorithm may not be a verifier, but an engineer who may not have the time or the mathematical preparation to independently verify the algorithm's correctness before using it in a deployed system.

For all of these reasons, it is not shocking that mistakes in concurrent algorithms are so prevalent, even in mission critical deployed code. To avoid such critical errors, we propose designing concurrent data structures whose correctness is *machine-verified* to limit the scope for human error.

1.2 Our Work

Informally, an object \mathcal{O} is linearizable, if *for all* finite runs R of any algorithm \mathcal{A} that uses \mathcal{O} , and every operation op that is performed on \mathcal{O} in the run R, *there exists* a point in time between op's invocation and return where it "appears to take place instantaneously". This definition, in particular the non-constructive existential quantifier "*there exists*" inside the universal quantification, makes it difficult to prove linearizability. This difficulty is only exacerbated if the proof must be simple enough for a machine to verify. In fact, if approached naïvely, the prover would need to map each run of the algorithm to a linearization, i.e., a description of where in its invocation-response time interval each operation "appears to take place instantaneously", and then prove that each such mapping is legitimate. This is a difficult task, given that it is known that proving even a single fixed run R linearizable is NP-hard [15].

Our goal however, is to devise a method for proving linearizability that not only works for a single implementation, or even a single type, but to devise a method that is *universal* and *complete*. By universal, we mean that our method should be powerful enough to allow for a proof of linearizability for implementations of *any* object type. By complete, we mean that *any linearizable implementation*, regardless of how complex its expression or linearization structure, must be provable by our method. Of course, our method will also be *sound*, meaning that any argument that is given using our method is indeed a correct mathematical proof of linearizability. Finally, we ensure that our method enables machine verifiable proofs by currently available proof assistants, which are generally built to verify proofs of simple program invariants.

1.2.1 Our Contributions

1. We develop a rigorous *universal*, *sound*, and *complete* method for proving linearizability. In particular, we define a universal transformation that takes an arbitrary implementation \mathcal{O} of an arbitrary type τ , and outputs an algorithm \mathcal{A}^* , called the *tracker*, and a simple invariant \mathcal{I}^* , and prove a theorem that:

 \mathcal{O} is a linearizable implementation of type τ if and only if \mathcal{I}^* is an invariant of \mathcal{A}^* .

(Thus, we can produce a machine-certified proof that \mathcal{I}^* is an invariant of \mathcal{A}^* to establish that \mathcal{O} is linearizable.)

2. In fact, we give a family of transformations that each output different algorithms \mathcal{A}' , called *partial trackers*, with associated invariants \mathcal{I}' , and prove that:

 \mathcal{O} is a linearizable *iff* some partial tracker \mathcal{A}' has its associated \mathcal{I}' as an invariant.

3. We develop a rigorous *universal*, *sound*, and *complete* method for proving strong linearizability. In particular, we show that for each partial tracker A', there is an alternate associated invariant \mathcal{I}'' , and we prove that:

 \mathcal{O} is strongly linearizable *iff* some partial tracker \mathcal{A}' has its associated \mathcal{I}'' as an invariant.

4. Finally, we demonstrate the power of our methods by producing machine-certified proofs of linearizability and strong linearizability for some notable data structures. In particular, we prove the linearizability of two famous data structures: (1) the aforementioned Herlihy-Wing queue [18], which is notorious for being hard to prove correct [30]; and (2) Jayanti's single-writer, single-scanner snapshot algorithm, in which processes play asymmetric roles [22]. We also prove the strong linearizability of the Jayanti-Tarjan union-find object [25, 23, 26], which is known to be the fastest algorithm for computing connected components on CPUs and GPUs [10, 20]. All our proofs have been certified by the proof assistant TLAPS (temporal logic of actions proof system) [29], and are publicly available on GitHub¹.

2 Related Work

Herlihy and Wing's landmark paper that introduced linearizability also seeded the discussion on proof techniques for linearizability [18]. In particular, their paper introduced the concept of *possibilities*, i.e. the notion that we can imagine several different orders in which partially completed operations could return in the future, and consider linearizations that are consistent with such possibilities. They expanded on this framework in a related publication [17]. Their initial ideas in these papers saw fruition in their proof of linearizability of the tricky Herlihy-Wing queue implementation.

Most work on machine-assisted reasoning about linearizability can be classified into three groups: model checking, proofs of particular objects, and more general techniques. Several works model check algorithms [7, 28, 34]. Model checking *does not* prove correctness; rather, it mechanically simulates small runs of the algorithm and returns a counter-example if it finds one. Some works machine-verify the linearizability of *specific implementations*, such as: Scott's lock-free queue [12], a concurrent open addressing hash table [14], and a list-based set algorithm [9]. Various other algorithms have also been proved linearizable using shape analyses that examine the pointer structures within an object [31, 6, 3]. Most general purpose techniques for proving linearizability, such as [32, 33], are sound but not complete or universal, i.e., they are targeted at showing the linearizability of a limited class of algorithms, rather than any linearizable implementation of any type.

To our knowledge, the only previous sound and complete technique is by Schellhorn et al. [30]. This technique mechanizes Herlihy and Wing's original possibilities proof strategy through the technology of observational refinement mappings and backward simulations. The authors give a single example demonstration of their technique—a mechanized proof of the Herlihy-Wing queue verified by the proof assistant KIV. In contrast to Schellhorn et al.'s technique, our method for proving linearizability only requires familiarity with the notion of an invariant.

Dongol and Derrick wrote an extensive survey on machine assisted proofs of (standard) linearizability [13]. To the best of our knowledge, we are the first to introduce machine-verifiable proof methods for strong linearizability.

3 Model and Definitions

A concurrent system consists of a set of asynchronous processes, Π , that communicate through operations on a set of shared objects, Ω . Each process has a distinct name and a set of private registers, including a program counter. Each object has a distinct name and a *type*, which specifies the operation's supported by the object and how these operations behave, i.e. how each operation changes the object's state and what response it returns. An algorithm specifies a program for each process, and an initial state for each object. An algorithm's execution proceeds in steps. In a step, any one process atomically executes the line pointed to by its program counter. It is common for algorithms to restrict each line in a program to apply at most one operation on a shared object; however, to ensure that our results apply

¹The proofs are available at: https://github.com/uguryavuz/machine-certified-linearizability

to a wider class of algorithms, we do not impose such a restriction. In an *asynchronous* execution of the algorithm, a (possibly) *adversarial scheduler* decides which process $\pi \in \Pi$ will execute the next step in its algorithm at each discrete time step. We formalize and expound these notions below.

Definition 3.1 (object type). An *object type* τ consists of the following *components*:

- a set of *states* Σ that the object can be in.
- a set of *operations OP* that can be invoked on the object.
- for each $op \in OP$, a set of *arguments* ARG_{op} that the operation op can be called with.
- a set of responses RES, a.k.a. return values.
- a *transition function* $\delta(\sigma, \pi, op, arg)$ that outputs the new state σ' and the return value *res* that result when the operation op with argument arg is performed by process π while the object is in state σ . Formally, the transition function is

 $\delta: \Sigma \times \Pi \times \{(op, arg) \mid op \in OP, arg \in ARG_{op}\} \to \Sigma \times RES$

Remark 3.2. Operations that require "no argument" (i.e., *read*) are modeled as taking an argument from a singleton set (i.e., $ARG_{read} = \{\bot\}$). Similarly, operations that return "no result" (i.e., *write*) are modeled as returning the result *ack*.

As an example of an object type, we present the formal description of a queue as Object Type 3.3.

Object Type 3.3 (Queue). A queue of elements from \mathbb{N}^+ is described as follows:

- $\Sigma = \bigcup_{n \in \mathbb{N}} (\mathbb{N}^+)^n$
- $OP = \{ENQUEUE, DEQUEUE\}$
- $ARG_{ENQUEUE} = \mathbb{N}^+, ARG_{DEQUEUE} = \{\bot\}.$
- $RES = \{ack\} \cup \mathbb{N}^+$
- Transition function δ is defined as follows:

-
$$\delta(\sigma, \pi, \text{ENQUEUE}, v) = (\sigma \circ v, ack)$$

- $\delta(\sigma, \pi, \text{DEQUEUE}, \bot) = (tail(\sigma), head(\sigma))$ where $\sigma \neq ()$, the empty sequence.

Definition 3.4 (algorithm). A (*concurrent*) algorithm is a tuple (Π, Ω, C_0) , where:

- Π is a set of processes, where each process π ∈ Π has a program and private registers, including a program counter pc_π which points to the line to be executed in the program. A process's state at any point in time is described by the values of its private registers.
- Ω is a set of objects; each object has a type, and is in one of its states at any point in time.
- C₀ is a non-empty set of configurations, called *initial configurations*, where a *configuration* is an assignment of a state to each object ω ∈ Ω and an assignment of values to the private registers of each process π ∈ Π.

Definition 3.5 (step, event, run).

- A step of an algorithm is a triple (C, (π, ℓ), C') such that C is a configuration, π is a process, ℓ is the line of code pointed to by π's program counter in C, and C' is a configuration that results when π executes line ℓ from C.
- The *event* corresponding to a step $(C, (\pi, \ell), C')$ is (π, ℓ) , i.e., process π executing line ℓ .
- A run of an algorithm is a finite sequence $C_0, (\pi_1, \ell_1), C_1, (\pi_2, \ell_2), C_2, \ldots, (\pi_k, \ell_k), C_k$ or an infinite sequence $C_0, (\pi_1, \ell_1), C_1, (\pi_2, \ell_2), C_2, \ldots$ such that C_0 is an initial configuration and each triple $(C_{i-1}, (\pi_i, \ell_i), C_i)$ is a step.

3.1 Implementation of an Object

Implementing complex objects, such as queues and snapshots, from primitive objects supported by the underlying hardware (registers supporting read, write, CAS etc.) is a central problem in multiprocessor programming. Below, we describe what an implementation entails. Later on, we will define what it means for an implementation to be *correct*, in the sense of linearizability.

Definition 3.6 (implementation). An *implementation* \mathcal{O} *of an object of type* τ *initialized to state* σ_0 for a set of processes Π specifies

- A set of objects Ω called the *base objects* along with their types and initial states.
- A set of procedures O.op_π(arg) for each π ∈ Π, op ∈ τ.OP, and arg ∈ τ.ARG_{op}. The objects accessed in the code of the procedures must all be in Ω.

To execute an operation op with argument arg on the implemented object \mathcal{O} , a process π invokes the method $O.op_{\pi}(arg)$ (and executes the code in the procedure). The value returned by the method is deemed \mathcal{O} 's response to this operation invocation.

Notice that this definition only captures the syntactic aspect of an implementation. We will now build up to defining the correctness of an implementation.

Intuitively, the implemented object is correct if it behaves like an atomic object of the same type. To formally capture correctness, we define *behavior*, the notion of an *atomic implementation*, and the correctness condition of *linearizability*.

3.2 Behaviors of an Implementation

Consider an object implementation \mathcal{O} , and a run R in which processes invoke operations on \mathcal{O} , execute the corresponding procedures of \mathcal{O} , and receive responses. By the definition of a run, R is an alternating sequence of configurations and events. Some of the events are *invocation events*, i.e. calls to \mathcal{O} 's procedures, and some are *response events*, i.e. the execution of return statements of \mathcal{O} 's procedures. (Of course, there are other events, such as the execution of other lines between the call and return of a procedure.) We call the subsequence of R that includes only the invocation and response events the *behavior* in R. For example, if \mathcal{O} is an initially empty queue, a behavior can be

 $(\pi_1, \textbf{invoke} \ \mathsf{Enqueue}_{\pi_1}(5)), (\pi_2, \textbf{invoke} \ \mathsf{Dequeue}_{\pi_2}()), (\pi_3, \textbf{invoke} \ \mathsf{Enqueue}_{\pi_3}(7)), (\pi_2, \textbf{response} \ 7), (\pi_2, \textbf{invoke} \ \mathsf{Enqueue}_{\pi_2}(9))$

Every possible behavior of an implementation O can be generated by the algorithm of Figure 1, where each process repeatedly chooses an operation non-deterministically, invokes it by calling the corresponding procedure, and executes the procedure until it returns (receives a response). The next definition captures this discussion.

Initial Configurations:

- ω is an object of type τ , in its initial state σ_0 .
- Each process $\pi \in \Pi$ is assigned the program $main_{\pi}()$; i.e. pc_{π} is initialized to line a.
- Every other private register of each $\pi \in \Pi$ is initialized arbitrarily.

program $main_{\pi}()$

a: while true do choose $(op, arg) \in \{(o, a) \mid o \in \tau. OP, a \in \tau. ARG_o\}$ and invoke $\mathcal{O}.op_{\pi}(arg)$

Figure 1: Generator algorithm $\mathcal{A}(\mathcal{O})$ that generates all behaviors of an implemented object \mathcal{O} of type τ . Code shown for process $\pi \in \Pi$.

Definition 3.7 (implementation runs and behaviors). Let \mathcal{O} be an implementation of a type τ initialized to σ_0 for a set Π of processes. We define the *runs* of \mathcal{O} to be the set of all runs of the *generator algorithm*, $\mathcal{A}(\mathcal{O})$, presented in Figure 1. Let \mathcal{R} be the set of all runs of \mathcal{O} . For any run $R \in \mathcal{R}$, we define *behavior*(R) to be the subsequence of all the invocation and response events in R. The set of all *behaviors* of \mathcal{O} is {*behavior*(R) | $R \in \mathcal{R}$ }.

3.3 The Atomic Implementation

Implementing an object from base objects of other types is often challenging, but implementing an object O from a base object ω of the same type is trivial: each procedure $O.op_{\pi}(arg)$ is implemented simply by executing $\omega.op_{\pi}(arg)$ and returning the received response. We call this implementation the *atomic implementation*.

Definition 3.8 (atomic implementation). The *atomic implementation* of an object \mathcal{O} of type τ , initialized to σ_0 , is the implementation presented in Figure 2. (On line 2, the implementation resets r_{π} to \perp as soon as it returns the value.)

```
Base Object: \omega is an object of type \tau, initialized to state \sigma_0.

procedure \mathcal{O}.op_{\pi}(arg \in \tau.ARG_{op}) \triangleright for each op \in \tau.OP

1: r_{\pi} \leftarrow \omega.op_{\pi}(arg)

2: return r_{\pi}

r_{\pi} \leftarrow \bot

Figure 2: Atomic implementation of \mathcal{O} of an object of type \tau initialized to state \sigma_0 \in \tau.\Sigma.
```

3.4 Linearizability

We are now ready to define *linearizability*. Intuitively, an object implementation is linearizable if it behaves like an atomic object of the same type. Formally:

Definition 3.9 (linearizability). For a set Π of processes, let \mathcal{O} be an implementation of an object of type τ initialized to σ_0 , and let \mathcal{O}_{atomic} be the atomic implementation of an object of type τ initialized to σ_0 . Furthermore, let \mathcal{R} be the set of all runs of $\mathcal{A}(\mathcal{O})$ and \mathcal{R}_{atomic} be the set of all runs of $\mathcal{A}(\mathcal{O}_{atomic})$. We say a run $R_{atomic} \in \mathcal{R}_{atomic}$ is a *linearization* of a run $R \in \mathcal{R}$ if *behavior*(R) = *behavior*(R_{atomic}). Correspondingly, we say that a run $R \in \mathcal{R}$ is *linearizable* if it has a linearizable if every finite run $R \in \mathcal{R}$ is linearizable. Equivalently, \mathcal{O} is linearizable if every finite behavior of \mathcal{O}_{atomic} .

3.5 Strong Linearizability

In general, a run R of a linearizable implementation can have multiple linearizations. Intuitively, a linearizable object implementation satisfies *strong linearizability* if for any run of the implementation R the object can "commit to a specific linearization" $\mathcal{L}(R)$, such that the linearization of any extension of the run R is an extension of $\mathcal{L}(R)$.

Definition 3.10. For a set Π of processes, let \mathcal{O} be an implementation of an object of type τ initialized to σ_0 , and let \mathcal{O}_{atomic} be the atomic implementation of an object of type τ initialized to σ_0 . Furthermore, let \mathcal{R} be the set of all runs of $\mathcal{A}(\mathcal{O})$ and \mathcal{R}_{atomic} be the set of all runs of $\mathcal{A}(\mathcal{O}_{atomic})$. An implementation is *strongly linearizable*, if there is a *linearization function* $\mathcal{L} : \mathcal{R} \to \mathcal{R}_{atomic}$ that maps each run R of the implementation to an atomic run $\mathcal{L}(R)$ of the atomic implementation that is a linearization of it, such that if R_{pre} is a prefix of R, then $\mathcal{L}(R_{pre})$ is a prefix of $\mathcal{L}(R)$.

Not all linearizable implementations are strongly linearizable, since, for some implementations, we need to extend different linearizations of a run R to linearize different extensions of R. This notion of *strong* linearizability is subtle, but has been shown important in preserving hyperproperties of composed algorithms, such as output probability distributions [16, 5].

4 Our Proof Technique for Linearizability

Our goal is to devise a scheme by which algorithmists can produce machine verifiable proofs that complex concurrent object implementations are linearizable. To prove linearizability of an implementation \mathcal{O} , our technique is to augment \mathcal{O} 's code to produce an *augmented implementation* $\overline{\mathcal{O}}$ in such a way, that \mathcal{O} is linearizable if and only if the generator of $\overline{\mathcal{O}}$, i.e. $\mathcal{A}(\overline{\mathcal{O}})$, satisfies a certain simple invariant. In the following, we describe the rules for augmentation, and some specific augmentations of interest.

4.1 Augmenting an Implementation

Informally, an *augmented implementation* \overline{O} has all the code of O, and more. In particular, \overline{O} may employ additional *auxiliary* base objects, and at each line manipulate these auxiliary objects along with performing the code of that line in the original implementation.

Definition 4.1 (augmentation). Let \mathcal{O} be an implementation of type τ with initial state σ_0 from base objects Ω for processes Π . An *augmentation* $\overline{\mathcal{O}}$ of \mathcal{O} is also an implementation of type τ with initial state σ_0 for processes Π , with the following properties:

- $\overline{\mathcal{O}}$ may employ an additional set of *auxiliary* base objects Ω_{aux} ; thus, $\overline{\mathcal{O}}$ is an implementation from $\overline{\Omega} = \Omega \cup \Omega_{aux}$.
- For each line ℓ of each procedure $\mathcal{O}.op_{\pi}(arg)$, the augmented procedure has a bijectively corresponding line $\overline{\ell}$ of $\overline{\mathcal{O}}.op_{\pi}(arg)$, such that; $\overline{\ell}$ contains all the code of the corresponding line ℓ and, optionally, some additional code that only changes objects in Ω_{aux} .

Since the additional code has no impact on the original base objects of \mathcal{O} or the private registers of any $\pi \in \Pi$ (including pc_{π}), we note that $\overline{\mathcal{O}}$ and \mathcal{O} have identical behaviors as summarized below.

Observation 1. If $\overline{\mathcal{O}}$ is an augmentation of \mathcal{O} , then the set of behaviors of $\overline{\mathcal{O}}$ is identical to the set of behaviors of \mathcal{O} .

When we have two implementations \mathcal{O} and $\overline{\mathcal{O}}$, we will often be interested in analyzing *coupled runs* of these implementations as defined below:

Definition 4.2 (coupled runs). Let \mathcal{O} and $\overline{\mathcal{O}}$ be implementations of the same object type τ for the same set of processes II, with bijectively corresponding lines. We say a run $R_k = C_0, (\pi_1, \ell_1), C_1, (\pi_2, \ell_2), \ldots, C_k$ of $\mathcal{A}(\mathcal{O})$ and a run $\overline{R}_k = \overline{C}_0, (\pi_1, \overline{\ell}_1), \overline{C}_1, (\pi_2, \overline{\ell}_2), \ldots, \overline{C}_k$ of $\mathcal{A}(\overline{\mathcal{O}})$ are coupled, if C_0 and \overline{C}_0 share an initialization for all their common variables, and each ℓ_i and $\overline{\ell}_i$ are corresponding lines for each $1 \leq i \leq k$.

4.2 The Full Tracker Augmentation

In this section, we consider an implementation \mathcal{O} of an object type τ , and we define a specific augmentation \mathcal{O}^* called the *full tracker* of \mathcal{O} , which aims to keep track of all possible linearizations of a run R of \mathcal{O} , as the run unfolds. Recall that by definition, a linearization R_{atomic} of a run R is a run of the atomic implementation \mathcal{O}_{atomic} of type τ whose behavior matches that of R. In practice, $\overline{\mathcal{O}}$ will actually maintain just the final configuration C_{atomic} of each linearization R_{atomic} , rather than the whole linearization, thus we now take a closer look at these atomic configurations.

After any run R_{atomic} , the final configuration can be characterized by the state $\sigma \in \tau . \Sigma$ of the atomic object, and the states of each of the processes $\pi \in \Pi$. For each process π , there are three types of possible states:

- 1. either π is *idle*, meaning π has no currently invoked but un-returned operation, i.e. pc_{π} points at the single line (line *a*) of the generator algorithm and $r_{\pi} = \bot$.
- 2. or π has invoked an operation $oper_{\pi}(argu)$ which is *yet-to-linearize*, i.e. pc_{π} points to line 1 of procedure oper's code and $r_{\pi} = \bot$.
- 3. or π has linearized its operation $oper_{\pi}(argu)$ with some response resp, i.e. pc_{π} points to line 2 of procedure oper's code and $r_{\pi} = resp$.

We capture the states of the processes with a function $f(\pi) = (f(\pi).op, f(\pi).arg, f(\pi).res)$, which maps each process π to a triple, where

- 1. if π is idle, then $f(\pi) = (\bot, \bot, \bot)$
- 2. if π has invoked an operation $oper_{\pi}(argu)$ which is yet-to-linearize, then $f(\pi) = (oper, argu, \perp)$
- 3. and if π has linearized its operation $oper_{\pi}(argu)$ with some response resp, then $f(\pi) = (oper, argu, resp)$

Thus, we identify each atomic configuration C_{atomic} , i.e. configuration of $\mathcal{A}(\mathcal{O}_{atomic})$, as an object-state, processstates pair $(C_{atomic}.\sigma, C_{atomic}.f)$ as described above. Here on, we will refer to these pairs as the atomic configurations.

For the full tracker, we augment the implementation \mathcal{O} with an object \mathcal{M}^* that stores the set of all final configurations of linearizations of the implemented object's run thus far. We call \mathcal{M}^* the *meta-configuration* of the tracker, since it "contains all the atomic configurations in which a corresponding atomic run can be in". The meta-configuration set is, in fact, the only auxiliary object we use in the tracker augmentation, thus $\Omega_{aux} = {\mathcal{M}^*}$.

Next, we complete the description of \mathcal{O}^* by describing how the meta-configuration \mathcal{M}^* is initialized and manipulated by the full tracker. Initially, all processes are idle, and \mathcal{O} is in its initial state σ_0 ; thus we initialize $\mathcal{M}^* = \{(\sigma_0, f_0)\}$, where $f_0(\pi) = (\bot, \bot, \bot)$ for all process $\pi \in \Pi$.

There are three types of lines in a procedure $\mathcal{O}.op_{\pi}(arg)$: *invocation*, *return*, and *intermediate lines*. The augmenting code at each line ℓ updates \mathcal{M}^* , based on ℓ 's type. Specifically,

- Case: ℓ is the invocation of $op_{\pi}(arg)$. We will maintain the invariant that \mathcal{M}^* stores all final configurations of linearizations of the implemented object's current run. Thus, every configuration $C \in \mathcal{M}^*$ will reflect that π is idle before the invocation. In the augmentation to the invocation line, we will update each $C \in \mathcal{M}^*$ to a C' which reflects that π invokes a pending operation op with argument arg, and then further evolve C' to reflect that any arbitrary subset of processes with pending operations (possibly including π) can linearize after π invokes its operation. Before formally stating the augmenting code to the invocation line, we develop some helpful notation.
 - For an atomic configuration $C = (C.\sigma, C.f)$ in which π is idle, we define:

$$invoke(C, \pi, op_{\pi}(arg)) \triangleq C'$$

where $C'.\sigma = C.\sigma, C'.f(\pi) = (op, arg, \bot)$, and for each $\bar{\pi} \neq \pi, C'.f(\bar{\pi}) = C.f(\bar{\pi})$.

– For an atomic configuration C, and a process $\pi \in \Pi$, we define the predicate

$$pending(\pi, C) \equiv C.f(\pi).op \neq \bot \land C.f(\pi).res = \bot$$

to capture whether π has a pending operation in C. We further define

$$pending(C) \equiv \{\pi \in \Pi \mid pending(\pi, C)\}$$

to be the set of all processes with pending operations in C.

- For any $S \subseteq pending(C)$ of processes with pending operations, and a permutation of those processes $\alpha = (\alpha_1, \ldots, \alpha_{|S|}) \in Perm(S)$, we define the transition function $\delta^*(C, \alpha)$ recursively below. (Informally, $\delta^*(C, (\alpha_1, \ldots, \alpha_k)) = C'$ if applying the pending operations of processes $\alpha_1, \ldots, \alpha_k$, in that order, updates the configuration C to C'.)
 - $\delta^*(C, ()) = C$, where () is the empty sequence
 - $\delta^*(C, (\alpha_1, \ldots, \alpha_k)) = \delta^*(C', (\alpha_2, \ldots, \alpha_k))$, where

$$\exists r \in RES: \quad (C'.\sigma, r) = \delta(C.\sigma, \alpha_1, C.f(\alpha_1).op, C.f(\alpha_1).arg) \\ \land \forall \pi \neq \alpha_1, C'.f(\pi) = C.f(\pi) \\ \land C'.f(\alpha_1) = (C.f(\alpha_1).op, C.f(\alpha_1).arg, r)$$

Formally, the augmenting code at line ℓ is: $\mathcal{M}^* \leftarrow EvolveInv(\mathcal{M}^*, op_{\pi}(arg))$, where EvolveInv is defined by

$$EvolveInv(\mathcal{M}, op_{\pi}(arg)) \triangleq \left\{ C'' \middle| \begin{array}{c} \exists C \in \mathcal{M}, C': \\ C' = invoke(C, \pi, op_{\pi}(arg)) \land \\ \exists S \subseteq pending(C'), \alpha \in Perm(S): C'' = \delta^{*}(C', \alpha) \end{array} \right\}$$
(4.1)

We say configuration C'' results from π invoking $op_{\pi}(arg)$ and $\alpha_1, \ldots, \alpha_k$ linearizing after configuration C.

• Case: ℓ is an intermediate line of $op_{\pi}(arg)$. The augmenting code for this line reflects that any time any process executes an intermediate line, it presents an opportunity for an arbitrary subset of pending operations to linearize in an arbitrary order. Formally, the augmenting code at line ℓ is: $\mathcal{M}^* \leftarrow Evolve(\mathcal{M}^*)$, where Evolve is defined by

$$Evolve(\mathcal{M}) \triangleq \{C' \mid \exists C \in M, S \subseteq pending(C), \alpha \in Perm(S) : C' = \delta^*(C, \alpha)\}$$
(4.2)

We say configuration C' results from $\alpha_1, \ldots, \alpha_k$ linearizing after configuration C.

- Case: *l* is a return *res* statement from a procedure *op*_π(*arg*). Those atomic configurations that do not reflect that the operation has linearized with a response of *res* are no longer tenable, and thus these are filtered out of *M**. On the other hand, the configurations that show this response of *res* are retained and updated to reflect that *π* becomes idle after the return. Furthermore, any arbitrary subset of pending processes can linearize after *π* returns. Before formally stating the augmenting code to the invocation line, we develop some helpful notation.
 - For an atomic configuration $C = (C.\sigma, C.f)$ in which π has linearized its operation $op_{\pi}(arg)$ with return value res, we define: $return(C, \pi, res) \triangleq C'$

where
$$C'.\sigma = C.\sigma, C'.f(\pi) = (\bot, \bot, \bot)$$
, and for each $\bar{\pi} \neq \pi, C'.f(\bar{\pi}) = C.f(\bar{\pi})$.

Formally, the augmenting code at line ℓ is: $\mathcal{M}^* \leftarrow EvolveRet(\mathcal{M}^*, \pi, res)$, where EvolveRet is defined by

$$EvolveRet(\mathcal{M}, \pi, res) \triangleq \left\{ C'' \middle| \begin{array}{c} \exists C \in \mathcal{M}, C': \\ C.f(\pi).res = res \land \\ C' = return(C, \pi, res) \land \\ \exists S \subseteq pending(C'), \alpha \in Perm(S): C'' = \delta^*(C', \alpha) \end{array} \right\}$$
(4.3)

We say configuration C'' results from π returning res and $\alpha_1, \ldots, \alpha_k$ linearizing after configuration C.

Definition 4.3 (full tracker). For any implementation \mathcal{O} , \mathcal{O}^* is the *full tracker* as specified above with the single auxiliary *meta-configuration* variable \mathcal{M}^* .

4.3 Main Theorem

The crafting of the tracking augmentation yields a powerful technique for producing *machine verified proofs* of linearizability. This technique falls out from the main theorem of this section, which reduces the complex question of whether an implementation \mathcal{O} is linearizable to the verification of a simple invariant. In particular, \mathcal{O} is linearizable *if and only if* $\mathcal{M}^* \neq \emptyset$ is an invariant of $\mathcal{A}(\mathcal{O}^*)$.

Exploiting the *if* direction of this theorem, we can obtain machine verified proofs of linearizability by proving the invariant in a software system such as TLAPS (Temporal Logic of Actions Proof System) or Coq. The *only if* direction of the theorem assures us that this proof technique is complete.

Theorem 4.4. Let \mathcal{O} be an implementation of an object of type τ initialized to state σ_0 for a set of processes Π , \mathcal{O} is linearizable if and only if $\mathcal{M}^* \neq \emptyset$ is an invariant of $\mathcal{A}(\mathcal{O}^*)$.

Recall that \mathcal{O}^* is the full tracker of \mathcal{O} with meta-configuration \mathcal{M}^* , and $\mathcal{A}(\mathcal{O}^*)$ is the algorithm from Figure 1 in which processes repeatedly make calls to procedures of \mathcal{O}^* . The remainder of the section develops the necessary machinery and proves Theorem 4.4.

Let \mathcal{O} be an implementation of an object of type τ initialized to σ_0 for a set of processes Π , and let \mathcal{O} be an atomic object with the same type and initialization, and for the same set of processes. Finally, recall that \mathcal{O}^* is the full tracker of \mathcal{O} with meta-configuration variable \mathcal{M}^* .

For a generic variable V of any given implementation I, and a run R_I of the generator $\mathcal{A}(I)$, we let $V(R_I)$ denote the value of V in the final configuration of $\mathcal{A}(I)$. We will be particularly interested in the meta-configurations $\mathcal{M}^*(R^*)$ for runs R^* of $\mathcal{A}(\mathcal{O}^*)$.

By Observation 1, \mathcal{O} is linearizable if and only if the finite behaviors of \mathcal{O}^* are behaviors of O. Our strategy to prove the main theorem thereby, will be to show that for any run R^* of \mathcal{O}^* , the set of atomic runs sharing its behavior will have exactly the final configurations $\mathcal{M}^*(R^*)$.

To express the above statement, we develop a bit more notation. For any behavior B, we let AtomicRuns(B) be the set of atomic runs that exhibit behavior B. For any run R^* of the implementation, we define $Linearizations(R^*) \triangleq$ $AtomicRuns(behavior(R^*))$ to be the set of all possible linearizations of R^* . Finally, for run R, we let C(R) denote the final configuration of R, and for a set of runs \mathcal{R} , we let $C(\mathcal{R}) \triangleq \{C(R) \mid R \in \mathcal{R}\}$ denote the set of final configurations of all those runs.

We are now ready to prove the key lemma, which states that the meta-configuration variable tracks, precisely, the set of final configurations of linearizations of an implementation run.

Lemma 4.5. Let R^* be any finite run of \mathcal{O}^* , then the following equality holds:

$$\mathcal{M}^*(R^*) = \mathcal{C}(Linearizations(R^*))$$

Proof. We present the full formal inductive proof of this lemma in Appendix A.

Theorem 4.4. Let \mathcal{O} be an implementation of an object of type τ initialized to state σ_0 for a set of processes Π , \mathcal{O} is linearizable if and only if $\mathcal{M}^* \neq \emptyset$ is an invariant of $\mathcal{A}(\mathcal{O}^*)$.

Proof. We will prove the theorem by showing the forward and reverse directions separately:

- For the forward direction: assume M^{*} ≠ Ø is an invariant of A(O^{*}). Thus, for any finite run R^{*} of A(O^{*}), we note M^{*}(R^{*}) is non-empty. So, by Lemma 4.5, there is a linearization L of R^{*}. Since, an arbitrary finite run R^{*} of A(O^{*}) is linearizable, we conclude that O^{*} is linearizable. Since O^{*} has the same behaviors as O, thus O is linearizable.
- For the reverse direction: assume that O is linearizable. This implies O* is linearizable. So, every finite run R* of A(O*) has at least one linearization L. Thus, by Lemma 4.5, M*(R*) is non-empty. Since, M*(R*) is non-empty for an arbitrary finite run R* of A(O*), we conclude that M* ≠ Ø is an invariant of A(O*).

5 (Partial) Trackers

The proof of Theorem 4.4 demonstrates that, for an implementation \mathcal{O} , the full tracker \mathcal{O}^* , in essence, tracks "all possible linearizations" in its meta-configuration. To show that \mathcal{O} is linearizable however, it suffices to show the existence of a single linearization. That is, we need not track *all* linearizations, but just ensure that we track *at least one*. In practice, tracking a subset of linearizations can be easier for a prover, especially one who knows the structure of the implementation well. Thus, in general, we will be interested in a (partial) tracker, whose meta-configuration \mathcal{M}^* maintains a subset of the full meta-configuration \mathcal{M}^* . We define such trackers.

Definition 5.1 (trackers). Let \mathcal{O} be an implementation of a type τ in the initial state σ_0 for a set of processes Π . An augmentation \mathcal{O}' is a *(partial) tracker* of \mathcal{O} , if the following conditions are met:

- The auxiliary variable set Ω_{aux} of O' contains a meta-configuration variable M' that holds a set of atomic configurations. (Ω_{aux} may also contain other additional variables.)
- \mathcal{M}' is initialized to $\{(\sigma_0, f_0)\}$, where $f_0(\pi) = (\bot, \bot, \bot)$ for every $\pi \in \Pi$.
- For each type of line ℓ (whether invocation, intermediate, or return) in the original algorithm, the augmented line ℓ' updates the tracker to ensure the new value of M' is a subset of the configurations that would arise by evolving M' according to the rules of the full tracker. That is, if the update rule of the tracker at line ℓ' is M' ← Evolveℓ(M'), then:
 - Case: ℓ is the invocation of $op_{\pi}(arg)$.

$$Evolve_{\ell}(\mathcal{M}') \subseteq EvolveInv(\mathcal{M}', op_{\pi}(arg))$$
(5.1)

- Case: ℓ is an intermediate line of $op_{\pi}(arg)$.

$$Evolve_{\ell}(\mathcal{M}') \subseteq Evolve(\mathcal{M}')$$
(5.2)

- Case: ℓ is a **return** res statement from a procedure $op_{\pi}(arg)$.

$$Evolve_{\ell}(\mathcal{M}') \subseteq EvolveRet(\mathcal{M}', \pi, res)$$
(5.3)

Theorem 5.2. Let \mathcal{O} be an implementation of an object of type τ initialized to state σ_0 for a set of processes Π , and \mathcal{O}' be any partial tracking augmentation of \mathcal{O} with meta-configuration variable \mathcal{M}' . If $\mathcal{M}' \neq \emptyset$ is an invariant of $\mathcal{A}(\mathcal{O}')$, then \mathcal{O} is linearizable.

Proof. Let \mathcal{M}^* be the meta-configuration of the full tracker \mathcal{O}^* . Consider any run $R^* = C_0^*, (\pi_1, \ell_1^*), C_1^*, (\pi_2, \ell_2^*), \ldots$ of $\mathcal{A}(\mathcal{O}^*)$, and recall that we say the run $R' = C'_0, (\pi_1, \ell'_1), C'_1, (\pi_2, \ell'_2), \ldots$ of $\mathcal{A}(\mathcal{O}')$ is coupled with R^* , if C'_0 has the same initialization for the private registers and objects in τ . Ω , and for each i, ℓ'_i is the line in \mathcal{O}' that corresponds to ℓ^*_i in \mathcal{O}^* , i.e., these are augmentations of corresponding lines in \mathcal{O} . Since \mathcal{O}^* and \mathcal{O}' augment the same implementation, all runs of $\mathcal{A}(\mathcal{O}^*)$ and $\mathcal{A}(\mathcal{O}')$ are coupled as (R^*, R') in this way. For coupled runs R^* and R', by definition of a partial tracking augmentation, it is clear that $\mathcal{M}' \subseteq \mathcal{M}^*$ throughout the coupled run. Thus, $\mathcal{M}' \neq \emptyset$ being an invariant of \mathcal{O}' implies $\mathcal{M}^* \neq \emptyset$ is an invariant of \mathcal{O}^* . So, by Theorem 4.4, the proof is complete.

6 Proving Strong Linearizability

In the previous section, we motivated partial trackers as simpler ways to prove standard linearizability. In this section, we will show how to use partial trackers to obtain a *sound and complete* method for proving *strong linearizability*.

The pivotal difference between strong linearizability and (standard) linearizability, is that the former consistency condition requires that we should be able to commit to a single linearization $\mathcal{L}(R)$ for any run R, such that the linearization of every extension of R will be an extension of $\mathcal{L}(R)$. Our key insight lies here. The full tracker's metaconfiguration \mathcal{M}^* maintains the final configurations of every possible linearization of R hoping to extend whichever ones may work as the future of the run unfolds; thus, it effectively ensures that "no linearization will be missed" thereby yielding a complete method for proving linearizability. However, informally speaking, by maintaining every possible linearization, it does exactly the opposite of *committing to single linearization*, which is the key to showing strong linearizability.

Our idea therefore, is to demonstrate strong linearizability by demonstrating a partial tracker \mathcal{O}' whose metaconfiguration \mathcal{M}' holds precisely one configuration at any point in time. The intuition is that maintaining a single configuration $\mathcal{M}'(R'_k) = \{C_k\}$ at the end of a run R'_k of length k is akin to committing to a single linearization L_k (with $\mathcal{C}(L_k) = C_k$) for this run, and that this unique linearization is getting extended as the run gets extended. Of course, there is a small catch. The configuration C_k could be the final configuration of many different linearizations, which all happen to have the same final configuration. Nevertheless, we will resolve this hiccup by proving that a cleverly chosen particular one of these linearizations can be picked as $\mathcal{L}(R'_k)$.

Theorem 6.1. Let \mathcal{O} be an implementation of an object of type τ initialized to state σ_0 for a set of processes Π , \mathcal{O} is strongly linearizable if and only if there exists a partial tracker \mathcal{O}' such that $\mathcal{A}(\mathcal{O}')$ satisfies the invariant $|\mathcal{M}'| = 1$.

Proof. We present the full inductive proof of this theorem in Appendix B.

7 Applying the Technique

We have used our tracking technique to produce machine-certified proofs of three concurrent data structures: we proved the linearizability of the Herlihy-Wing queue and Jayanti's single-writer single-scanner snapshot; and we have proved the strong linearizability of the Jayanti-Tarjan union-find object. The Herlihy-Wing queue implementation, presented in Figure 3, is particularly notorious for being difficult to prove correct, so we will use that data structure as a running example in this section. We present the other two results in Appendices E and D, respectively.

This section has two goals: (1) describing the *proof process*, i.e., the steps taken by a *human-prover* in order to produce a machine-certified proof of linearizability; and (2) describing the *verification process*, i.e., the steps required of the *human-verifier* in order to confirm the proof's correctness. Overall, with the tracking technique, the prover does work comparable to what would be done in a pen-and-paper proof. The verifier's job on the other hand, becomes very simple and fast.

Base Objects:

- X is a F&Inc/read register initialized to 1.
- Q[1, 2, ...] is an infinite FAS/read/write array, where each Q[i] is initialized to \bot .

1: procedure \mathcal{O} .ENQUEUE_{π} (v_{π}) 5: **procedure** \mathcal{O} .DEQUEUE_{π}() 2: $i_{\pi} \leftarrow F\&INC(X)$ 6: $l_{\pi} \leftarrow X$ $Q[i_{\pi}] \leftarrow v_{\pi}$ 7: if $l_{\pi} = 1$ then go o 6 else $j_{\pi} \leftarrow 1$ 3: $x_{\pi} \leftarrow \operatorname{FAS}(Q[j_{\pi}], \bot)$ 4: return ack 8: if $x_{\pi} = \bot$ then if $j_{\pi} = l_{\pi} - 1$ then goto 6 else $\{j_{\pi} \leftarrow j_{\pi} + 1; \text{goto } 8\}$ 9: return x_{π}

Figure 3: Herlihy-Wing queue implementation [18]. Each numbered line in the implementation has at most one shared memory instruction, and is performed atomically.

7.1 The proof process

To show that an implementation \mathcal{O} is linearizable via the tracking technique, the prover must present a tracker $\overline{\mathcal{O}}$ and a machine-certified proof that the statement $\mathcal{I}_L \equiv (\mathcal{M} \neq \emptyset)$ is an invariant of $\mathcal{A}(\overline{\mathcal{O}})$. Generally, we prove \mathcal{I}_L 's invariance by induction over the length of the run. \mathcal{I}_L holds in the initial configuration by the tracker definition, so the base case is straightforward. \mathcal{I}_L 's validity in subsequent configurations however, relies not only on its validity in the current configuration, but also on the design of the algorithm, i.e., other invariants of the algorithm that capture the states of the various program variables (objects and registers). Thus, in order to go through with the induction, we must strengthen \mathcal{I}_L to a stronger invariant \mathcal{I} that meets two conditions: (a) \mathcal{I} is *inductive* and (b) \mathcal{I} implies \mathcal{I}_L . In general, we accomplish (b) by ensuring that \mathcal{I}_L is a conjunct in the statement \mathcal{I} (i.e., $\mathcal{I} \equiv \mathcal{I}_L \land \ldots$). The task of strengthening \mathcal{I}_L to an inductive \mathcal{I} is the main intellectual work that the prover (*unlike the verifier*) must still understand the algorithm well in order to give the proof. Of course, the prover must subsequently *prove* \mathcal{I} by induction; but our experience through proving several algorithms suggests that this latter step, while potentially time-taking due to the length of the proof, is intellectually easy once the correct \mathcal{I} is identified. In summary, to prove an implementation \mathcal{O} is linearizable, the human-prover:

- 1. Presents a tracker $\overline{\mathcal{O}}$ of the implementation \mathcal{O} .
- 2. Identifies an inductive invariant \mathcal{I} that contains \mathcal{I}_L as a conjunct.
- 3. Publishes a machine-certified inductive proof that \mathcal{I} is an invariant of $\mathcal{A}(\overline{\mathcal{O}})$.

To demonstrate the proof process, we now present our proof of the Herlihy-Wing queue. Since the principal purpose here is to explain the proof process, rather than the queue implementation, we will focus the discussion on the process and make as few references to the particulars of the implementation as possible. We now describe each of the three steps:

1. <u>Tracker</u>: We present our partial tracker \overline{O} in Figure 4. To make the correspondence with the original implementation clear, we color the augmenting code purple. A simple inspection of the augmentations shows that \overline{O} conforms to the initialization rule, and invocation, intermediate, and return line rules of a partial tracker.

Specifying a *partial* tracker, as opposed to a *full* tracker, allows us to express our insights into exactly when and how the implemented object linearizes operations. For instance, we have embedded our understanding that every operation can be linearized at line 2 or line 8 of some process's code by only augmenting those two intermediate lines. Furthermore, our augmentation implies that it suffices to only track linearizations that linearize an operation by π' when π executes line 2 if the program counter of π' is at line 3 or 4. Embedding such insights into the tracker makes identifying and proving the inductive invariant \mathcal{I} easier.

Base Objects:

- X is a F&Inc/read register initialized to 1.
- Q[1, 2, ...] is an infinite FAS/read/write array, where each Q[i] is initialized to \bot .
- M initialized to {(σ₀, f₀)} is a meta-configuration, where σ₀ is the empty sequence, and f₀ maps each process π ∈ Π to (⊥, ⊥, ⊥).

1: **procedure** $\overline{\mathcal{O}}$.ENQUEUE_{π}(v_{π}) $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, \mathsf{ENQUEUE}_{\pi}(v_{\pi}))\}$ $i_{\pi} \leftarrow F\&INC(X)$ 2: $\mathcal{M} \leftarrow \left\{ C' \mid \exists C \in \mathcal{M}, S \subseteq pending(C), \alpha \in Perm(S) : \\ C' = \delta^*(C, \alpha) \land \forall \pi' \in S : pc_{\pi'} \in \{3, 4\} \lor \pi' = \pi \right\}$ 3: $Q[i_{\pi}] \leftarrow v_{\pi}$ 4: return ack $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, ack)\}$ 5: procedure $\overline{\mathcal{O}}$. DEQUEUE_{π}() $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, \mathsf{DEQUEUE}_{\pi}())\}$ $l_{\pi} \leftarrow X$ 6: 7: if $l_{\pi} = 1$ then go o 6 else $j_{\pi} \leftarrow 1$ $x_{\pi} \leftarrow \text{FAS}(Q[j_{\pi}], \bot)$ 8: if $x_{\pi} = \bot$ then if $j_{\pi} = l_{\pi} - 1$ then goto 6 else $\{j_{\pi} \leftarrow j_{\pi} + 1; \text{goto } 8\}$ else $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = \delta^*(C, \pi)\}$ return x_{π} 9: $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, x_{\pi})\}$

Figure 4: Tracker $\overline{\mathcal{O}}$ for the queue implementation \mathcal{O} presented in Figure 3

Figure 5: Invariant \mathcal{I} of $\mathcal{A}(\overline{\mathcal{O}})$, where $\overline{\mathcal{O}}$ is the implementation of the queue tracker in Figure 4.

$$\mathcal{I} \equiv \mathcal{I}_L \land \mathcal{I}_X \land \mathcal{I}_Q \land \mathcal{I}_v \land \mathcal{I}_i \land \mathcal{I}_l \land \mathcal{I}_j \land \mathcal{I}_x \land \mathcal{I}_{pc} \land \mathcal{I}_{\mathcal{M}} \\ \land \mathcal{I}_{1.5} \land \mathcal{I}_2 \land \mathcal{I}_3 \land \mathcal{I}_4 \land \mathcal{I}_6 \land I_7 \land \mathcal{I}_8 \land \mathcal{I}_9 \land \mathcal{I}_a \land \mathcal{I}_b$$

In the above expression, the various conjuncts on the right hand side are defined below. Appendix C contains a full explanation of the invariant and the predicates used in it.

• $\mathcal{I}_L \equiv \mathcal{M} \neq \emptyset$

 $\begin{array}{l} \cdot \ \mathcal{I}_{X} \equiv X \in \mathbb{N}^{+}, \mathcal{I}_{Q} \equiv \forall k \in \mathbb{N}^{+} : Q[k] \in \mathbb{N}^{+} \cup \{\bot\}, \mathcal{I}_{v} \equiv \forall \pi \in \Pi : v_{\pi} \in \mathbb{N}^{+}, \mathcal{I}_{i} \equiv \forall \pi \in \Pi : i_{\pi} \in \mathbb{N}^{+} \\ \mathcal{I}_{l} \equiv \forall \pi \in \Pi : l_{\pi} \in \mathbb{N}^{+}, \mathcal{I}_{j} \equiv \forall \pi \in \Pi : j_{\pi} \in \mathbb{N}^{+}, \mathcal{I}_{x} \equiv \forall \pi \in \Pi : x_{\pi} \in \mathbb{N}^{+} \cup \{\bot\}, \mathcal{I}_{pc} \equiv \forall \pi \in \Pi : pc_{\pi} \in [9] \\ \cdot \ \mathcal{I}_{\mathcal{M}} \equiv \mathcal{M} \subseteq \{(\sigma, f) : \sigma \in \bigcup_{n \in \mathbb{N}} (\mathbb{N}^{+})^{n}, f \in (\{\text{ENQUEUE}, \text{DEQUEUE}\} \times (\mathbb{N}^{+} \cup \{\bot\}) \times (\mathbb{N}^{+} \cup \{ack, \bot\}))^{\Pi} \} \\ \cdot \ \mathcal{I}_{1,5} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{1,5\} \implies f(\pi) = (\bot, \bot, \bot) \\ \cdot \ \mathcal{I}_{2} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 2 \implies f(\pi) = (\text{ENQUEUE}, v_{\pi}, \bot) \\ \cdot \ \mathcal{I}_{3} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 3 \implies f(\pi) \in \{\text{ENQUEUE}\} \times \{v_{\pi}\} \times \{ack, \bot\} \wedge (1 \leq i_{\pi} < X) \wedge (Q[i_{\pi}] = \bot) \\ \wedge (\forall \pi' \in \Pi - \{\pi\} : pc_{\pi'} \in \{3,4\} \implies i_{\pi'} \neq i_{\pi}) \\ \cdot \ \mathcal{I}_{4} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 4 \implies f(\pi) \in \{\text{ENQUEUE}\} \times \{v_{\pi}\} \times \{ack, \bot\} \wedge (1 \leq i_{\pi} < X) \\ \wedge (\forall \pi' \in \Pi - \{\pi\} : pc_{\pi'} \in \{3,4\} \implies i_{\pi'} \neq i_{\pi}) \\ \cdot \ \mathcal{I}_{6} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 6 \implies f(\pi) = (\text{DEQUEUE}, \bot, \bot) \\ \cdot \ \mathcal{I}_{7} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 7 \implies f(\pi) = (\text{DEQUEUE}, \bot, \bot) \wedge 1 \leq l_{\pi} \leq X \\ \cdot \ \mathcal{I}_{8} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 9 \implies f(\pi) \in (\text{DEQUEUE}\} \times \{\bot\} \times (\mathbb{N}^{+} \cup \{\bot\}) \\ \cdot \ \mathcal{I}_{a} \equiv \forall k \in \mathbb{N}^{+} : k > X - 1 \implies Q[k] = \bot \\ \cdot \ \mathcal{I}_{b} \equiv \forall A \subseteq [X - 1] : GoodEnqSet(A) \implies (\forall s \in Perm(A) : (JInvSeq(S) \\ \implies (\exists C \in \mathcal{M} : GoodRes(A, C) \land ValuesMatchInds(s, C)))) \\ \end{array}$

- 2. <u>Inductive invariant</u>: We identify an inductive invariant \mathcal{I} of $\overline{\mathcal{O}}$, and display it in Figure 5. (Appendix C contains a full explanation of the invariant and the predicates used in it.) Notice that \mathcal{I}_L is one of the conjuncts in \mathcal{I} . The exact statement of the invariant comes from a careful study of the algorithm to determine which truths it maintains in order to be linearizable in the manner captured by the partial tracker. A birdseye view of the invariant is as follows: invariant conjuncts \mathcal{I}_x , where x is a variable in the implementation, express truths about what values those variables take; invariant conjuncts \mathcal{I}_ℓ , where ℓ is a line number, express truths that can be inferred when a process π has its program counter at line ℓ .
- 3. Machine-certified proof: With the partial tracker $\overline{\mathcal{O}}$ and the corresponding invariant \mathcal{I} in hand, the actual induction proof is quite mechanical, making it a perfect fit to be checked and certified by a machine. The proof of the induction step has eight cases, one for each line ℓ of the implementation, and it comprehensively justifies why each of the invariant conjuncts holds after an arbitrary process π whose program counter currently points to ℓ executes that line of code. Our inductive proof of \mathcal{I} and the additional (trivial) claim that $\mathcal{I}_L \equiv (\mathcal{M} \neq \emptyset)$ is an invariant of $\overline{\mathcal{O}}$ have been checked by the Temporal Language of Action Proof System (TLAPS). We have made this machine-certified proof available at: https://github.com/uguryavuz/ machine-certified-linearizability.

7.2 The verification process

Convincing the reader that the implementation is linearizable, is very simple: the reader simply needs to check that the augmented implementation in Figure 4 is indeed a partial tracker of the queue, and then confirm that TLAPS has already certified that $|\mathcal{M}| \neq \emptyset$ is an invariant of the partial tracker at: https://github.com/uguryavuz/machine-certified-linearizability. Done! In particular, the reader *does not* need to read or understand the proof of the invariant; in fact, the reader *does not* even need to understand the code of the implementation! It suffices to simply observe that the machine has verified the invariant $\mathcal{M} \neq \emptyset$. In summary, to verify an implementation \mathcal{O} is linearizable, the human-verifier simply:

- 1. Checks that the augmentation $\overline{\mathcal{O}}$ presented by the prover is indeed a tracker of \mathcal{O} .
- 2. Confirms that a machine proof-assistant has certified that $\mathcal{M} \neq \emptyset$ is an invariant of $\mathcal{A}(\overline{\mathcal{O}})$.

8 Conclusion and Remarks

We have presented the *tracking technique* for proving linearizability and strong linearizability of concurrent data structures, and have demonstrated the technique's efficacy by penning machine-verified proofs of algorithms that are noted for their complexity and speed. We look forward to many more algorithms being successfully machine-verified, both by us and by others in the community.

Due to the inherent complexity of concurrent algorithms, we believe that machine-verification can play an even wider role in providing robust, trusted guarantees. We are extending our technique to incorporate other variants of linearizability, such as *durable linearizability* [21, 4] and *strict linearizability* [1]. We are also designing techniques to verify properties of mutual exclusion locks, such as starvation-freedom and first-come-first-served. Finally, we are developing techniques to produce machine-verified proofs of time complexity guarantees of multiprocess algorithms. We believe an interesting related open problem is the development of proof methods for consistency criteria that are weaker than linearizability, such as *sequential consistency*.

A Proof of the Key Lemma for Full Trackers

Lemma 4.5. Let R^* be any finite run of \mathcal{O}^* , then the following equality holds:

$$\mathcal{M}^*(R^*) = \mathcal{C}(Linearizations(R^*))$$

Proof. The proof is by induction on the number of events in the run R^* .

- **Base Case:** Every implementation run R^* with zero events is simply an initial configuration C_0^* of algorithm $\mathcal{A}(\mathcal{O}^*)$. In this case, $behavior(R^*)$ is the empty behavior, and thus only the empty atomic run is in $Linearizations(R^*) = AtomicRuns(behavior(R^*))$. The final (and only) configuration of this run is the unique initial atomic configuration $C_0 = (\sigma_0, f_0)$; thus $\mathcal{C}(Linearizations(R^*)) = \{(\sigma_0, f_0)\}$ which is the definition of $\mathcal{M}^*(C_0^*)$.
- Induction Step: Let $R_k^* = C_0^*, \ldots, C_{k-1}^*, (\pi_k, \ell_k), C_k^*$ be run with $k \ge 1$ events. We consider the prefix-run $R_{k-1}^* = C_0^*, \ldots, C_{k-1}^*$, and note that the induction hypothesis states that:

$$\mathcal{M}^*(R_{k-1}^*) = \mathcal{C}(Linearizations(R_{k-1}^*))$$

For notational convenience, we define $B_k = behavior(R_k^*)$ and $B_{k-1} = behavior(R_{k-1}^*)$. The last line executed in R^* , i.e. ℓ_k , can be one of three types of lines: invocation, intermediate, or return.

- Case: ℓ_k is an invocation op_π(arg). First, we show that RHS ⊆ LHS. That is, letting L_k ∈ Linearizations(R^{*}_k), we must first prove that C(L_k) ∈ M^{*}(R^{*}_k). To this effect, define L_{k-1} to be the longest prefix of L_k, such that behavior(L_{k-1}) = B_{k-1}. By definition of atomic runs, L_k results when L_{k-1} is followed immediately by the invocation op_π(arg) and subsequently by a (possibly empty) sequence of linearization steps by processes α = α₁,..., α_h that are yet to linearize in invoke(C(L_{k-1}), π, op_π(arg)). In particular, no other invocation or return events are possible, since behavior(L_k) = B_k which has just the single invocation more than B_{k-1}. Thus, by definition C(L_k) results from π invoking op_π(arg) and α₁,..., α_h linearizing after configuration C(L_{k-1}). Since C(L_{k-1}) ∈ M^{*}(R^{*}_{k-1}) by the inductive hypothesis, C(L_k) ∈ EvolveInv(M^{*}(R^{*}_{k-1}), op_π(arg)) = M^{*}(R^{*}_k).

Second we prove that LHS \subseteq RHS. That is, let $C_k \in \mathcal{M}^*(R_k^*)$, we must prove that there is a linearization L_k of R_k^* with final configuration $\mathcal{C}(L_k) = C_k$. To this effect, we note that $\mathcal{M}^*(R_k^*) = EvolveInv(\mathcal{M}^*(R_{k-1}^*), op_{\pi}(arg))$. That is, there is a configuration $C_{k-1} \in \mathcal{M}^*(R_{k-1}^*)$ such that C_k results from π invoking $op_{\pi}(arg)$ and some sequence of processes $\alpha = \alpha_1, \ldots, \alpha_h$ linearizing after C_{k-1} . By the inductive hypothesis, there is a linearization L_{k-1} of R_{k-1}^* whose final configuration is $\mathcal{C}(L_{k-1}) = C_{k-1}$ in which π is idle and $\alpha_1, \ldots, \alpha_h$ are yet-to-linearize in $invoke(C_{k-1}, \pi, op_{\pi}(arg))$. Thus, the atomic run L_k that extends L_{k-1} with π invoking and α linearizing after C_{k-1} is a linearization of R_k^* whose final configuration is $\mathcal{C}(L_k) = C_k$, which concludes the proof of the case.

- <u>Case</u>: ℓ_k is an intermediate line. Since $behavior(R_k^*) = behavior(R_{k-1}^*)$, we invoke the inductive hypothesis to get the equality:

$$\mathcal{M}^*(R_{k-1}^*) = \mathcal{C}(Linearizations(R_{k-1}^*)) = \mathcal{C}(Linearizations(R_k^*))$$

Now, we observe that when $\mathcal{M}^*(R_{k-1}^*)$ is already the full set of final configurations of linearizations with the behavior $B_{k-1} = B_k$, evolving does not change the set, that is:

$$\mathcal{M}^*(R_k^*) = Evolve(\mathcal{M}^*(R_{k-1}^*)) = Evolve(\mathcal{C}(Linearizations(R_k^*))) = \mathcal{C}(Linearizations(R_k^*))$$

Thus, we conclude the proof of the case.

- Case: ℓ_k is a return return res. This case is very similar to the first case. Once again, we first show that RHS \subseteq LHS. That is, let $L_k \in Linearizations(R_k^*)$; we must first prove that $\mathcal{C}(L_k) \in \mathcal{M}^*(R_k^*)$. To this effect, define L_{k-1} to be the longest prefix of L_k , such that $behavior(L_{k-1}) = B_{k-1}$. By definition of atomic runs, L_k results when L_{k-1} is followed immediately by the return of res and subsequently by a (possibly empty) sequence of linearization steps by processes $\alpha = \alpha_1, \ldots, \alpha_h$ that are yet to linearize in $return(\mathcal{C}(L_{k-1}), \pi, res)$. In particular, no other invocation or return events are possible, since $behavior(L_k) = B_k$ which has just the single return more than B_{k-1} . Thus, by definition $\mathcal{C}(L_k)$ results from π returning res and $\alpha_1, \ldots, \alpha_h$ linearizing after configuration $\mathcal{C}(L_{k-1})$. Since $\mathcal{C}(L_{k-1}) \in$ $\mathcal{M}^*(R_{k-1}^*)$ by the inductive hypothesis, $\mathcal{C}(L_k) \in EvolveRet(\mathcal{M}^*(R_{k-1}^*), \pi, res) = \mathcal{M}^*(R^*).$ Second we prove that LHS \subseteq RHS. That is, let $C_k \in \mathcal{M}^*(R_k^*)$, we must prove that there is a linearization L_k of R_k^* with final configuration $\mathcal{C}(L_k) = C_k$. To this effect, we note that $\mathcal{M}^*(R_k^*) =$ $EvolveRet(\mathcal{M}^*(R_{k-1}^*), \pi, res)$. That is, there is a configuration $C_{k-1} \in \mathcal{M}^*(R_{k-1}^*)$ such that C_k results from π returning res and some sequence of processes $\alpha = \alpha_1, \ldots, \alpha_h$ linearizing after C_{k-1} . By the inductive hypothesis, there is a linearization L_{k-1} of R_{k-1}^* whose final configuration is $C(L_{k-1}) = C_{k-1}$ in which π has linearized with return value res and $\alpha_1, \ldots, \alpha_h$ are yet-to-linearize in return (C_{k-1}, π, res) . Thus, the atomic run L_k that extends L_{k-1} with π returning and α linearizing after C_{k-1} is a linearization of R_k^* whose final configuration is $\mathcal{C}(L_k) = C_k$, which concludes the proof of the case.

B Proof of Strong Linearizability Verification Theorem via Partial Trackers

Theorem 6.1. Let \mathcal{O} be an implementation of an object of type τ initialized to state σ_0 for a set of processes Π , \mathcal{O} is strongly linearizable if and only if there exists a partial tracker \mathcal{O}' such that $\mathcal{A}(\mathcal{O}')$ satisfies the invariant $|\mathcal{M}'| = 1$.

Proof. We split the proof into two parts, proving the *only if* direction, and then proving the *if* direction.

1. To prove the only if direction, we assume there is a linearization function \mathcal{L} that maps each finite run $R_k = C_0, (\pi_1, \ell_1), C_1, \dots, (\pi_k, \ell_k), C_k$ of $\mathcal{A}(\mathcal{O})$ to a linearization $\mathcal{L}(R_k)$. We claim there is a tracker \mathcal{O}' which maintains a meta-configuration \mathcal{M}' , whose value $\mathcal{M}'(R'_k)$ after any run R'_k that is coupled with run R_k of \mathcal{O} is equal to $\mathcal{M}'(R'_k) = {\mathcal{L}(R_k)}$. We prove this claim by induction.

Base Case: note that if $R_k = R_0$ is a zero-event run, then its only linearization is the zero-event atomic run $L_0 = C_0$ that (starts and) ends in the initial atomic configuration (σ_0, f_0) , thus $\mathcal{L}(R_0) = L_0$ and \mathcal{M}' 's initialization is indeed $\{(\sigma_0, f_0)\}$, which concludes the base case.

Induction Step: if $\mathcal{M}'(R'_k) = \{\mathcal{L}(R_k)\}$ for some $k \ge 0$, and the run R_k extends to R_{k+1} in a single step, then by assumption $L_{k+1} = \mathcal{L}(R_{k+1})$ is an extension of $L_k = \mathcal{L}(R_k)$. Here, we break the argument into cases, depending on which type of line ℓ_{k+1} is (invocation, intermediate, or return):

- (a) Case: ℓ is the invocation of op_π(arg). C(L_{k+1}) must result from some processes α₁,..., α_{h1} linearizing, then π_{k+1} invoking op_π(arg), then α_{h1+1},..., α_{h2} linearizing after C(L_k) for some 0 ≤ h₁ ≤ h₂. However, since linearizing an operation before or after an invocation makes no difference to the final configuration, we can obtain the same C(L_{k+1}) after C(L_k) by π invoking op_π(arg) and then linearizing α₁,..., α_{h2}. Thus, C(L_{k+1}) ∈ EvolveInv(M'(R'_k), op_π(arg)).
- (b) Case: ℓ is an intermediate line of $op_{\pi}(arg)$. $C(L_{k+1})$ must result from linearizing some sequence of processes $\alpha_1, \ldots, \alpha_h$ after $C(L_k)$. Thus, $C(L_{k+1}) \in Evolve(\mathcal{M}'(R'_k))$.
- (c) Case: ℓ is a **return** res statement from a procedure $op_{\pi}(arg)$. $C(L_{k+1})$ must result from some processes $\alpha_1, \ldots, \alpha_{h_1}$ linearizing, then π_{k+1} returning res then $\alpha_{h_1+1}, \ldots, \alpha_{h_2}$ linearizing after $C(L_k)$ for some $0 \le h_1 \le h_2$. However, since linearizing an operation before or after a return makes no

difference to the final configuration, we can obtain the same $C(L_{k+1})$ after $C(L_k)$ by π returning res and then linearizing $\alpha_1, \ldots, \alpha_{h_2}$. Thus, $C(L_{k+1}) \in EvolveRet(\mathcal{M}'(R'_k), \pi, res)$.

That completes the proof of the only if direction.

- 2. To prove the *if* direction, we assume that there is a tracker \mathcal{O}' that always maintains a singleton meta-configuration \mathcal{M}' . We now recursively define a prefix preserving linearization function \mathcal{L} on runs of $\mathcal{A}(\mathcal{O})$, such that for coupled runs R of \mathcal{O} and R' of \mathcal{O}' , $\mathcal{M}'(R') = C(\mathcal{L}(R))$:
 - If R₀ is a zero event run of A(O), define L(R₀) ≜ (σ₀, f₀). (This is clearly a (indeed the only) linearization of R₀.)
 - If R_k is a k event run for $k \ge 0$, consider the prefix run R_{k-1} such that $R_k = R_{k-1}, (\pi_k, \ell_k), C(R_k)$. Also consider the corresponding k - 1 and k event coupled runs of \mathcal{O}' : R'_{k-1} and R'_k , and their metaconfigurations: $\mathcal{M}'(R'_{k-1}) = \{C_{k-1}\}$ and $\mathcal{M}'(R'_k) = \{C_k\}$. We now finish the definition with three cases:
 - (a) Case: ℓ is the invocation of $op_{\pi}(arg)$. C_k must result from π invoking $op_{\pi}(arg)$ and some sequence of processes $\alpha_1, \ldots, \alpha_h$ linearizing after $C_{k-1} = \mathcal{L}(R_{k-1})$. We define $\mathcal{L}(R_k)$ to be the run resultant from $\mathcal{L}(R_{k-1})$ being extended by that invocation and those linearization events.
 - (b) Case: ℓ is an intermediate line of $op_{\pi}(arg)$. C_k must result from some sequence of processes $\alpha_1, \ldots, \alpha_h$ linearizing after $C_{k-1} = \mathcal{L}(R_{k-1})$. We define $\mathcal{L}(R_k)$ to be the run resultant from $\mathcal{L}(R_{k-1})$ being extended by those linearization events.
 - (c) Case: ℓ is a **return** res statement from a procedure $op_{\pi}(arg)$. C_k must result from π returning res and some sequence of processes $\alpha_1, \ldots, \alpha_h$ linearizing after $C_{k-1} = \mathcal{L}(R_{k-1})$. We define $\mathcal{L}(R_k)$ to be the run resultant from $\mathcal{L}(R_{k-1})$ being extended by that return and those linearization events.

By construction, we see that \mathcal{L} is a prefix preserving linearization function of the runs of implementation \mathcal{O} . That concludes the proof.

C Herlihy-Wing Queue Full Invariant

We present the strengthened invariant \mathcal{I} of the Herlihy-Wing queue implementation in Figure 6. \mathcal{I} is a conjunction, with \mathcal{I}_L among its conjuncts. Thus, when we prove its invariance, we have \mathcal{I}_L by implication. The remaining conjuncts can be understood as follows:

- The conjuncts $\mathcal{I}_X, \mathcal{I}_Q, \mathcal{I}_v, \mathcal{I}_i, \mathcal{I}_l, \mathcal{I}_j, \mathcal{I}_x, \mathcal{I}_{pc}, \mathcal{I}_M$ express type safety. That is, the various variables in the algorithm always take on values that we would expect satisfy their types.
- The conjuncts $\mathcal{I}_{1,5}$, \mathcal{I}_2 , \mathcal{I}_3 , \mathcal{I}_4 , \mathcal{I}_6 , \mathcal{I}_7 , \mathcal{I}_8 , \mathcal{I}_9 express truths that pertain to a process π when its program counter pc_{π} has a particular value, both regarding the meta-configurations permitted by the suggested tracker, as well as the values of the variables of the original implementation.
- The conjuncts \mathcal{I}_a and \mathcal{I}_b express general truths about the implementation and the tracker. \mathcal{I}_a asserts that for any index k of Q greater than X 1, it is the case that $Q[k] = \bot$, which should be trivial since X denotes the foremost unused index of Q. The discussion of \mathcal{I}_b requires defining a number of additional predicates first.

Let us first define a predicate GoodEnqSet that, given a set A of indices between 1 and X-1, determines whether the set can correspond to a set of linearized ENQUEUE operations. If an index $k \in [X - 1]$ corresponds to a non- \bot element stored in Q, then it comes from a linearized ENQUEUE operation and must appear in A. Otherwise, an index k that appears in A and is such that $Q[k] = \bot$, must appear in A by virtue of the existence of a process π at line 3, that has claimed k as the index of Q it will write its argument into. We can then formally define GoodEnqSet(A) for any $A \subseteq [X - 1]$ as follows:

$$GoodEnqSet(A) \triangleq \forall k \in [X-1] : (Q[k] \neq \bot \implies k \in A)$$

$$\land ((Q[k] = \bot \land k \in A) \implies \exists \pi' \in \Pi : pc_{\pi'} = 3 \land i_{\pi'} = k).$$

Figure 6: Invariant \mathcal{I} of $\mathcal{A}(\overline{\mathcal{O}})$, where $\overline{\mathcal{O}}$ is the implementation of the queue tracker in Figure 4.

$$\begin{split} \mathcal{I} \equiv \mathcal{I}_L \\ & \wedge \ \mathcal{I}_X \wedge \mathcal{I}_Q \wedge \mathcal{I}_v \wedge \mathcal{I}_i \wedge \mathcal{I}_l \wedge \mathcal{I}_j \wedge \mathcal{I}_x \wedge \mathcal{I}_{pc} \wedge \mathcal{I}_{\mathcal{M}} \\ & \wedge \ \mathcal{I}_{1,5} \wedge \mathcal{I}_2 \wedge \mathcal{I}_3 \wedge \mathcal{I}_4 \wedge \mathcal{I}_6 \wedge I_7 \wedge \mathcal{I}_8 \wedge \mathcal{I}_9 \\ & \wedge \ \mathcal{I}_a \wedge \mathcal{I}_b \end{split}$$

In the above expression, the various conjuncts on the right hand side are defined below.

$$\begin{split} & \mathcal{I}_{L} \equiv \mathcal{M} \neq \emptyset \\ & \mathcal{I}_{X} \equiv X \in \mathbb{N}^{+} \\ & \mathcal{I}_{Q} \equiv \forall k \in \mathbb{N}^{+} : Q[k] \in \mathbb{N}^{+} \cup \{\bot\} \\ & \mathcal{I}_{v} \equiv \forall \pi \in \Pi : v_{\pi} \in \mathbb{N}^{+} \\ & \mathcal{I}_{i} \equiv \forall \pi \in \Pi : v_{\pi} \in \mathbb{N}^{+} \\ & \mathcal{I}_{i} \equiv \forall \pi \in \Pi : i_{\pi} \in \mathbb{N}^{+} \\ & \mathcal{I}_{j} \equiv \forall \pi \in \Pi : i_{\pi} \in \mathbb{N}^{+} \\ & \mathcal{I}_{j} \equiv \forall \pi \in \Pi : p_{\pi} \in [9] \\ & \mathcal{I}_{M} \equiv \mathcal{M} \subseteq \{(\sigma, f) : \sigma \in \bigcup_{n \in N} (\mathbb{N}^{+})^{n}, \\ & f \in (\text{ENQUEUE}, \text{DEQUEUE}\} \times (\mathbb{N}^{+} \cup \{\bot\}) \times (\mathbb{N}^{+} \cup \{ack, \bot\}))^{\Pi} \} \\ & \mathcal{I}_{1,5} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{1,5\} \implies f(\pi) = (\bot, \bot, \bot) \\ & \mathcal{I}_{2} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 2 \implies f(\pi) = (\text{ENQUEUE}, v_{\pi}, \bot) \\ & \mathcal{I}_{3} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 3 \implies f(\pi) \in \{\text{ENQUEUE}\} \times \{v_{\pi}\} \times \{ack, \bot\} \\ & \wedge (1 \leq i_{\pi} < X) \land (Q[i_{\pi}] = \bot) \\ & \wedge (\forall \pi' \in \Pi - \{\pi\} : pc_{\pi'} \in \{3,4\} \implies i_{\pi'} \neq i_{\pi}) \\ \end{cases} \\ & \mathcal{I}_{4} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 6 \implies f(\pi) \in (\text{ENQUEUE}\} \times \{v_{\pi}\} \times \{ack, \bot\} \\ & \wedge (1 \leq i_{\pi} < X) \\ & \wedge (\forall \pi' \in \Pi - \{\pi\} : pc_{\pi'} \in \{3,4\} \implies i_{\pi'} \neq i_{\pi}) \\ \end{cases} \\ & \mathcal{I}_{4} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 6 \implies f(\pi) = (\text{DEQUEUE}, \bot, \bot) \land 1 \le l_{\pi} \le X \\ & \mathcal{I}_{8} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 9 \implies f(\pi) = (\text{DEQUEUE}, \bot, \bot) \land 1 \le j_{\pi} < I_{\pi} \le X \\ & \mathcal{I}_{9} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 9 \implies f(\pi) \in (\text{DEQUEUE} \times \{\bot\} \times (\mathbb{N}^{+} \cup \{\bot\}) \\ & \mathcal{I}_{a} \equiv \forall k \in \mathbb{N}^{+} : k > X - 1 \implies \emptyset[k] = \bot \\ & \mathcal{I}_{b} \equiv \forall A \subseteq [X - 1] : \text{GoodEngStel}(A) \\ \implies (\forall S \in \text{Perm}(A) : (JInvSeq(S) \\ \implies (\exists C \in \mathcal{M} : \text{GoodRes}(A, C) \land ValuesMatchInds(s, C))))) \\ \end{aligned}$$

Let us then consider the responses processes should receive under specific linearizations. If a process π is at line 4 or 9, its operation must have been linearized and the process must have been assigned a return value of either *ack* or x_{π} , respectively for ENQUEUE and DEQUEUE. Moreover, it must have been assigned a response value of *ack* at line 3 if π , or some other process, linearized π 's ENQUEUE as part of their update to \mathcal{M} in line 2. With this observation, let A be a conjectured set of the indices of Q between 1 and X - 1, claimed for use by the linearized ENQUEUE operations. Then, any π at line 3 whose picked index i_{π} appears in A, must also be linearized and also assigned a return value of *ack*. Besides these three cases, no other processes are assigned return values. In the light of these observations, for a conjectured set of linearized ENQUEUE indices $A \subseteq [X - 1]$ and a configuration $C \in \mathcal{M}$, let us define the predicate

GoodRes(A, C) which indicates that the response field of C.f has return values that correspond to the linearizations conjectured by A:

$$GoodRes(A,C) \triangleq \forall \pi' \in \Pi : C.f(\pi').res = \begin{cases} ack & \text{if } pc_{\pi'} = 3 \land i_{\pi'} \in A \\ ack & \text{if } pc_{\pi'} = 4 \\ x_{\pi'} & \text{if } pc_{\pi'} = 9 \\ \bot & \text{otherwise.} \end{cases}$$

Akin to how we define a valid correspondence between the response fields of configurations in \mathcal{M} and return values resulting from particular conjectured linearizations in GoodRes, we can also define a correspondence between the state fields of configurations and the values of variables in the implementation. If s, a permutation of $A \subseteq [X - 1]$, is a sequence of indices in the order which the corresponding enqueue operations are conjectured to linearize, then the state of the implemented object should be a sequence of values pointed to by the indices (or in the case where the value pointed to by the index is \bot , the argument of the process having picked the given index), in the order the indices appear in s. Then, for any $s \in Perm(A)$ where $A \subseteq [X - 1]$ and a configuration $C \in \mathcal{M}$, let us define the predicate ValuesMatchInds(s, C), which indicates that $C.\sigma$ indeed corresponds to the order of linearizations conjectured by the sequence of indices s:

$$\begin{aligned} ValuesMatchInds(s,C) &\triangleq C.\sigma = (\alpha_1,\alpha_2,\ldots,\alpha_{|s|}) \text{ where} \\ \alpha_k &= \begin{cases} Q[s_k] & \text{if } Q[s_k] \neq \bot \\ v_{\pi'} & \text{where } \pi' \in \Pi : pc_{\pi'} = 3 \land i_{\pi'} = s_k. \end{cases} \end{aligned}$$

We note that this is a well-defined expression for all A where GoodEnqSet(A) holds true, as this would (along with invariant \mathcal{I}_3) guarantee the existence of a unique process π' where the second case is applicable.

For the final necessary definition, let us once again consider a permutation s of a set $A \subseteq [X - 1]$ of the conjectured set of indices claimed for use by the linearized ENQUEUE operations, and reflect about what might render s a potentially correct sequence of linearizations. Before all else, if s is simply the sequence of non-empty indices of Q in the order in which they appear in Q, it should clearly represent a potentially correct sequence of linearizations, since an incoming dequeuing process can execute successive DEQUEUE operations and indeed empty the queue in this order, meaning that this sequence corresponds to a potentially correct state of the implemented object. Let us consider the cases where s does not follow this order, and suppose there exists a pair m, n such that n < m yet $s_m < s_n$. In this case, if s_m points to an empty component in Q, s constitutes a potentially correct ordering of the indices, as a dequeuing process might very well pass through s_m as it loops through indices, before reaching s_n . However, if $Q[s_m] \neq \bot$, it is not immediately clear whether s is a potentially correct ordering. In order to be able to justify this, we must ensure that there is a dequeuing process π which is past s_m in its loop (i.e. $s_m < j_{\pi}$), such that $s_n < l_{\pi}$ (which would otherwise fall outside the scope of indices π could dequeue from).

Then, to capture this idea, let an *inversion* for a sequence s of indices of Q, denote a pair $m, n \in [|s|]$ for which $n < m, s_m < s_n$ and $Q[s_m] \neq \bot$. For a sequence of indices to correspond to a potentially correct sequence of linearizations, the inversions it contains must all be *justified*. A *justified inversion*, as discussed in the preceding paragraph, is an inversion for which there is a dequeuing process π at line 8, such that $s_n < l_{\pi}$ and $s_m < j_{\pi}$. We can formally define this as a predicate JInvSeq(s), for $s \in Perm(A)$ for some $A \subseteq [X - 1]$, as follows:

$$JInvSeq(s) \triangleq \forall m, n \in [|s|] : (n < m \land s_m < s_n \land Q[s_m] \neq \bot) \implies (\exists \pi' \in \Pi : pc_{\pi'} = 8 \land s_n < l_{\pi'} \land s_m < j_{\pi'}).$$

This finishes the definition of *I*. Our TLAPS-certified proof of this invariant and the linearizability of the Herlihy-Wing queue can be found at: https://github.com/uguryavuz/machine-certified-linearizability.

D The Jayanti-Tarjan Union-Find Object

In this section, we consider Jayanti and Tarjan's concurrent union-find implementation [25, 23, 26], and describe our TLAPS certified proof of its strong linearizability. We chose Jayanti and Tarjan's algorithm due its extensive use in practice—it is the fastest algorithm for computing connected components of a graph on CPUs [10] and GPUs [20], and has several other applications [2].

D.1 The Union-Find Type

The union-find type maintains a partition of the *elements* in $[n] = \{1, 2, ..., n\}$ and supports two operations.

- FIND(x) returns the maximum element in element x's part of the partition.
- UNITE(x, y) merges the parts containing x and y if they are different and returns ack.

Formally, we specify the partition as a function $\sigma : [n] \to \mathcal{P}([n])$ from the set of elements to the powerset of the set of elements, such that $\sigma(x)$ is the part containing element x. Of course, if two elements x and y are in the same part of the partition, then $\sigma(x) = \sigma(y)$. We give the full formal specification of the union-find type in the figure Object Type D.1.

Object Type D.1 (Union-Find Object). A union-find type of *n* elements $[n] = \{1, ..., n\}$ is described as follows: • $\Sigma = \left\{ \sigma : [n] \rightarrow \mathcal{P}([n]) \mid \{\sigma(x) \mid x \in [n]\} \text{ is a partition of } [n], \text{ and } \forall x \in [n] : x \in \sigma(x) \right\}$ • $OP = \{\text{UNITE, FIND}\}$ • $ARG_{\text{UNITE}} = [n] \times [n], ARG_{\text{FIND}} = [n]$ • $RES = \{ack\} \cup [n]$ • Transition function δ is defined by: - $\delta(\sigma, \pi, \text{FIND}, x) = \max \sigma(x)$ - $\delta(\sigma, \pi, \text{UNITE}, (x, y)) = \begin{cases} (\sigma, ack), & \text{if } \sigma(x) = \sigma(y) \\ (\sigma', ack), & \text{if } \sigma(x) \neq \sigma(y) \\ (\sigma', ack), & \text{if } \sigma(x) \neq \sigma(y) \\ \text{where } \forall z \notin \sigma(x) \cup \sigma(y), \sigma'(z) = \sigma(z) \\ \text{and} \quad \forall z \in \sigma(x) \cup \sigma(y), \sigma'(z) = \sigma(x) \cup \sigma(y) \end{cases}$

D.2 The Jayanti-Tarjan Union-Find Implementation

We present Jayanti and Tarjan's implementation of union-find in Figure 7. Each numbered line in the implementation requires the performance of at most one shared memory instruction, and is performed atomically.

A special note about our implementation In the implementation, each element is represented by a node, and each node z has a parent pointer field z.par that points to another node. Each part of the partition is represented as a single parent pointer tree, so $\sigma(z) = \sigma(z.par)$, and we maintain the invariant that the parent of z is always greater than or equal to z (i.e. $z.par \ge z$). Thus, the roots of the trees are the largest elements in their respective partition; if w is a root of its tree than w.par = w. In the initial state σ_0 , all elements are in their own singleton part of the partition, i.e. $\forall z \in [n], \sigma_0(z) = \{z\}$. Correspondingly, the implementation starts with $\forall z \in [n], z.par = z$.

With this representation, a process π could perform FIND_{π}(x_{π}) by starting a node u_{π} at x_{π} (line 1), walking u_{π} up the parent pointers until it reaches a root, and returning that root, which must be the maximum element in the set. However, for efficiency of future find operations, the Jayanti and Tarjan observed that it helps to *compact the tree*, i.e., change the parent pointers of the intermediate nodes encountered along the x_{π} -to-root *find path* to point closer to the root. They presented two variants of compaction for their algorithm [26], called: *one-try splitting* and *two-try splitting*. In one-try splitting: for each intermediate node u_{π} on the find path, the implementation attempts to *improve* u_{π} .par from its parent a_{π} (line 2), to its grand-parent b_{π} (line 3) via a CAS, and then moves on to the next node (the **goto** line

Base Objects:

• x.par is a Read/CAS register initialized to x.par = x, for each node $x \in [n]$.

1: procedure \mathcal{O} .FIND_{π} (x_{π}) $u_{\pi} \leftarrow x_{\pi}$ $a_{\pi} \leftarrow u_{\pi}.par$ 2: if $u_{\pi} = a_{\pi}$ then goto line 6 3: $b_{\pi} \leftarrow a_{\pi}.par$ $CAS(u_{\pi}.par, a_{\pi}, b_{\pi})$; goto line 2 or 5 4: $u_{\pi} \leftarrow a_{\pi}$; goto line 2 5: 6: return u_{π} 7: **procedure** \mathcal{O} .UNITE_{π} (x_{π}, y_{π}) $u_{\pi} \leftarrow x_{\pi}; v_{\pi} \leftarrow y_{\pi}$ if $u_{\pi} = v_{\pi}$ then goto line 17 8: else if $u_{\pi} < v_{\pi}$ then if CAS $(u_{\pi}.par, u_{\pi}, v_{\pi})$ then goto line 17 else if $u_{\pi} > v_{\pi}$ then if CAS $(v_{\pi}.par, v_{\pi}, u_{\pi})$ then goto line 17 9: $a_{\pi} \leftarrow u_{\pi}.par$ if $u_{\pi} = a_{\pi}$ then goto line 13 10: $b_{\pi} \leftarrow a_{\pi}.par$ $CAS(u_{\pi}.par, a_{\pi}, b_{\pi})$; goto line 9 or 12 11: 12: $u_{\pi} \leftarrow a_{\pi}$; goto line 9 13: $a_{\pi} \leftarrow v_{\pi}.par$ if $v_{\pi} = a_{\pi}$ then goto line 8 14: $b_{\pi} \leftarrow a_{\pi}.par$ $CAS(v_{\pi}.par, a_{\pi}, b_{\pi})$; goto line 13 or 16 15: 16: $v_{\pi} \leftarrow a_{\pi}$; goto line 13 return ack 17: Figure 7: Jayanti and Tarjan's implementation of a union-find object on n nodes $\{1, 2, \ldots, n\}$ each initially in its own singleton part of the partition, i.e., the initial state is $\sigma_0: [n] \to \mathcal{P}([n])$ defined by $\forall x \in [n], \sigma_0(x) = x$.

5 path on line 4). In two-try splitting: the implementation attempts to improve each u_{π} .par again (the **goto** line 2 path on line 4). Using non-determinism at line 4, we have incorporated both variants into a single implementation. In fact, our implementation allows any number of tries on each intermediate node (by taking the **goto** line 2 path repeatedly), and varying number of tries on different nodes. Our proof thereby applies to a wide class of concurrent union-find variants that we dub "any-try splitting". Incidentally, two-try splitting has the better theoretical efficiency bound [26], but one-try splitting seems to perform slightly better in practice on most test cases [10, 20]. To our knowledge, other variations of any-try splitting are yet to be tested in practice. Splitting is also done when the implementation walks up the path from x_{π} and y_{π} in the UNITE procedure (lines 9-16), and we similarly apply our non-determinism strategy to incorporate any-try splitting (lines 11 and 15). Otherwise, our implementation mimics the original implementation of Jayanti and Tarjan [25].

D.3 The Tracker

We present our partial tracker in Figure 8. Since we are proving *strong linearizability*, rather than just linearizability, we choose a partial tracker that will ensure that there will be exactly one configuration in the meta-configuration variable \mathcal{M} at any point in time. Our key insight into the implementation to write down this tracker is our ability to identify a unique linearization point for each operation.

```
Base Objects:
           • x.par is a Read/CAS register initialized to x.par = x, for each node x \in [n].
          • \mathcal{M} initialized to \{(\sigma_0, f_0)\} is a meta-configuration, where \sigma_0 maps each x \in [n] to \{x\} and f_0 maps each
              \pi \in \Pi to (\bot, \bot, \bot).
 1: procedure \overline{\mathcal{O}}.FIND<sub>\pi</sub>(x_{\pi})
           u_{\pi} \leftarrow x_{\pi}
           \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, FIND_{\pi}(x_{\pi}))\}
           a_{\pi} \leftarrow u_{\pi}.par
2:
           if u_{\pi} = a_{\pi} then
                  \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = \delta^*(C, \pi)\}
                  goto line 6
           b_{\pi} \leftarrow a_{\pi}.par
 3:
           CAS(u_{\pi}.par, a_{\pi}, b_{\pi}); goto line 2 or 5
 4:
           u_{\pi} \leftarrow a_{\pi}; goto line 2
 5:
           return u_{\pi}
 6:
           \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, u_{\pi})\}
 7: procedure \overline{\mathcal{O}}.UNITE<sub>\pi</sub>(x_{\pi}, y_{\pi})
           u_{\pi} \leftarrow x_{\pi}; v_{\pi} \leftarrow y_{\pi}
           \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, \mathsf{UNITE}_{\pi}(x_{\pi}, y_{\pi}))\}
           if u_{\pi} = v_{\pi} then goto line 17
 8:
           else if u_{\pi} < v_{\pi} then if CAS(u_{\pi}.par, u_{\pi}, v_{\pi}) then goto line 17
           else if u_{\pi} > v_{\pi} then if CAS(v_{\pi}.par, v_{\pi}, u_{\pi}) then goto line 17
           if (u_{\pi} = v_{\pi}) \lor (u_{\pi} < v_{\pi} \land u_{\pi} = u_{\pi}.par) \lor (u_{\pi} > v_{\pi} \land v_{\pi} = v_{\pi}.par) then
                  \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = \delta^*(C, \pi)\}
           a_{\pi} \leftarrow u_{\pi}.par
9:
           if u_{\pi} = a_{\pi} then goto line 13
           b_{\pi} \leftarrow a_{\pi}.par

14:
           b_{\pi} \leftarrow a_{\pi}.par
           CAS(v_{\pi}.par, a_{\pi}, b_{\pi}); goto line 13 or 16
15:
           v_{\pi} \leftarrow a_{\pi}; goto line 13
16:
17:
           return ack
           \mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, ack)\}
                            Figure 8: Tracker \overline{\mathcal{O}} for the union-find implementation \mathcal{O} presented in Figure 7.
```

D.4 Proving The Invariant

Our task is to prove that the statement $\mathcal{I}_S \equiv (|\mathcal{M}| = 1)$ is an invariant of $\mathcal{A}(\overline{\mathcal{O}})$ in order to deduce that \mathcal{O} is strongly linearizable. Of course, \mathcal{I}_S implies $\mathcal{I}_L \equiv (\mathcal{M} \neq \emptyset)$, so we also obtain the result that the Jayanti-Tarjan union-find is linearizable. (Of course, any strongly linearizable implementation is linearizable, so there is no surprise here.)

We present our strengthened invariant \mathcal{I} in Figure 9, which is conjunction with \mathcal{I}_S and \mathcal{I}_L as conjuncts. Our TLAPS-verified proof of \mathcal{I} , and the corollaries that \mathcal{I}_S and \mathcal{I}_L are invariants of $\overline{\mathcal{O}}$ are publicly available in the GitHub repository, and certify that all variants of the Jayanti-Tarjan union-find object are strongly linearizable.

Figure 9: Invariant \mathcal{I} of $\mathcal{A}(\overline{\mathcal{O}})$, where $\overline{\mathcal{O}}$ is the union-find tracker in Figure 8. $\mathcal{I} \equiv \mathcal{I}_L \wedge \mathcal{I}_S$ $\land \ \mathcal{I}_{par} \land \mathcal{I}_{x} \land \mathcal{I}_{y} \land \mathcal{I}_{y} \land \mathcal{I}_{v} \land \mathcal{I}_{a} \land \mathcal{I}_{b} \land \mathcal{I}_{pc} \land \mathcal{I}_{\mathcal{M}}$ $\wedge \mathcal{I}_{UF1} \wedge \mathcal{I}_{UF2} \wedge \mathcal{I}_{UF3} \wedge \mathcal{I}_{UF4} \wedge \mathcal{I}_{UF5}$ $\wedge \ \mathcal{I}_{1.7} \wedge \mathcal{I}_2 \wedge \mathcal{I}_3 \wedge \mathcal{I}_{4.5} \wedge \mathcal{I}_6 \wedge \mathcal{I}_{8.9,13} \wedge \mathcal{I}_{10} \wedge \mathcal{I}_{11,12} \wedge \mathcal{I}_{14} \wedge \mathcal{I}_{15,16} \wedge \mathcal{I}_{17}$ In the above expression, the various conjuncts on the right hand side are defined below. • $\mathcal{I}_L \equiv \mathcal{M} \neq \emptyset$ • $\mathcal{I}_S \equiv |\mathcal{M}| = 1$ • $\mathcal{I}_{par} \equiv \forall z \in [n] : z.par \in [n]$ • $\mathcal{I}_x \equiv \forall \pi \in \Pi : x_\pi \in [n]$ • $\mathcal{I}_{y} \equiv \forall \pi \in \Pi : y_{\pi} \in [n]$ • $\mathcal{I}_u \equiv \forall \pi \in \Pi : u_\pi \in [n]$ • $\mathcal{I}_v \equiv \forall \pi \in \Pi : v_\pi \in [n]$ • $\mathcal{I}_a \equiv \forall \pi \in \Pi : a_\pi \in [n]$ • $\mathcal{I}_b \equiv \forall \pi \in \Pi : b_\pi \in [n]$ • $\mathcal{I}_{pc} \equiv \forall \pi \in \Pi : pc_{\pi} \in [17]$ • $\mathcal{I}_{\mathcal{M}} \equiv \mathcal{M} \subseteq \{(\sigma, f) : \sigma \in \mathcal{P}([n])^{[n]}, f \in (\{\text{FIND}, \text{UNITE}\} \times ([n] \cup [n]^2]) \times ([n] \cup \{ack, \bot\}))^{\Pi}\}$ • $\mathcal{I}_{UF1} \equiv \forall z \in [n] : z.par \ge z$ • $\mathcal{I}_{UF2} \equiv \forall z \in [n] : \forall (\sigma, f) \in \mathcal{M} : z \in \sigma(z)$ • $\mathcal{I}_{UF3} \equiv \forall w, z \in [n] : \forall (\sigma, f) \in \mathcal{M} : (w \in \sigma(z) \implies \sigma(w) = \sigma(z))$ • $\mathcal{I}_{UF4} \equiv \forall w, z \in [n] : \forall (\sigma, f) \in \mathcal{M} : (w.par = z \implies \sigma(w) = \sigma(z))$ • $\mathcal{I}_{UF5} \equiv \forall w, z \in [n] : \forall (\sigma, f) \in \mathcal{M} : ((w \neq z \land w.par = w \land z.par = z) \implies \sigma(w) \neq \sigma(z))$ • $\mathcal{I}_{1,7} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{1, 7\} \implies f(\pi) = (\bot, \bot, \bot)$ • $\mathcal{I}_2 \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 2 \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) \land f(\pi) = (\text{FIND}, x_{\pi}, \bot))$ • $\mathcal{I}_3 \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 3 \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) = \sigma(a_{\pi}) \land f(\pi) = (\text{FIND}, x_{\pi}, \bot))) \land a_{\pi} \ge u_{\pi}$ • $\mathcal{I}_{4,5} \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{4, 5\} \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) = \sigma(b_{\pi}) = \sigma(b_{\pi})$ $\wedge f(\pi) = (\text{FIND}, x_{\pi}, \bot))) \wedge b_{\pi} \geq a_{\pi} \geq u_{\pi}$ • $\mathcal{I}_6 \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_\pi = 6 \implies f(\pi) = (Find, x_\pi, u_\pi))$ • $\mathcal{I}_{8,9,13} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{8, 9, 13\} \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) \land \sigma(v_{\pi}) = \sigma(y_{\pi})$ $\wedge f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), \bot))$ • $\mathcal{I}_{10} \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 10 \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) = \sigma(a_{\pi})) \land \sigma(v_{\pi}) = \sigma(y_{\pi})$ $\wedge f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), \bot))) \wedge a_{\pi} \geq u_{\pi}$ • $\mathcal{I}_{11,12} \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{11, 12\} \implies (\sigma(u_{\pi}) = \sigma(x_{\pi}) = \sigma(b_{\pi}))$ $\wedge \, \sigma(v_{\pi}) = \sigma(y_{\pi})$ $\wedge f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), \bot))) \wedge b_{\pi} \geq a_{\pi} \geq u_{\pi}$ • $\mathcal{I}_{14} \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 14 \implies (\sigma(v_{\pi}) = \sigma(y_{\pi}) = \sigma(a_{\pi}) \land \sigma(u_{\pi}) = \sigma(x_{\pi}))$ $\wedge f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), \bot))) \wedge a_{\pi} \geq v_{\pi}$ • $\mathcal{I}_{15,16} \equiv \forall \pi \in \Pi : (\forall (\sigma, f) \in \mathcal{M} : pc_{\pi} \in \{15, 16\} \implies (\sigma(v_{\pi}) = \sigma(y_{\pi}) = \sigma(a_{\pi})) = \sigma(b_{\pi}))$ $\wedge \, \sigma(u_{\pi}) = \sigma(x_{\pi})$ $\wedge f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), \bot))) \wedge b_{\pi} \geq a_{\pi} \geq v_{\pi}$ • $\mathcal{I}_{17} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : pc_{\pi} = 17 \implies f(\pi) = (\text{UNITE}, (x_{\pi}, y_{\pi}), ack))$

E Jayanti's Single-Writer Single-Scanner Snapshot

In this example, we apply our technique to Jayanti's single-scanner, single-writer snapshot object implementation [22] and produce a machine-certified proof of its linearizability by TLAPS. Below, we simply present the formal data type definition, the implementation and our partial tracker for it, and the complete inductive invariant. Recall once again, that in order to verify the linearizability of the implementation, it suffices to check that the partial tracker is indeed well-formed and confirm that TLAPS has verified the invariant $\mathcal{M} \neq \emptyset$.

E.1 The Single-Scanner, Single-Writer Snapshot Type

An *m*-component snapshot object embodies an array of *m* elements from \mathbb{N}^+ that supports two operations:

- WRITE(i, v) writes v into the *i*th component of the array.
- SCAN() retrieves the state of the array.

Additionally, a single-scanner, single-writer snapshot object has two constraints: (1) no two SCAN() operations may be concurrent with each other, and (2) no two WRITE(i, v) and WRITE(i, v') operations may be concurrent with each other. Therefore, for any implementation \mathcal{O} of the single-scanner, single-writer snapshot, the generator algorithm $\mathcal{A}(\mathcal{O})$ picks operations and arguments such that the following property is maintained:

$$\mathcal{I}_{SWSS} \equiv \forall \pi, \pi' \in \Pi : op_{\pi} = op_{\pi'} \land \pi \neq \pi' \implies op_{\pi} = \text{WRITE} \land i_{\pi} \neq i_{\pi'}$$

We provide the full formal specification of the single-writer, single-scanner snapshot object in the figure Object Type E.1.

Object Type E.1 (Single-writer, single-scanner snapshot). A single-writer, single-scanner snapshot of size m with elements from \mathbb{N}^+ is described as follows:

- $\Sigma = (\mathbb{N}^+)^m$
- $OP = \{WRITE, SCAN\}$
- $ARG_{WRITE} = (\{0, \dots, m-1\}, \mathbb{N}^+), ARG_{SCAN} = \{\bot\}.$
- $RES = \{ack\} \cup (\mathbb{N}^+)^m$
- Transition function δ is defined as follows:

- $\delta(\sigma, \pi, \text{WRITE}, (i, v)) = (\sigma', ack)$, where $\sigma'[i] = v \land \forall k \in \{0, \dots, m-1\} : k \neq i \implies \sigma[i] = \sigma'[i]$

- $\delta(\sigma, \pi, \mathbf{SCAN}, \bot) = (\sigma, \sigma)$

E.2 The Jayanti Single-Writer, Single-Scanner Snapshot Implementation

We present the Jayanti implementation of the single-scanner, single-writer object in Figure 10. As before, each numbered line in the implementation requires the performance of at most one shared memory instruction and is performed atomically. For brevity, we omit the modified generator $\mathcal{A}(\mathcal{O})$ and the constraint \mathcal{I}_{SWSS} .

Base Objects:

- A[0, ..., m-1] is a read/write array initialized to the desired initial state of the object.
- $B[0, \ldots, m-1]$ is a read/write array, arbitrarily initialized.
- X is a Boolean initialized to *false*.

1: **procedure** \mathcal{O} .WRITE_{π} (i_{π}, v_{π}) 2: $A[i_{\pi}] \leftarrow v_{\pi}$ if X then 3: $B[i_{\pi}] \leftarrow v_{\pi}$ 4: 5: return ack 6: **procedure** \mathcal{O} .SCAN_{π}() $X \gets \textit{true}$ 7: for $j_{\pi} = 0$ to m - 1 do $B[j_{\pi}] \leftarrow \bot$ 8: for $j_{\pi} = 0$ to m - 1 do $a_{\pi}[j_{\pi}] \leftarrow A[j_{\pi}]$ 9: $X \leftarrow false$ 10: for $j_{\pi} = 0$ to m - 1 do 11: $b_{\pi} \leftarrow B[j_{\pi}]$ if $b_{\pi} \neq \bot$ then $a_{\pi}[j_{\pi}] \leftarrow b_{\pi}$ return a_{π} 12:

Figure 10: Jayanti's single-writer, single-scanner snapshot implementation.

E.3 The Tracker

Our partial tracker of the implementation is shown in Figure 11. We leverage our knowledge that this implementation linearizes operations at lines 2 and 10 by augmenting these two lines.

Base Objects:

• $A[0, \ldots, m-1]$ is a read/write array initialized to the desired initial state of the object. • $B[0, \ldots, m-1]$ is a read/write array, arbitrarily initialized. • X is a Boolean initialized to *false*. • \mathcal{M} initialized to $\{(A, f_0)\}$ is a meta-configuration, where f_0 maps each process $\pi \in \Pi$ to (\bot, \bot, \bot) . 1: **procedure** $\overline{\mathcal{O}}$.WRITE_{π} (i_{π}, v_{π}) $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, WRITE_{\pi}(i_{\pi}, v_{\pi}))\}$ $A[i_{\pi}] \leftarrow v_{\pi}$ 2: $\mathcal{M} \leftarrow \mathcal{M} \cup \{C' \mid \exists C \in \mathcal{M} : C' = \delta^*(C, \pi)\}$ if X then 3: $B[i_{\pi}] \leftarrow v_{\pi}$ 4: **return** *ack* 5: $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, ack)\}$ 6: procedure $\overline{\mathcal{O}}$.SCAN_{π}() $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = invoke(C, \pi, \mathbf{SCAN}_{\pi}())\}$ $X \leftarrow true$ 7: for $j_{\pi} = 0$ to m - 1 do $B[j_{\pi}] \leftarrow \bot$ 8: for $j_{\pi} = 0$ to m - 1 do $a_{\pi}[j_{\pi}] \leftarrow A[j_{\pi}]$ 9: $X \leftarrow false$ 10: $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = \delta^*(C, \pi \circ \alpha), \alpha \in Perm(\{\pi' \in pending(C) : pc_{\pi'} \in \{3, 4, 5\}\}\})$ for $j_{\pi} = 0$ to m - 1 do 11: $b_{\pi} \leftarrow B[j_{\pi}]$ if $b_{\pi} \neq \bot$ then $a_{\pi}[j_{\pi}] \leftarrow b_{\pi}$ return a_{π} 12: $\mathcal{M} \leftarrow \{C' \mid \exists C \in \mathcal{M} : C' = return(C, \pi, a_{\pi})\}$ Figure 11: Jayanti's single-writer, single-scanner snapshot implementation.

E.4 Proving The Invariant

To prove that the statement $I_L \equiv \mathcal{M} \neq \emptyset$ is an invariant of $\mathcal{A}(\overline{\mathcal{O}})$, where $\overline{\mathcal{O}}$ is the implementation of the snapshot tracker, we begin with a few technical definitions that will help us build our inductive invariant I. First, let s be the unique element in $S \triangleq \{\pi \in \Pi : pc_{\pi} \in \{7, \ldots, 12\}\}$ or \bot if S is empty. This clearly denotes the unique active scanning process, if there exists one.

Let us then consider the possible return values for a_s for $s \neq \bot$ and, in particular, the set of values that could be returned for the kth element of the snapshot by SCAN_s. More specifically, for $k \in \{0, ..., m-1\}$, we define KthReturnSet(k) to be the set of valid values for $\sigma[k]$ before s executes line 10 and that of C.f(s).res[k] after s executes line 10 in any tracked configuration (σ, f) $\in \mathcal{M}$ and specify its value as follows:

- If $s = \bot$ or $pc_s = 7$, $KthReturnSet(k) = \{A[k]\}$.
- If $pc_s = 8$,

$$KthReturnSet(k) = \begin{cases} \{A[k], B[k]\} & \text{if } k < j_s \land B[k] \neq \bot \\ \{A[k]\} & \text{otherwise} \end{cases}$$

• If $pc_s = 9$,

$$KthReturnSet(k) = \begin{cases} \{A[k], B[k]\} & \text{if } B[k] \neq \bot \\ \{A[k], a_{\pi}[k]\} & \text{if } k < j_s \land B[k] \neq \bot \\ \{A[k]\} & \text{otherwise} \end{cases}$$

• If $pc_s = 10$,

$$KthReturnSet(k) = \begin{cases} \{A[k], B[k]\} & \text{if } B[k] \neq \bot \\ \{A[k], a_s[k]\} & \text{otherwise} \end{cases}$$

• If $pc_s = 11$,

$$KthReturnSet(k) = \begin{cases} \{A[k], B[k]\} & WB(k) \land B[k] \neq \bot \land k \ge j_s \\ \{A[k], a_s[k]\} & WB(k) \land B[k] = \bot \land k \ge j_s \\ \{B[k]\} & \neg WB(k) \land B[k] \neq \bot \land k \ge j_s \\ \{a_s[k]\} & \text{otherwise} \end{cases}$$

where $WB(k) \triangleq \exists \pi \in \Pi : pc_{\pi} = 4 \land i_{\pi} = k$, a predicate that essentially denotes whether there is a writer that could write to the kth component of B.

• If $pc_s = 12$, $KthReturnSet(k) = \{a_s[k]\}$.

Thus, the set of possible values for σ before s executes line 10 and that of C.f(s).res after s executes line 10 is ScanReturnSet, defined as

$$ScanReturnSet \triangleq KthReturnSet(0) \times \cdots \times KthReturnSet(m-1)$$

This definition helps us make some observations about configurations (σ, f) that are guaranteed to be in \mathcal{M} and to complete the inductive invariant \mathcal{I} in Figure 12 that proves I_L is an invariant of $\overline{\mathcal{O}}$. Our TLAPS-certified proof of the invariant and hence the linearizability of Jayanti's single-writer single-scanner snapshot object can be found at: https://github.com/uguryavuz/machine-certified-linearizability.

Figure 12: Invariant \mathcal{I} of $\mathcal{A}(\overline{\mathcal{O}})$, where $\overline{\mathcal{O}}$ is the implementation of the snapshot tracker in Figure 11.

$$\begin{split} \mathcal{I} \equiv \mathcal{I}_L \\ & \wedge \mathcal{I}_X \wedge \mathcal{I}_A \wedge \mathcal{I}_B \wedge \mathcal{I}_M \wedge \mathcal{I}_a \wedge \mathcal{I}_j \wedge \mathcal{I}_i \wedge \mathcal{I}_v \wedge \mathcal{I}_{pc} \\ & \wedge \mathcal{I}_{1,6} \wedge \mathcal{I}_2 \wedge \mathcal{I}_{3,4,5} \wedge \mathcal{I}_{7,8,9,10} \wedge \mathcal{I}_{11,12} \\ & \wedge \mathcal{I}_C \wedge \mathcal{I}_{W1} \wedge \mathcal{I}_{W2} \wedge \mathcal{I}_{W3} \wedge \mathcal{I}_{W4} \wedge \mathcal{I}_{S1} \wedge \mathcal{I}_{S2} \wedge \mathcal{I}_{S3} \\ & \wedge \mathcal{I}_{\mathcal{M}1} \wedge \mathcal{I}_{\mathcal{M}2} \end{split}$$

In the above expression, the various conjuncts on the right hand side are defined below.

$$\begin{split} & T_L \equiv \mathcal{M} \neq \emptyset \\ & T_X \equiv X \in \{true, false\} \\ & T_X \equiv A \in (\mathbb{N}^+)^m \\ & T_B \equiv B \in (\mathbb{N}^+ \cup \{\bot\})^m \\ & T_B \equiv B \in (\mathbb{N}^+ \cup \{\bot\})^m \\ & T_B \equiv B \in (\mathbb{N}^+ \cup \{\bot\})^m \\ & T_B \equiv B \in (\mathbb{N}^+)^m \\ & T_B \equiv B \in (\mathbb{N}^+)^m \\ & T_B \equiv a \in (\mathbb{N}^+)^m \\ & T_J \equiv \forall \pi \in \Pi : j_\pi \in \{0, \dots, m-1\} \\ & T_J \equiv \forall \pi \in \Pi : j_\pi \in \{0, \dots, m-1\} \\ & T_J \equiv \forall \pi \in \Pi : i_\pi \in \{0, \dots, m-1\} \\ & T_\pi \equiv \forall \pi \in \Pi : p_\pi \in [12] \\ & T_{1,6} \equiv \forall \pi \in \Pi : p_\pi \in [12] \\ & T_{1,6} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{C_\pi} = 2 \implies \sigma[i_\pi] = A[i_\pi] \land f(\pi) = (\mathbb{W}\operatorname{RITE}, (i_\pi, v_\pi)) \land \{ack, \bot\} \\ & T_{7,8,9,10} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{C_\pi} \in \{3, 4, 5\} \implies f(\pi) \in (\mathbb{W}\operatorname{RITE}, (i_\pi, v_\pi)) \land \{ack, \bot\} \\ & T_{7,8,9,10} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{C_\pi} \in \{3, 4, 5\} \land f(\pi) \in (\operatorname{SCAN}, \bot, \bot) \\ & T_{1,1,2} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{C_\pi} \in \{3, 4, 5\} \land f(\pi) \in (\operatorname{SCAN}, \bot) \times ((\mathbb{N}^+)^m \cup \{\bot\}) \\ & T_C \equiv \forall \pi, \pi' \in \Pi : (p_{C_\pi}, p_{C_\pi'} \in \{3, 4, 5\} \land \sigma[i_\pi] \neq A[i_\pi]) \\ \implies f(\pi) = (\mathbb{W}\operatorname{RITE}, (i_\pi, v_\pi), \bot) \\ & T_{W_1} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{C_\pi} \in \{3, 4, 5\} \land f(\pi) \in \mathbb{H} : C' = \delta^*(C, \pi) \\ & T_{W_1} \equiv \forall \pi \in \Pi : \forall (\sigma, f) \in \mathcal{M} : p_{T_\pi} \in \{1: \neg (p_{C_\pi} = \{3, 4, 5\} \land a[i_\pi] = n_\pi] \\ & T_{W_2} \equiv \forall \pi \in \Pi : p_{C_\pi} \in \{3, 4, 5\} \implies A[i_\pi] = v_\pi \\ & T_{W_2} \equiv \forall \pi \in \Pi : p_{C_\pi} \in \{3, 4, 5\} \implies A[i_\pi] = v_\pi \\ & T_{W_2} \equiv \forall \pi \in \Pi : p_{C_\pi} \in \{3, 4, 5\} \implies A[i_\pi] = v_\pi \\ & T_{W_2} \equiv \forall \pi \in \Pi : p_{C_\pi} \in \{3, 4, 5\} \implies A[i_\pi] = v_\pi \\ & T_{W_3} \equiv \exists \pi \in \Pi : p_{C_\pi} \in \{8, 9, 10\} \iff X = true \\ & T_{S_2} \equiv \forall \pi \in \Pi : \forall k \in \{0, \dots, m - 1\} : ((p_{C_\pi} \in \Pi : \neg (p_{C_\pi} = \{3, 4, 5\} \land i_\pi = k)) \\ \implies \sigma[k] = a_\pi[k] \\ & T_{S_3} \equiv \forall \pi \in \Pi : \forall k \in \{0, \dots, m - 1\} : (p_{C_\pi} \in \{1: 0 \cup (p_{C_\pi} = 8 \land k < j_\pi)) \land B[k] = \bot \\ \land (\forall \pi' \in \Pi : \neg (i_{\pi'} = k \land p_{C_{\pi'}} \in \{3, 4\}))) \\ \implies A[k] = a_\pi[k] \\ & T_{M_4} \equiv \forall \alpha \in ScanReturnSet : (s = \bot \lor p_{C_8} \in \{7, \dots, 10\}) \\ \implies A[k] = B[k] \\ & T_{M_4} \equiv \forall \alpha \in ScanReturnSet : (s \in 1 \lor p_{C_8} \in \{7, \dots, 10\}) \\ \implies A[k] = \pi \in M : \forall \alpha \in ScanReturnSet : (s \in 1 \lor p_{C_8} \in \{1, 1, 2\} \\ \implies \exists (\sigma, f) \in M : \sigma = A \land f(s) = (ScAn, \bot, \omega) \\ \end{aligned}$$
