Abstract

Moiré superlattices in van der Waals heterostructures offer highly tunable quantum systems with emergent electronic and excitonic properties such as superconductivity [1], topological edge states [2], and moiré-trapped excitons [3]. Theoretical calculations [4, 5] predicted the existence of the moiré potential at elevated temperatures; however, its impact on the optical properties of interlayer excitons (IXs) at room temperature is lacking, and the benefits of the moiré effects for lasing applications remain unexplored. We report that the moiré potential in a molybdenum disulfide-tungsten diselenide ($\text{MoS}_2/\text{WSe}_2$) heterobilayer system can significantly enhance light emission, elongate the IX lifetime, and modulate the IX emission energy at room temperature. By integrating a moiré superlattice with a silicon topological nanocavity, we achieve ultra-low-threshold lasing at the technologically important telecommunication O-band thanks to the significant moiré modulation. Moreover, the high-quality topological nanocavities facilitate the highest spectral coherence of < 0.1 nm linewidth among all reported two-dimensional material-based laser systems. Our findings not only open a new avenue for studying correlated states at elevated temperatures, but also enable novel architectures for integrated on-chip photonics and optoelectronics.

Keywords: 2D material, moiré superlattice, interlayer exciton, nanolaser

Introduction

Monolayer transition metal dichalcogenides (TMDs) have emerged as a new class of gain materials for lasing applications [6–10] due to their direct band gap, large exciton binding energy (on the order of 500 meV) and easy integration with various materials including the highly-developed silicon platform. The type-II band-aligned heterostructure with appropriately combined monolayer TMD gives rise to IXs, where the electrons and holes are spatially separated in different layers and bound by the Coulomb interaction. Compared to intralayer excitons in monolayer TMDs, IXs show much smaller oscillator strengths (around two to three orders of magnitude lower) and longer exciton lifetimes (ns instead of ps), thus enabling efficient IX accumulation and population inversion [11, 12]. Moreover, for such a heterostructure, it is by now widely recognized that moiré superlattices can form due to a small twist angle and lattice mismatch between two monolayers [13]. The appearance of moiré superlattices creates a lateral periodic potential for excitons, resulting in exciton localization (known as moiré excitons shown in Fig. 1a), which has been widely observed at cryogenic temperatures [3, 14, 15]. From first-principle calculations [3, 4], the depth of the moiré potential is predicted to be approximately 100-200 meV, much larger than the thermal energy of ~ 27 meV at room temperature. A very recent experiment [16] correlates the multipeak feature in IX emission spectra from free-standing WS_2/WSe_2 heterobilayers with moiré

IXs, however still lacking strong evidence for the presence of moiré potential at room temperature. Furthermore, the additional in-plane quantum confinement in moiré superlattices could potentially enhance the quantum yield of light emission and lead to a large optical gain at low pumping levels, akin to quantum dots which showed lower lasing thresholds than quantum wells and bulk materials [17]. However, the study of the moiré superlattice on laser performance has remained unexplored.

Here we report the existence of room-temperature moiré excitons in $\text{MoS}_2/\text{WSe}_2$ heterobilayers by twist-angle-dependent photoluminescence (PL) measurements, reflection contrast spectroscopy, power-dependent measurements, and time-resolved PL dynamics. We find that the moiré potential gives rise to an ultra-wide emission tunability of IXs and strongly suppressed non-radiative recombinations. By integrating moiré superlattices with silicon topological photonic crystal nanocavities, to the best of our knowledge, we for the first time explore the potential of room-temperature moiré IX for high-performance laser applications. The combination of a high-quality-factor (Q-factor, $> 10^4$) cavities and moiré IX states leads to ultra-low-threshold lasing with emission wavelength extended to the optical fibre communication (OFC) O-band (1260-1360 nm), high side-mode suppression ratio (SMSR), and the highest spectral coherence among two-dimensional (2D) layered materials based lasers [18] (Supplementary Table S2). These findings encourage studying novel exciton physics in moiré superlattices at room temperature and open new avenues for using these artificial quantum materials in high-performance device applications.

Results

In this work, we use $\text{MoS}_2/\text{WSe}_2$ heterobilayers (HB) for their bright K-K transition of IXs with emission energy below 1.1 eV [19], which is compatible with well-developed silicon photonics. Monolayer MoS_2 and WSe_2 are exfoliated mechanically and stacked with the dry transfer technique (details in Methods) [20] to obtain a clean interface and high-quality optical properties. We prepare more than 25 $\text{MoS}_2/\text{WSe}_2$ heterobilayer samples with various twist angles and all measurements are carried out at room temperature. Fig. 1b shows the peak energy of IX emission as a function of the twist angle θ . The exciton energy changes significantly with the twist angle (>200 meV), in particular at angles below 2° . This pronounced energy shift is similar to that observed in $\text{MoSe}_2/\text{WSe}_2$ heterobilayers at cryogenic temperatures, where the large energy shift is ascribed to the moiré potential on top of the twist angle-dependent momentum mismatch [21].

We further perform power-dependent measurements for two representative samples with different twist angles up to the same pumping level. For a heterobilayer of $\theta = 2.83^\circ$ (Fig. 1c), the IX has an emission energy of ~ 1.12 eV (~ 1107 nm) and this energy remains constant with increasing power. In stark contrast, a remarkable blue-shift and the emergence of high-energy states are

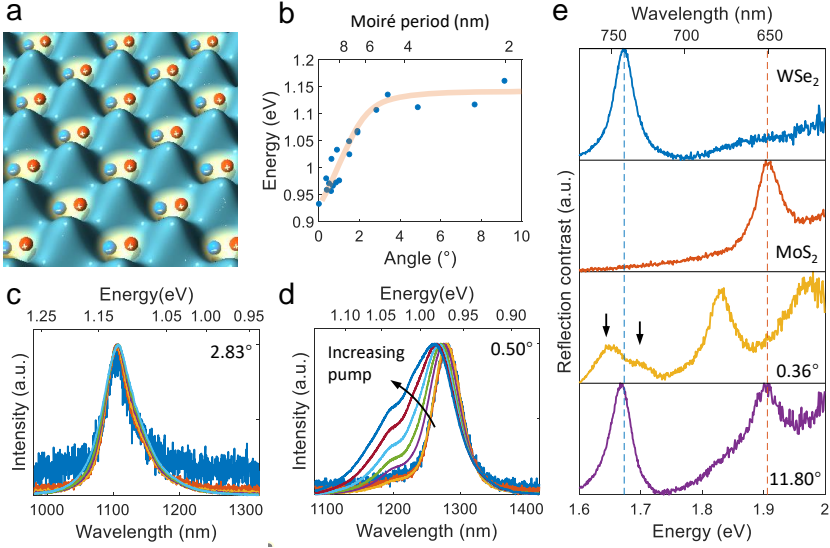

Fig. 1 Evidence of room-temperature moiré IXs in MoS₂/WSe₂ heterobilayers. (a) Schematic of IXs trapped in moiré potentials. (b) IX peak emission energy versus twist angle. The light red line is a guide to the eye. The twist angles are the relative rotation angles between the monolayers. Power-dependent PL spectra of heterobilayers with twist angles of 2.83° (c) and 0.50° (d) up to the same maximum power level. For the heterobilayer with a small twist angle in (d), the evolution with power exhibits a strong blue shift and the emergence of high-energy states, indicated by the black arrow. (e) Reflection contrast spectra of heterobilayers with twist angles of 0.36° (yellow) and 11.80° (purple), together with spectra of reference monolayers WSe₂ (blue) and MoS₂ (red). As a reference, the vertical blue (red) dashed line presents A exciton peaks for monolayer WSe₂ (MoS₂). The multi-peak appearance (two black arrows) indicates the existence of the moiré effect when the twist angle is 0.36° (yellow).

observed when $\theta = 0.50^\circ$ (Fig. 1d). We attribute these to the existence of the moiré potential that acts as an exciton reservoir for different exciton states and enhances the exciton-exciton interaction. As the potential confines excitons laterally resulting in quantized energy level [3], IXs obtain a larger chance to fill higher-energy moiré excitonic states when the pumping power increases. The filling to higher-energy states leads to the occurrence of the blue shift for the emission envelope. We also report the observation of spectrally resolved moiré states in hexagonal boron nitride (hBN) encapsulated heterobilayers, which is shown in Supplementary fig. S1 and will be discussed later.

The moiré potential not only traps IXs but also affects intralayer excitons [14]. Here we present another piece of evidence for the existence of moiré potentials at room temperature by characterizing the absorption properties of intralayer excitons using reflection contrast spectroscopy. Fig. 1e presents the reflection contrast spectra, where the reference signals of monolayer WSe₂ and MoS₂ are shown in blue and red, respectively. We focus on the WSe₂ A exciton in the range between 1.6 and 1.75 eV. The heterobilayer with the twist angle of $\sim 0.36^\circ$ (yellow) shows an emergent doublet (highlighted by two

arrows in Fig. 1e) with comparable oscillator strengths near the WSe₂ exciton (1.675 eV). By contrast, the heterobilayer with the large twist angle ($\sim 11.80^\circ$) shows a single exciton resonance. The appearance of multiple emergent peaks around the original WSe₂ exciton serves as strong evidence for the presence of moiré excitons at room temperature. It has already been observed at low temperatures [14, 22, 23] and is well explained by the theoretical model where the moiré potential generates multiple flat moiré minibands [14].

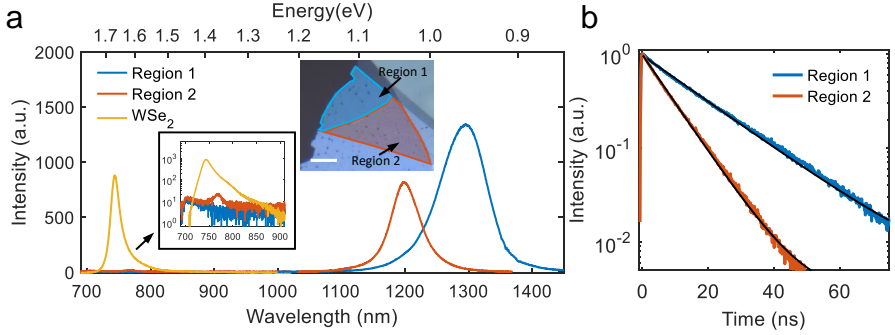

Fig. 2 Moiré modulated IX emission. (a) PL spectra from Region 1 (blue), Region 2 (red) and a reference monolayer WSe₂ (yellow). The PL spectra of the intralayer exciton on a logarithmic scale (black frame inset) show the higher interlayer coupling in Region 1. Inset: the optical image of the heterobilayer consisting of two artificially colored regions. Scale bar: 10 μm . (b) Time-resolved PL dynamics from two regions for IXs emission longer than 900 nm. The black curves are exponential fits to the data, giving an IX lifetime of 17.6 ns (8.5 ns) for Region 1 (Region 2).

Recent studies clearly show that the atomic registry of the moiré superlattice dictates the behaviour of interlayer electronic coupling [5], which can be used as a tuning knob for novel 2D electronic systems. Here we examine the influence of the moiré potential on the IX lifetime that plays a crucial role in population inversion. The twist angle has a substantial impact on the IX lifetime, as it generates not only a relative shift in momentum space but also modifies the moiré superlattices [24]. However, it is challenging to differentiate the contributions to radiative decay from the momentum mismatch (without moiré potential) and the moiré effect. To largely exclude the effect of the momentum mismatch, we choose a representative near-zero-twist-angle heterobilayer shown as the inset in Fig. 2a, where the optical image shows two clearly distinguishable separated regions. These two regions (Region 1 and Region 2) can be identified by their different optical contrast, implying the presence of different interlayer coupling while simultaneously having the same twist angle. The PL spectra shown in Fig. 2a cover the WSe₂ exciton emission (~ 750 nm) and IX emission (~ 1000 -1400 nm). Both regions feature strong interlayer coupling supported by the approximately two orders of magnitude emission quenching of the WSe₂ A excitons. On the logarithmic scale (see the inset with black frame), the different intralayer exciton intensities from

the two regions further indicate that Region 1 has a better coupling than Region 2. Compared to Region 2, the IX emission from Region 1 exhibits a brighter emission intensity and lower emission energy (see the right part of Fig. 2a). These results can be explained by: (1) Stronger interlayer coupling, i.e., the increased overlap of the wavefunctions of the spatially separated electrons and holes, results in a larger probability of IX radiative recombination. (2) The interlayer coupling determines the depth of the moiré potential [3], and stronger interlayer coupling leads to a deeper moiré potential which thus can trap IXs in lower energy states. The increased radiative recombination due to the strong interlayer coupling usually leads to fast decay. However, our time-resolved PL measurements (Fig. 2b) show that the IXs in Region 1 feature a longer lifetime (~ 17.6 ns) than Region 2 (~ 8.5 ns). This counter-intuitive result can be explained by the strong suppression of non-radiative recombination at elevated temperatures due to the spatial confinement of IXs with moiré potential [25] that impedes the exciton diffusion to non-radiative centers [26, 27]. We conclude that the moiré potential not only enhances the light emission of IX but also prolongs its lifetime, which is favourable for lasing applications.

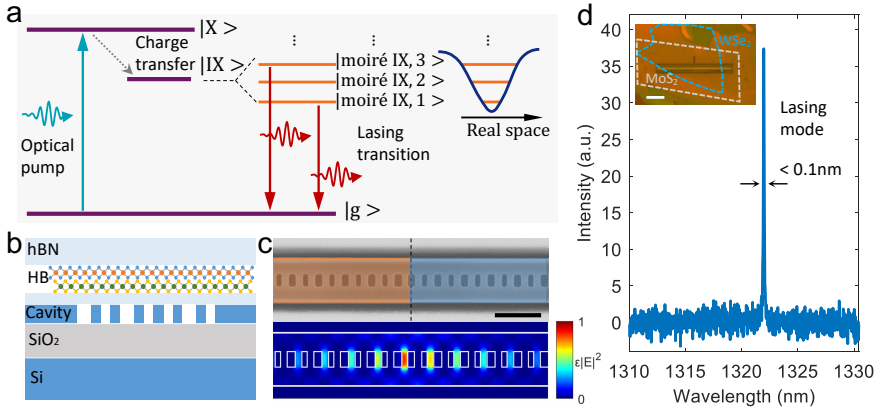

Fig. 3 Demonstration of moiré IX lasers. (a) Energy level diagram of moiré IX states for lasing emission. (b) Schematic of the hBN-encapsulated $\text{MoS}_2/\text{WSe}_2$ heterobilayer integrated with a SiO_2 -supported silicon topological nanobeam cavity. (c) SEM image (the upper panel) of the cavity. The light red and blue areas illustrate two photonic crystals with different Zak phases, leading to the appearance of a cavity mode at their interface. The simulated mode profile is illustrated in the lower panel. Scale bar, 500 nm. (d) The emission spectrum of Device 1 at an excitation power intensity of ~ 4.39 kW/cm^2 . Inset: Optical microscope image of the device. The blue and grey dashed boxes outline the monolayer WSe_2 and MoS_2 areas. The top and bottom hBN layers are not shown. Scale bar, 5 μm .

To explore the potential of moiré IX for laser applications, a rotationally aligned $\text{MoS}_2/\text{WSe}_2$ moiré superlattice is integrated with a silicon photonic crystal cavity. An equivalent three-level system considering the multiple moiré

states and a sketch of the device are shown in Figs. 3a and 3b, respectively. Intralayer exciton states $|X\rangle$ are first generated after optical pumping and follow an ultrafast charge transfer process to form IX states $|IX\rangle$. The moiré potential leads to the formation of quantized IX energy levels, marked as $|\text{moiré IX}, 1\rangle, |\text{moiré IX}, 2\rangle, |\text{moiré IX}, 3\rangle$, etc. The heterobilayer is encapsulated within two hBN flakes to prevent optical performance degradation in ambient environments [28] and to suppress inhomogeneous linewidth broadening [3]. Thanks to this hBN encapsulation, one can observe a clear multipeak feature in PL spectra (see Supplementary fig. S1), reinforcing the presence of moiré IX states. Photonic topological cavities are chosen here due to their demonstrated robust single-mode operation [29, 30], preventing mode competition thus simplifying the study of moiré IX-cavity interaction. The inset in Fig. 3d presents the optical image of Device 1 fabricated by standard e-beam lithography and polymer-based transfer technique [20] (details in Methods). The top panel in Fig. 3c shows the scanning electron microscopy (SEM) image of our fabricated topological cavity, and the simulated electric energy distribution shown in Fig. 3b (the bottom panel) illustrates the single cavity mode localized at the interface between two photonic crystals with distinct Zak phases [30]. We highlight that the Q-factor ($> 10^4$) of our cavity is one order of magnitude larger compared to the previous heterobilayer-based IX lasers [11, 12], offering a low-loss reservoir for the photons thus enhancing coherent emission.

As displayed in Fig. 1b, the presence of moiré potential extends the light emission of IX to the OFC O-band, which is essential for high-speed data transmission and other applications. By coupling the deeply trapped IX to the cavity mode, we observe a pronounced sharp emission line at ~ 1321 nm (Fig. 3d) under optical pumping, denoted as Device 1. It should be noted that the measured emission linewidth of ~ 0.1 nm is limited by the spectral limit of our spectrometer with high-resolution grating (1200 grooves/mm), showing the highest spectral purity of our device among the reported 2D material lasers (see the comparison in Supplementary Table S2). This narrow linewidth corresponds to a coherence time of ~ 45 ps (see the formula in Methods), one order of magnitude longer than the previously reported IX laser (1.7 ps) [12], thus giving strong evidence for highly coherent light emission. To obtain more details about the optical coupling between moiré IX and cavity resonance, a low-resolution grating (150 grooves/mm) is used to acquire a broad emission spectrum that includes the moiré IX emission and lasing mode (see the red curve in Fig. 4a). It is obvious that a single lasing mode dominates the spectrum, which confirms the non-trivial property of the topological cavity. In addition, the lasing wavelength locates at the low-energy part of the spontaneous emission peak of moiré IX with an SMSR up to ~ 10 dB that is significantly larger than the typical value (~ 3 -4 dB, shown in Supplementary Table S2) of the reported 2D material lasers [12]. Interestingly, we find that the output intensity of Device 1 is linearly increased with pump intensity (Fig. 4b)

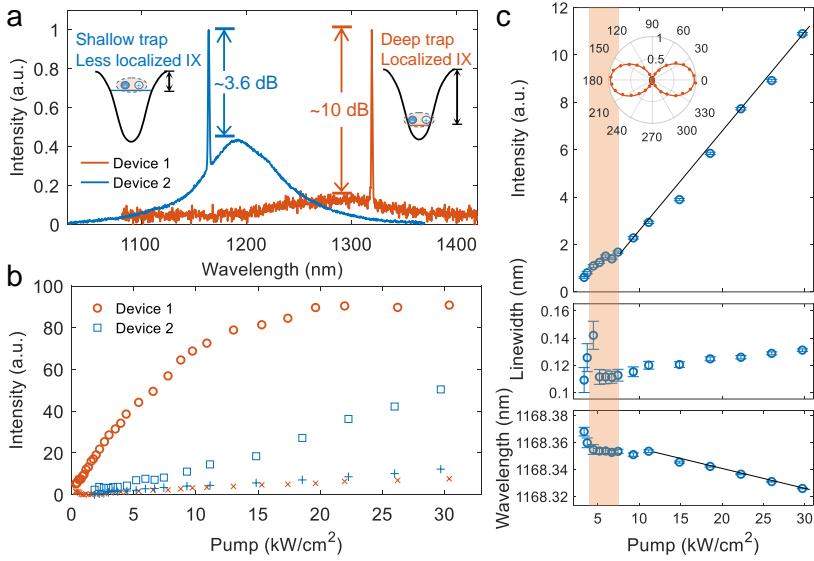

Fig. 4 Signatures of high-performance lasing. (a) Two types of lasing operation: Device 1 (with localized moiré IX) and Device 2 (with less localized moiré IX) at an excitation power intensity of ~ 4.04 kW/cm^2 and ~ 18.12 kW/cm^2 respectively. The black lines indicate the effective moiré potential depth. (b) Output behaviour of two devices. The hollow circle/square (cross) represents the lasing emission (spontaneous emission). (c) Integrated intensity, linewidth, and wavelength of the output of Device 2 as a function of pump intensity. The experimental data are fitted by a Lorentzian function, and the error bars correspond to the 95% confidence interval of the Lorentzian fit. The threshold region is highlighted by the light red shaded area and the inset shows the linear polarization of the emitted mode characterized by polarization-resolved measurements.

and the lasing mode keeps dominating the emission even at low pumping levels. We believe that a large excitonic gain at OFC O-band is obtained due to the shift of the absorption peak of moiré IXs, which gives rise to a low lasing threshold beyond the measurement capability of our instruments.

For comparison, we design another device (Device 2) where the cavity resonance is mainly coupled to high-energy moiré IXs (Supplementary fig. S1). In this case, the effective potential for IXs is shallower (left inset of Fig. 4a) which is analogous to the previously reported delocalized IX laser[12], and the lasing mode starts to dominate the emission spectrum at high pumping levels. With the increased excitation power, the evolution of the emission spectrum of Device 2 is investigated (Fig. 4c). The L-L curve (i.e., output intensity as a function of input power) presents a super-linear behaviour, which is a typical signature of lasing behaviour. In addition, a clear narrowing of the emission linewidth is observed near the threshold (~ 5 kW/cm^2), suggesting the occurrence of a phase transition from thermal to coherent emission. It should be noted that the observed threshold is reproducible (see Supplementary fig. S3). Below the threshold, we obtain a Q-factor of the loaded cavity around 10^4 ,

indicating a low-loss laser system that allows us to reach the lasing condition with a relatively small optical gain. This can be attributed to the high Q factor of the passive cavity and the negligible absorption loss of IXs. When pumping at higher levels ($> 10 \text{ kW/cm}^2$), the lasing mode is blueshifted and accompanied by linewidth broadening (Fig. 4c), which can be explained by free-carrier absorption in the silicon cavity [31]. Our device barely suffers from pumping-induced heating as observed in previous works [9, 32], thanks to the supported cavity design and hBN encapsulation enabling the efficient thermal energy dissipation [33]. Furthermore, the device exhibits excellent linear polarization with a degree of polarization (defined in Methods) of ~ 0.94 of the emission line (inset of Fig. 4a), showing the efficient coupling between moiré IX and cavity mode. These observations indicate the presence of moiré excitonic gain for lasing. Furthermore, Fig. 4b exhibits that the output intensity of Device 1 grows faster (i.e., larger slope efficiency) than Device 2, indicating the existence of a high-gain medium that amplifies the light emission more efficiently. This can be further confirmed by the higher output intensity and lower saturation pumping power of Device 1. These findings prove the lower-threshold feature of Device 1 and suggest a relatively larger optical gain of the low-energy moiré IX states. The observation of lasing emission at 1321 nm and 1168 nm suggests a broad gain spectrum of the moiré excitons. This can possibly be ascribed to enhanced IX-IX interactions in our system arising from the additional quantum confinement by the moiré potential that acts as a reservoir for the accumulation of IXs.

Discussion

In summary, we demonstrate the impact of moiré potentials on the light emission of IX at room temperature and their great potential for high-performance nanolasers. The combination of moiré IXs and high-Q silicon topological nanocavities results in ultra-coherent light emission with a low threshold. We emphasize that due to low signal it is challenging to perform photon correlation measurements, which can provide further evidence for laser operation [34]. We note that a complete description of the moiré IX lasing behaviour requires a sophisticated model that fully accounts for the gain mechanisms in the moiré superlattices, which is beyond the scope of this study. Although the direct measurement of IXs absorption in TMDs at low temperatures has recently been achieved with electromodulation spectroscopy [21], further development of absorption measurement techniques at room temperature is strongly desired for determining the gain mechanisms in moiré superlattices. The discovery of moiré exciton gain at room temperature opens up the possibility of high-performance optoelectronic devices.

Methods

Sample fabrication

TMD monolayers were prepared by mechanical exfoliation from flux-grown bulk crystals (2D semiconductors) using polydimethylsiloxane (PDMS). The layer thickness was measured by optical contrast and PL emission energy. The heterobilayers were aligned by the straight edges of the TMD monolayers and stacked with the dry transfer technique [20]. The twist angles are determined based on the straight edges of the stacked heterobilayers as reported in previous work [35] and are consistent with our second harmonic generation (SHG) measurements (Supplementary fig. S2).

Device fabrication

The topological photonic nanobeam cavities were fabricated on a commercial 220 nm-SOI wafer with a 2 μm sacrificial silicon dioxide layer (SOITEC). A 180 nm layer of e-beam resist (CSAR AR-P6200) was prepared, followed by an electron beam lithography process (JBX-9500FSZ, JEOL). After development, the cavity was created via an inductively coupled plasma dry-etching process. The residual resist was finally dissolved in 1165 solvent. The hBN thin films were exfoliated onto a SiO_2/Si substrate for encapsulation. The bottom hBN layer was kept thinner than 10 nm for good coupling between moiré IXs and the cavity mode. The hBN-encapsulated $\text{MoS}_2/\text{WSe}_2$ heterostructures were assembled and transferred to the nanocavities using the polymer-based dry-transfer method [20].

Optical measurements

All measurements were performed at room temperature. For the PL measurements, a 637 nm continuous-wave laser diode was used to pump the devices. A 50x objective lens with a numerical aperture (NA) of 0.65 (LCPLN50XIR, Olympus) was used for both excitation and collection. The laser light was blocked through longpass spectral filters, and the PL signals were sent to a Czerny-Turner monochromator (SR500i, Andor) with a cooled InGaAs 1D-array camera (DU491A-1,7, Andor). A 150 grooves/mm grating is used for the wide-range light emission from moiré IXs (shown in Figs. 1c, 1d, 2a and 4a). For a better spectral resolution, the lasing mode was detected via a 600-grooves/mm grating (with a resolution of 0.22 nm) or a 1200 grooves/mm grating (0.1 nm). The reflection contrast spectra were measured by using a white light source (SuperK Compact). The time-resolved PL measurements were performed using a time-correlated single-photon counting (TCSPC) technique with a time tagger. We excited the device with a 640 nm pulsed laser (LDH-IB-640-B, PicoQuant) with a pulse width of < 90 ps and a repetition rate of 10 MHz. The signals with wavelengths longer than 900 nm were sent to a single-photon detector (id220-FR, iDQ). Polarization-dependent SHG measurements were used to determine the twist angle of heterobilayers and were

carried out with an excitation wavelength of 960 nm (repetition rate 2 kHz) from an amplified Ti:sapphire femtosecond laser system (Spectra-Physics Solstice Ace). The polarization orientation of the excitation beam was tailored by rotating a half-wave plate (HWP). The laser light after the HWP was focused onto the sample by a 40x objective lens (NA=0.75, Nikon). The transmitted SHG signal was collected by another 40x objective lens (NA=0.5, Nikon), and passed through a linear polarizer. A 700-nm short-pass filter was placed after the polarizer to cut off the excitation beam. The final signal was detected by a photomultiplier tube (PMT) (Hamamatsu). Through the SHG measurements, the measured twist angle was correlated with IX energy (Supplementary fig. S2).

Numerical simulation

The topological photonic nanobeam cavity that we adopted was first proposed in Ref. [30]. We retained a SiO₂ layer to support silicon nanobeams as our previous design [28] that was mechanically robust for the 2D material transfer process and was preferable for efficient heat dissipation. We optimized the cavity mode and parameters to reach a desired resonant wavelength using the finite-difference time-domain method (Lumerical, Ansys). The detailed structure parameters of the cavities are shown in Supplementary Table 1.

Coherence time

The coherence time was estimated by the formula [36]: $\tau_c = \sqrt{8\ln 2}\lambda^2 / (c\Delta\lambda)$, where λ is wavelength, $\Delta\lambda$ is spectral linewidth.

Degree of polarization

The degree of polarization is defined as $(I_{\max} - I_{\min}) / (I_{\max} + I_{\min})$, where I_{\max} (I_{\min}) is the maximum (minimum) output intensity.
