# Efficient Computation of Shap Explanation Scores for Neural Network Classifiers via Knowledge Compilation 

Leopoldo Bertossi ${ }^{1 \star}$ and Jorge E. León ${ }^{2 \star \star}$<br>${ }^{1}$ SKEMA Business School, Montreal, Canada<br>${ }^{2}$ Universidad Adolfo Ibáñez (UAI), Santiago, Chile

#### Abstract

The use of Shap scores has become widespread in Explainable AI. However, their computation is in general intractable, in particular when done with a black-box classifier, such as neural network. Recent research has unveiled classes of open-box Boolean Circuit classifiers for which Shap can be computed efficiently. We show how to transform binary neural networks into those circuits for efficient Shap computation. We use logic-based knowledge compilation techniques. The performance gain is huge, as we show in the light of our experiments.

## 1 Introduction

In recent years, there has been a growing demand for methods to explain and interpret the results from machine learning (ML) models. Explanations come in different forms, and can be obtained through different approaches. A common one assigns attribution scores to the features values associated to an input that goes through an ML-based model, to quantify their relevance for the obtained outcome. We concentrate on local scores, i.e. associated to a particular input, as opposed to a global score that indicated the overall relevance of a feature. We also concentrate on explanations for binary classification models that assign labels 0 or 1 to inputs.

A popular local score is Shap [18], which is based on the Shapley value that was introduced in coalition game theory and practice [32, 30]. Shap scores can be computed with a black-box or an open-box model [31]. With the former, we do not know or use its internal components, but only its input/output relation. This is the most common approach. In the latter case, we can have access to its internal structure and components, and we can use them for score computation. It is common to consider neural-networkbased models as black-box models, because their internal gates and structure may be difficult to understand or process when it comes to explaining classification outputs. However, a decision-tree model, due to its much simpler structure and use, is considered to be open-box for the same purpose.

Even for binary classification models, the complexity of Shap computation is provably hard, actually \#P-hard for several kinds of binary classification models, independently from whether the internal components of the model are used when computing Shap [4, 1, 2]. However, there are classes of classifiers for which, using the model components and structure, the complexity of Shap computation can be brought down to polynomial time [19, 2, 38].

[^0]A polynomial time algorithm for Shap computation with deterministic and decomposable Boolean circuits (dDBCs) was presented in [2]. From this result, the tractability of Shap computation can be obtained for a variety of Boolean circuit-based classifiers and classifiers that can be represented as (or compiled into) them. In particular, this holds for Ordered Binary Decision Diagrams (OBDDs) [8], decision trees, and other established classification models that can be compiled into (or treated as) OBDDs [34, 11, 23]. This applies, in particular, to Sentential Decision Diagrams (SDDs) [14] that form a convenient knowledge compilation target language [12, 37].

In this work, we show how to use logic-based knowledge compilation techniques to attack, and -to the best of our knowledge-for the first time, the important and timely problem of efficiently computing explanations scores in ML, which, without these techniques, would stay intractable.

More precisely, we concentrate on explicitly developing the compilation-based approach to the computation of Shap for binary (or binarized) neural networks (BNNs) [17, 28, 36, 23]. For this, a BNN is transformed into a dDBC using techniques from knowledge compilation [12], an area that investigates the transformation of (usually) propositional theories into an equivalent one with a canonical syntactic form that has some good computational properties, e.g. tractable model counting. The compilation may incur in a relatively high computational cost [12, 13], but it may still be worth the effort when a particular property is checked often, as is the case of explanations for the same BNN.

More specifically, we describe in detail how a BNN is first compiled into a propositional formula in Conjunctive Normal Form (CNF), which, in its turn, is compiled into an SDD, which is finally compiled into a dDBC. Our method applies at some steps established transformations that are not commonly illustrated or discussed in the context of real applications, which we do here. The whole compilation path and the application to Shap computation are new. We show how Shap is computed on the resulting circuit via the efficient algorithm in [2]. This compilation is performed once, and is independent from any input to the classifier. The final circuit can be used to compute Shap scores for different input entities.

We also make experimental comparisons of computation times between this openbox and circuit-based Shap computation, and that based directly on the BNN treated as a black-box, i.e. using only its input/output relation. For our experiments, we consider real estate as an application domain, where house prices depend on certain features, which we appropriately binarize $3^{3}$ The problem consists in classifying property blocks, represented as entity records of thirteen feature values, as high-value or low-value, a binary classification problem for which a BNN is used.

To the best of our knowledge, our work is the first at using knowledge compilation techniques for efficiently computing Shap scores, and the first at reporting experiments with the polynomial time algorithms for Shap computation on binary circuits. We confirm that Shap computation via the dDBC vastly outperforms the direct Shap computation on the BNN. It is also the case that the scores obtained are fully aligned,

[^1]as expected since the dDBC represents the BNN. The same probability distribution associated to the Shapley value is used with all the models.

Compilation of BNNs into OBDDs was done in [34, 11] for other purposes, not for Shap computation or any other kind of attribution score. In this work we concentrate only on explanations based on Shap scores. There are several other explanations mechanisms for ML-based classification and decision systems in general, and also specific for neural networks. See [16] and [29] for surveys.

This paper is structured as follows. Section 2 contains background on Shap and Boolean circuits (BCs). Section 3 shows in detail, by means of a running example, the kind of compilation of BNNs into dDBCs we use for the experiments. Section 4 presents the experimental setup, and the results of our experiments with Shap computation. In Section 5we draw some conclusions.

## 2 Preliminaries

In coalition game theory and its applications, the Shapley value is a established measure of the contribution of a player to a shared wealth that is modeled as a game function. Given a set of players $S$, and a game function $G: \mathcal{P}(S) \rightarrow \mathbb{R}$, mapping subsets of players to real numbers, the Shapley value for a player $p \in S$ quantifies its contribution to $G$. It emerges as the only measure that enjoys certain desired properties [30]. In order to apply the Shapley value, one has to define an appropriate game function.

Now, consider a fixed entity $\mathbf{e}=\left\langle F_{1}(\mathbf{e}), \ldots, F_{N}(\mathbf{e})\right\rangle$ subject to classification. It has values $F_{i}(\mathbf{e})$ for features in $\mathcal{F}=\left\{F_{1}, \ldots, F_{N}\right\}$. These values are 0 or 1 for binary features. In [18, 19], the Shapley value is applied with $\mathcal{F}$ as the set of players, and with the game function $\mathcal{G}_{\mathbf{e}}(s):=\mathbb{E}\left(L\left(\mathbf{e}^{\prime}\right) \mid \mathbf{e}_{s}^{\prime}=\mathbf{e}_{s}\right)$, giving rise to the Shap score. Here, $s \subseteq \mathcal{F}$, and $\mathbf{e}_{s}$ is the projection (or restriction) of $\mathbf{e}$ on (to) the $s$. The label function $L$ of the classifier assigns values 0 or 1 . The $\mathbf{e}^{\prime}$ inside the expected value is an entity whose values coincide with those of $\mathbf{e}$ for the features in $s$. For feature $F \in \mathcal{F}$ :

$$
\begin{align*}
& \operatorname{Shap}\left(\mathcal{F}, \mathcal{G}_{\mathbf{e}}, F\right)= \sum_{s \subseteq \mathcal{F} \backslash\{F\}} \frac{|s|!(|\mathcal{F}|-|s|-1)!}{|\mathcal{F}|!}[  \tag{1}\\
&\left.\mathbb{E}\left(L\left(\mathbf{e}^{\prime}\right) \mid \mathbf{e}_{s \cup\{F\}}^{\prime}=\mathbf{e}_{s \cup\{F\}}\right)-\mathbb{E}\left(L\left(\mathbf{e}^{\prime}\right) \mid \mathbf{e}_{s}^{\prime}=\mathbf{e}_{s}\right)\right] .
\end{align*}
$$

The expected value assumes an underlying probability distribution on the entity population. Shap quantifies the contribution of feature value $F(\mathbf{e})$ to the outcome label.

In order to compute Shap, we only need function $L$, and none of the internal components of the classifier. Given that all possible subsets of features appear in its definition, Shap is bound to be hard to compute. Actually, for some classifiers, its computation may become \#P-hard [2]. However, in [2], it is shown that Shap can be computed in polynomial time for every deterministic and decomposable Boolean circuit (dDBC) used as a classifier. The circuit's internal structure is used in the computation.

Figure 1 shows a Boolean circuit that can be used as a binary classifier, with binary features $x_{1}, x_{2}, x_{3}$, whose values are input at the bottom nodes, and then propagated upwards through the Boolean gates. The binary label is read off from the top node. This circuit is deterministic in that, for every $\vee$-gate, at most one of its inputs is 1 when the output is 1 . It is decomposable in that, for every $\wedge$-gate, the inputs do not share
features. The dDBC in the Figure is also smooth, in that sub-circuits that feed a same $\vee$-gate share the same features. It has a fan-in at most two, in that every $\wedge$-gate and $\vee$-gate have at most two inputs. We denote this subclass of dDBCs with $\mathrm{dDBCSFi}(2)$.

Fig. 1: A dDBC.

Fig. 2: A BNN.

More specifically, in [2] it is established that Shap can be computed in polynomial time for $\mathrm{dDBCSFi}(2)$-classifiers, assuming that the underlying probability distribution is the uniform, $P^{\mathrm{u}}$, or the product distribution, $P^{\times}$. They are as follows for binary features: $P^{\mathrm{u}}(\mathbf{e}):=\frac{1}{2^{N}}$ and $P^{\times}(\mathbf{e}):=\Pi_{i=1}^{N} p_{i}\left(F_{i}(\mathbf{e})\right)$, where $p_{i}(v)$ is the probability of value $v \in\{0,1\}$ for feature $F_{i}$.

## 3 Compiling BNNs into dDBCs

In order to compute Shap with a BNN, we convert the latter into a dDBC, on which Shap scores will be computed with the polynomial time algorithm in [2]. The transformation goes along the the following path that we describe in this section:

$$
\begin{equation*}
\text { BNN } \underset{(\mathrm{a})}{\leftrightarrows} \text { CNF } \underset{(\mathrm{b})}{\longrightarrow} \text { SDD } \underset{(\mathrm{c})}{\leftrightarrows} \text { dDBC } \tag{2}
\end{equation*}
$$

A BNN can be converted into a CNF formula [35, 23], which, in its turn, can be converted into an $\operatorname{SDD}[14,25]$. It is also known that SDDs can be compiled into a formula in d-DNNF (deterministic and decomposable negated normal form) [12], which forms a subclass of dDBCs. More precisely, the resulting dDBC in 22 is finally compiled in polynomial time into a dDBCSFi(2).

Some of the steps in (2) may not be polynomial-time transformations, which we will discuss in more technical terms later in this section. However, we can claim at this stage that: (a) Any exponential cost of a transformation is kept under control by a usually small parameter. (b) The resulting $\mathrm{dDBCSFi}(2)$ is meant to be used multiple times, to explain different and multiple outcomes; and then, it may be worth taking a one-time, relatively high transformation cost. A good reason for our transformation path is the availability of implementations we can take advantage of ${ }^{4}$

[^2]We will describe, explain and illustrate the conversion path (2) by means of a running example with a simple BNN, which is not the BNN used for our experiments. For them, we used a BNN with one hidden layer with 13 gates.

Example 1 The BNN in Figure 2 has hidden neuron gates $h_{1}, h_{2}, h_{3}$, an output gate $o$, and three input gates, $x_{1}, x_{2}, x_{3}$, that receive binary values. The latter represent, together, an input entity $\bar{x}=\left\langle x_{1}, x_{2}, x_{3}\right\rangle$ that is being classified by means of a label returned by $o$. Each gate $g$ is activated by means of a step function $\phi_{g}(\bar{i})$ of the form:

$$
s p\left(\bar{w}_{g} \bullet \bar{i}+b_{g}\right):=\left\{\begin{align*}
1 & \text { if } \bar{w}_{g} \bullet \bar{i}+b_{g} \geq 0  \tag{3}\\
-1 & \text { otherwise and } g \text { is hidden } \\
0 & \text { otherwise and } g \text { is output }
\end{align*}\right.
$$

which is parameterized by a vector of binary weights $\bar{w}_{g}$ and a real-valued constant bias $b_{g} \bigsqcup^{5}$ The • is the inner vector product. For technical, non-essential reasons, for a hidden gate, $g$, we use 1 and -1 , instead of 1 and 0 , in $\bar{w}_{g}$ and outputs. Similarly, $\bar{x} \in\{-1,1\}^{3}$. Furthermore, we assume we have a single output gate, for which the activation function does return 1 or 0 , for true or false, respectively.

For example, $h_{1}$ is true, i.e. outputs 1 , for an input $\bar{x}=\left(x_{1}, x_{2}, x_{3}\right)$ iff $\bar{w}_{h_{1}} \bullet$ $\bar{x}+b_{h_{1}}=(-1) \times x_{1}+(-1) \times x_{2}+1 \times x_{3}+0.16 \geq 0$. Otherwise, $h_{1}$ is false, i.e. it returns -1 . Similarly, output gate $o$ is true, i.e. returns label 1 for a binary input $\bar{h}=\left(h_{1}, h_{3}, h_{3}\right)$ iff $\bar{w}_{o} \bullet \bar{h}=1 \times h_{1}+1 \times h_{2}+(-1) \times h_{3}-0.01 \geq 0$, and 0 otherwise.

The first step, (a) in (2), represents the BNN as a CNF formula, i.e. as a conjunction of disjunctions of literals, i.e. atomic formulas or their negations.

Each gate of the BNN is represented by a propositional formula, initially not necessarily in CNF, which, in its turn, is used as one of the inputs to gates next to the right. In this way, we eventually obtain a defining formula for the output gate. The formula is converted into CNF. The participating propositional variables are logically treated as true or false, even if they take numerical values 1 or -1 , resp.

### 3.1 Representing BNNs as Formulas in CNF

Our conversion of the BNN into a CNF formula is inspired by a technique introduced in [23], in their case, to verify properties of BNNs. In our case, the NN is fully binarized in that inputs, parameters (other than bias), and outputs are always binary, whereas they may have real values as parameters and outputs. Accordingly, they have to binarize values along the transformation process. They also start producing logical constraints that are later transformed into CNF formulas. Furthermore, [23] introduces auxiliary variables during and at the end of the transformation. With them, in our case, such a BC could not be used for Shap computation. Furthermore, the elimination of auxiliary variables, say via variable forgetting [26], could harm the determinism of the final circuit. In the following we describe a transformation that avoids introducing auxiliary variables ${ }^{6}$ However, before describing the method in general, we give an example, to convey the main ideas and intuitions.

[^3]Example 2 (example 1 cont.) Consider gate $h_{1}$, with parameters $\bar{w}=\langle-1,-1,1\rangle$ and $b=0.16$, and input $\bar{i}=\left\langle x_{1}, x_{2}, x_{3}\right\rangle$. An input $x_{j}$ is said to be conveniently instantiated if it has the same sign as $w_{j}$, and then, contributing to having a larger number on the LHS of the comparison in (3). E.g., this is the case of $x_{1}=-1$. In order to represent as a propositional formula its output variable, also denoted with $h_{1}$, we first compute the number, $d$, of conveniently instantiated inputs that are necessary and sufficient to make the LHS of the comparison in (3) greater than or equal to 0 . This is the (only) case when $h_{1}$ becomes true; otherwise, it is false. This number can be computed in general by [23]:

$$
\begin{equation*}
d=\left\lceil\left(-b+\sum_{j=1}^{|\bar{i}|} w_{j}\right) / 2\right\rceil+\# \text { of negative weights in } \bar{w} . \tag{4}
\end{equation*}
$$

For $h_{1}$, with 2 negative weights: $d\left(h_{1}\right)=\lceil(-0.16+(-1-1+1)) / 2\rceil+2=2$. With this, we can impose conditions on two input variables with the right sign at a time, considering all possible convenient pairs. For $h_{1}$ we obtain its condition to be true:

$$
\begin{equation*}
h_{1} \longleftrightarrow\left(-x_{1} \wedge-x_{2}\right) \vee\left(-x_{1} \wedge x_{3}\right) \vee\left(-x_{2} \wedge x_{3}\right) \tag{5}
\end{equation*}
$$

This DNF formula is directly obtained -and just to convey the intuition- from considering all possible convenient pairs (which is already better that trying all cases of three variables at a time). However, the general iterative method presented later in this subsection, is more expedite and compact than simply listing all possible cases; and still uses the number of convenient inputs. Using this general algorithm, we obtain, instead of (5), this equivalent formula defining $h_{1}$ :

$$
\begin{equation*}
h_{1} \longleftrightarrow\left(x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right) \tag{6}
\end{equation*}
$$

Similarly, we obtain defining formulas for $h_{2}, h_{3}$, and $o$ : (for all of them, $d=2$ )

$$
\begin{align*}
h_{2} & \longleftrightarrow\left(-x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right), \\
h_{3} & \longleftrightarrow\left(x_{3} \wedge\left(x_{2} \vee x_{1}\right)\right) \vee\left(x_{2} \wedge x_{1}\right), \\
o & \longleftrightarrow\left(-h_{3} \wedge\left(h_{2} \vee h_{1}\right)\right) \vee\left(h_{2} \wedge h_{1}\right) . \tag{7}
\end{align*}
$$

Replacing the definitions of $h_{1}, h_{2}, h_{3}$ into (7), we finally obtain:

$$
\begin{align*}
o \longleftrightarrow & \left(-\left[\left(x_{3} \wedge\left(x_{2} \vee x_{1}\right)\right) \vee\left(x_{2} \wedge x_{1}\right)\right] \wedge\left(\left[\left(-x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right)\right]\right.\right. \\
& \left.\left.\vee\left[\left(x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right)\right]\right)\right) \vee\left(\left[\left(-x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\right.\right. \\
& \left.\left.\left(-x_{2} \wedge-x_{1}\right)\right] \wedge\left[\left(x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right)\right]\right) \tag{8}
\end{align*}
$$

The final part of step (a) in path (2), requires transforming this formula into CNF. In this example, it can be taken straightforwardly into CNF. For our experiments, we implemented and used the general algorithm presented right after this example. It guarantees that the generated CNF formula does not grow unnecessarily by eliminating some redundancies along the process. The resulting CNF formula is, in its turn, simplified into a shorter and simpler new CNF formula by means of the Confer SAT solver [20]. For this example, the simplified CNF formula is as follows:

$$
\begin{equation*}
o \longleftrightarrow\left(-x_{1} \vee-x_{2}\right) \wedge\left(-x_{1} \vee-x_{3}\right) \wedge\left(-x_{2} \vee-x_{3}\right) \tag{9}
\end{equation*}
$$

Having a CNF formula will be convenient for the next steps along path (2).

In more general terms, consider a BNN with $L$ layers, numbered with $Z \in[L]:=$ $\{1, \ldots, L\}$. W.l.o.g., we may assume all layers have $M$ neurons (a.k.a. gates), except for the last layer that has a single, output neuron. We also assume that every neuron receives an input from every neuron at the preceding layer. Accordingly, each neuron at the first layer receives the same binary input $\bar{i}_{1}=\left\langle x_{1}, \ldots, x_{N}\right\rangle$ containing the values for the propositional input variables for the BNN. Every neuron at a layer $Z$ to the right receives the same binary input $\bar{i}_{Z}=\left\langle i_{1}, \ldots, i_{M}\right\rangle$ formed by the output values from the $M$ neurons at layer $Z-1$. Variables $x_{1}, \ldots, x_{N}$ are the only variables that will appear in the final CNF representing the BNN $]^{7}$

To convert the BNN into a representing CNF, we iteratively convert every neuron into a CNF, layerwise and from input to output (left to right). The CNFs representing neurons at a given layer $Z$ are used to build all the CNFs representing the neurons at layer $Z+1$.

Now, for each neuron $g$, at a layer $Z$, the representing $\operatorname{CNF}, \varphi^{g}$, is constructed using a matrix-like structure $M^{g}$ with dimension $M \times d_{g}$, where $M$ is the number of inputs to $g$ (and $N$ for the first layer), and $d_{g}$ is computed as in (4), i.e. the number of inputs to conveniently instantiate to get output 1 . Formula $\varphi^{g}$ represents $g$ 's activation function $s p\left(\bar{w}_{g} \bullet \bar{i}+b_{g}\right)$. The entries $c_{i j}$ of $M^{g}$ contain terms of the form $w_{k} \cdot i_{k}$, which are not interpreted as numbers, but as propositions, namely $i_{k}$ if $w_{k}=1$, and $\neg i_{k}$ if $w_{k}=-1$ (we recall that $i_{k}$ is the $k$-th binary input to $g$, and $w_{k}$ is the associated weight).

Each $M^{g}$ is iteratively constructed in a row-wise manner starting from the top, and then column-wise from left to right, as follows: (in it, the $c_{i k}$ are entries already created in the same matrix)

$$
M^{g}=\left[\begin{array}{ccccc}
w_{1} \cdot i_{1} & \text { false } & \text { false } & \cdots & \text { false }  \tag{10}\\
w_{2} \cdot i_{2} & w_{2} \cdot i_{2} & \text { false } & \cdots & \text { false } \\
\vee c_{11} & \wedge c_{11} & & & \\
w_{3} \cdot i_{3} & \left(w_{3} \cdot i_{3}\right. & w_{3} \cdot i_{3} & \ldots & \text { false } \\
\vee c_{21} & \left.\wedge c_{21}\right) & \wedge c_{22} & \wedge & \cdots
\end{array}\right]
$$

The $k$-th row represents the first $k \in[M]$ inputs considered for the encodings, and each column, the threshold $t \in\left[d_{g}\right]$ to surpass, meaning that at least $t$ inputs should be instantiated conveniently. For every component $c_{k, t}$ with $k<t$, the threshold cannot be reached, which makes every component in the upper-right triangle false.

The propositional formula of interest, namely the one that represents neuron $g$ and will be passed over as an "input" to the next layer to the right, is the bottom-right most, $c_{M d_{g}}$ (underlined). Notice that it is not necessarily a CNF; nor does the construction of $M^{g}$ requires using CNFs. It is also clear that, as we construct the components of matrix $M^{g}$, they become formulas that keep growing in size. Accordingly, before passing over this formula, it is converted into a $\mathrm{CNF} \varphi^{g}$ that has also been simplified by means of a SAT solver (this, at least experimentally, considerably reduces the size of the CNF). The vector $\left\langle\varphi^{g_{1}}, \ldots, \varphi^{g_{M}}\right\rangle$ becomes the input for the construction of the matrices $M^{g^{\prime}}$,

[^4]for neurons $g \prime$ in layer $Z+1$. Reducing the sizes of these formulas is important because the construction of $M^{g \prime}$ will make the the formula sizes grow furher.

Example 3 (ex. 2 cont.) Let us encode neuron $h_{1}$ using the matrix-based construction. Since $d_{h_{1}}=2$, and it has 3 inputs, matrix $M^{h_{1}}$ will have dimension $3 \times 2$. Here, $\bar{w}_{h_{1}}=$ $\langle-1,-1,1\rangle$ and $\bar{i}_{h_{1}}=\left\langle x_{1}, x_{2}, x_{3}\right\rangle$. Accordingly, $M_{h_{1}}$ has the following structure:

$$
\left[\begin{array}{cc}
w_{1} \cdot i_{1} & \text { false } \\
w_{2} \cdot i_{2} \vee c_{11} & w_{2} \cdot i_{2} \wedge c_{11} \\
w_{3} \cdot i_{3} \vee c_{21} & \underline{\left(w_{3} \cdot i_{3} \wedge c_{21}\right) \vee c_{22}}
\end{array}\right]
$$

Replacing in its components the corresponding values, we obtain:

$$
\left[\begin{array}{cc}
-x_{1} & \text { false } \\
-x_{2} \vee-x_{1} & -x_{2} \wedge-x_{1} \\
x_{3} \vee-x_{2} \vee-x_{1} & \underline{\left(x_{3} \wedge\left(-x_{2} \vee-x_{1}\right)\right) \vee\left(-x_{2} \wedge-x_{1}\right)}
\end{array}\right]
$$

The highlighted formula coincides with that in (6).
In our implementation, and this is a matter of choice and convenience, it turns out that each component of $M^{g}$ is transformed right away into a simplified CNF before being used to build the new components. This is not essential, in that we could, in principle, use (simplified) propositional formulas of any format all long the process, but making sure that the final formula representing the whole BNN is in CNF. Notice that all the $M^{g}$ matrices for a same layer $Z \in L$ can be generated in parallel and without interaction. Their encodings do not influence each other. With this construction, no auxiliary propositional variables other that those for the initial inputs are created.

Departing from [23], our use of the $M^{g}$ arrays helps us directly build (and work with) CNF formulas without auxiliary variables all along the computation. The final CNF formula, which then contains only the input variables for the BNN, is eventually transformed into a dDBC. The use of a SAT solver for simplification of formulas is less of a problem in [23] due to the use of auxiliary variables. Clearly, our simplification steps make us incur in an extra computational cost. However, it helps us mitigate the exponential growth of the CNFs generated during the transformation of the BNN into the representing CNF.

Overall, and in the worst case that no formula simplifications are achieved, having still used the SAT solver, the time complexity of building the final CNF is exponential in the initial input. This is due to the growth of the formulas along the process. The number of operations in which they are involved in the matrices construction is quadratic.

### 3.2 Building an SDD Along the Way

Following with step (b) along path (2), the resulting CNF formula is transformed into a Sentential Decision Diagram (SDD) [14, 37], which, as a particular kind of decision diagram [6], is a directed acyclic graph. So as the popular OBDDs [8], that SDDs generalize, they can be used to represent general Boolean formulas, in particular, propositional formulas (but without necessarily being per se propositional formulas).

Example 4 (example 2 cont.) Figure 3(a) shows an $\mathrm{SDD}, \mathcal{S}$, representing our CNF formula on the RHS of (9). An SDD has different kinds of nodes. Those represented with encircled numbers are decision nodes [37], e.g. (1) and (3), that consider alternatives for the inputs (in essence, disjunctions). There are also nodes called elements. They are labeled with constructs of the form $\left[\ell_{1} \mid \ell_{2}\right]$, where $\ell_{1}, \ell_{2}$, called the prime and the sub, resp., are Boolean literals, e.g. $x_{1}$ and $\neg x_{2}$, including $\top$ and $\perp$, for 1 or 0 , resp. E.g. $\left[\neg x_{2} \mid \top\right]$ is one of them. The sub can also be a pointer, $\bullet$, with an edge to a decision node. $\left[\ell_{1} \mid \ell_{2}\right]$ represents two conditions that have to be satisfied simultaneously (in essence, a conjunction). An element without • is a terminal. (See [7, 22] for a precise definition of SDD.)

Fig. 3: An SDD (a) and a vtree (b).
An SDD represents (or defines) a total Boolean function $F_{\mathcal{S}}:\left\langle x_{1}, x_{2}, x_{3}\right\rangle \in\{0,1\}^{3} \mapsto$ $\{0,1\}$. For example, $F_{\mathcal{S}}(0,1,1)$ is evaluated by following the graph downwards. Since $x_{1}=0$, we descent to the right; next via node (3) underneath, with $x_{2}=1$, we reach the instantiated leaf node labeled with $[1 \mid 0]$, a "conjunction", with the second component due to $x_{3}=1$. We obtain $F_{\mathcal{S}}(0,1,1)=0$.

In SDDs, the orders of occurrence of variables in the diagram must be compliant with a so-called vtree (for "variable tree") ${ }^{8}$ The connection between a vtree and an SDD refers to the compatibility between the partitions $[$ prime $\mid$ sub $]$ and the tree structure (see Example 5below). Depending on the chosen vtree, substructures of an SDD can be better reused when representing a Boolean function, e.g. a propositional formula, which becomes important to obtain a compact representation. SDDs can easily be combined via propositional operations, resulting in a new SDD [14].

A vtree for a set of variables $\mathcal{V}$ is binary tree that is full, i.e. every node has 0 or 2 children, and ordered, i.e. the children of a node are totally ordered, and there is a bijection between the set of leaves and $\mathcal{V}$ [7].

Example 5 (example 4 cont.) Figure 3(b) shows a vtree, $\mathcal{T}$, for $\mathcal{V}=\left\{x_{1}, x_{2}, x_{3}\right\}$. Its leaves, $0,2,4$, show their associated variables in $\mathcal{V}$. The SDD $\mathcal{S}$ in Figure $3(a)$ is compatible with $\mathcal{T}$. Intuitively, the variables at $\mathcal{S}$ 's terminals, when they go upwards

[^5]through decision nodes $(n$, also go upwards through the corresponding nodes $n$ in $\mathcal{T}$. (See [7, 22, 6] for a precise, recursive definition.)

The SDD $S$ can be straightforwardly represented as a propositional formula by interpreting decision points as disjunctions, and elements as conjunctions, obtaining $\left[x_{1} \wedge\left(\left(-x_{2} \wedge-x_{3}\right) \vee\left(x_{2} \wedge \perp\right)\right)\right] \vee\left[-x_{1} \wedge\left(\left(x_{2} \wedge-x_{3}\right) \vee\left(-x_{2} \wedge \top\right)\right)\right]$, which is logically equivalent to the formula on the RHS of 9 that represents our BNN.

For the running example and experiments, we used the $P y S D D$ system [21]: Given a CNF formula $\psi$, it computes an associated vtree and a compliant SDD, both optimized in size [9, 10]. This compilation step, the theoretically most expensive along path (2], takes exponential space and time only in $T W(\psi)$, the tree-width of the primal graph $\mathcal{G}$ associated to $\psi$ [14, 25]. $\mathcal{G}$ contains the variables as nodes, and undirected edges between any of them when they appear in a same clause. The tree-width measures how close the graph is to being a tree. This is a positive fixed-parameter tractability result [15], in that $T W(\psi)$ is in general smaller than $|\psi|$. For example, the graph $\mathcal{G}$ for the formula $\psi$ on the RHS of (9) has $x_{1}, x_{2}, x_{3}$ as nodes, and edges between any pair of variables, which makes $\mathcal{G}$ a complete graph. Since every complete graph has a tree-width equal to the number of nodes minus one, we have $T W(\psi)=2$. Overall, this step in the transformation process has a time complexity that, in the worst case, is exponential in the size of the tree-width of the input CNF.

### 3.3 The Final dDBC

Our final dDBC is obtained from the resulting SDD: An SDD corresponds to a d-DNNF Boolean circuit, for which decomposability and determinism hold, and has only variables as inputs to negation gates [14]. And d-DNNFs are also dDBCs. Accordingly, this step of the whole transformation is basically for free, or better, linear in the size of the SDD if we locally convert decision nodes into disjunctions, and elements into conjunctions (see Example 55.

The algorithm in [1] for efficient Shap computation needs the dDBC to be a $\mathrm{dDBCSFi}(2)$. To obtain the latter, we use the transformation Algorithm 1 below, which is based on [1, sec. 3.1.2]. In a bottom-up fashion, fan-in 2 is achieved by rewriting every $\wedge$-gate (resp., and $\vee$-gate) of fan-in $m>2$ with a chain of $m-1 \wedge$-gates (resp., $\checkmark$-gates) of fan-in 2. After that, to enforce smoothness, for every disjunction gate (now with a fan-in 2) of subcircuits $C_{1}$ and $C_{2}$, find the set of variables in $C_{1}$, but not in $C_{2}$ (denoted $V_{1-2}$ ), along with those in $C_{2}$, but not in $C_{1}$ (denoted $V_{2-1}$ ). For every variable $v \in V_{2-1}$, redefine $C_{1}$ as $C_{1} \wedge(v \vee-v)$. Similarly, for every variable $v \in V_{1-2}$, redefine $C_{2}$ as $C_{2} \wedge(v \vee-v)$. For example, for $\left(x_{1} \wedge x_{2} \wedge x_{3}\right) \vee\left(x_{2} \wedge-x_{3}\right)$, becomes $\left(\left(x_{1} \wedge x_{2}\right) \wedge x_{3}\right) \vee\left(\left(x_{2} \wedge-x_{3}\right) \wedge\left(x_{1} \vee-x_{1}\right)\right)$. This algorithm takes quadratic time in the size of the dDBC, which is its number of edges [1] sec. 3.1.2], [33].

Example 6 (example 4 cont.) By interpreting decision points and elements as disjunctions and conjunctions, resp., the SDD in Figure 3(a) can be easily converted into d-DNNF circuit. Only variables are affected by negations. Due to the children of node (3), that do not have the same variables, the resulting dBBC is not smooth (but it has fan-in 2). Algorithm 1 transforms it into the dDBCSFi(2) in Figure 1 .

```
Algorithm 1: From dDBC to dDBCSFi(2)
    Input : Original \(d D B C\) (starting from root node).
    Output: A \(d D B C S F i(2)\) equivalent to the given \(d D B C\).
    function FIX_NODE( \(d D B C\) _node)
        if \(d D B C\) _node is a disjunction then
            \(c_{\text {new }}=\) false
            for each subcircuit \(s c\) in \(d D B C \_\)node
                \(s c_{f i x e d}=\operatorname{FIX} \operatorname{NODE}(s c)\)
                    if \(s c_{\text {fixed }}\) is a true value or is equal to \(\neg c_{\text {new }}\) then
                    return true
            else if \(s c_{f i x e d}\) is not a false value then
                for each variable \(v\) in \(c_{n e w}\) and not in \(s c_{f i x e d}\)
                \(s c_{\text {fixed }}=s c_{\text {fixed }} \wedge(v \vee \neg v)\)
                for each variable \(v\) in \(s c_{\text {fixed }}\) and not in \(c_{n e w}\)
                \(\mid \quad c_{\text {new }}=c_{\text {new }} \wedge(v \vee \neg v)\)
                \(c_{\text {new }}=c_{\text {new }} \vee s c_{\text {fixed }}\)
            return \(c_{\text {new }}\)
        else if \(d D B C\) _node is a conjunction then
            \(c_{\text {new }}=\) true
            for each subcircuit \(s c\) in \(d D B C\) _node
            \(s c_{\text {fixed }}=\) FIX_NODE \((s c)\)
            if \(s c_{f i x e d}\) is a false value or is equal to \(\neg c_{n e w}\) then
                return false
            else if \(s c_{\text {fixed }}\) is not a true value then
                \(c_{\text {new }}=c_{\text {new }} \wedge s c_{\text {fixed }}\)
            return \(c_{\text {new }}\)
        else if \(d D B C \_n o d e\) is a negation then
            return \(\neg\) FIX_NODE \((\neg d D B C\) _node \()\)
        else
            return dDBC_node
    dDBCSFi(2) = FIX_NODE(root_node)
```

## 4 Shap Computation: Experiments

The "California Housing Prices" dataset was used for our experiments (it can be downloaded from Kaggle [24]). It consists of 20,640 observations for 10 features with information on the block groups of houses in California, from the 1990 Census. Table 1 lists and describes the features, and the way they are binarized, actually by considering if the value is above the average or not ${ }^{9}$ to better The categorical feature \#1 is one-hot encoded, giving rise to 5 binary features: $\# 1_{a}, \ldots, \# 1_{e}$. Accordingly, we end up with 13 binary input features, plus the binary output feature, \#10, representing whether the median price at each block is high or low, i.e. above or below the average of the original \#10. We used the "Tensorflow" and "Larq"| Python libraries to train a BNN with one

[^6]hidden layer, with as many neurons as predictors, i.e. 13, and one neuron for the output. For the hidden neurons, the activation functions are step function, as in (3).

Table 1: Features of the "California Housing Prices" dataset.

| Id \# | Feature Name | Description | Original Values | Binarization |
| :---: | :---: | :---: | :---: | :---: |
| \#1 | ocean_proximity | A label of the location of the house w.r.t sea/ocean | Labels 1h_ocean, inland, island, near_bay and near_ocean | Five features (one representing each label), for which 1 means a match with the value of ocean_proximity, and -1 otherwise |
| \#2 | households | The total number of households (a group of people residing within a home unit) for a block | Integer numbers from 1 to 6,082 | 1 (above average of the feature) or -1 (below average) |
| \#3 | housing_median_age | The median age of a house within a block (lower numbers means newer buildings) | Integer numbers from 1 to 52 | 1 (above average of the feature) or -1 (below average) |
| \#4 | latitude | The angular measure of how far north a block is (the higher value, the farther north) | Real numbers from <br> 32.54 to 41.95  | 1 (above average of the feature) or -1 (below average) |
| \#5 | longitude | The angular measure of how far west a block is (the higher value, the farther west) | Real numbers from -124.35 to -114.31 | 1 (above average of the feature) or -1 (below average) |
| \#6 | median_income | The median income for households within a block (measured in tens of thousands of US dollars) | $\begin{aligned} & \text { Real numbers from } 0.50 \\ & \text { to } 15.00 \end{aligned}$ | 1 (above average of the feature) or -1 (below average) |
| \#7 | population | The total number of people residing within a block | Integer numbers from 3 to 35,682 | 1 (above average of the feature) or -1 (below average) |
| \#8 | total_bedrooms | The total number of bedrooms within a block | Integer numbers from 1 to 6,445 | 1 (above average of the feature) or -1 (below average) |
| \#9 | total_rooms | The total number of rooms within a block | Integer numbers from 2 to 39,320 | 1 (above average of the feature) or -1 (below average) |
|  |  |  |  |  |
| Id \# | Output | Description | Original Values | Labels |
| \#10 | median_house_value | The median house value for households within a block (measured in US dollars) | Integer numbers from  <br> 14,999 to 500,001  | 1 (above average of the feature) or 0 (below average) |

According to the transformation path (2), the constructed BNN was first represented as a CNF formula with 2,391 clauses. It has a tree-width of 12 , which makes sense having a middle layer of 13 gates, each with all features as inputs. The CNF was transformed, via the $\operatorname{SDD}$ conversion, into a $\operatorname{dDBCSFi}(2), \mathcal{C}$, which ended up having 18,671 nodes (without counting the negations affecting only input gates). Both transformations were programmed in Python. For the intermediate simplification of the CNF, the Riss SAT solver was used [20]. The initial transformation into CNF took 1.3 hrs . This is the practically most expensive step, as was explained at the end of Section 3.1. The conversion of the simplified CNF into the $\mathrm{dDBCSFi}(2)$ took 0.8276 secs.

With the resulting BC, we computed Shap, for each input entity, in three ways:
(a) Directly on the BNN as a black-box model, using formula (1) and its input/output relation for multiple calls;
(b) Similarly, using the circuit $\mathcal{C}$ as a black-box model; and
(c) Using the efficient algorithm in [1] page 18] treating circuit $\mathcal{C}$ as an open-box model.

Fig. 4: Seconds taken to compute all Shap scores on 20, 40, 60, 80 and 100 input entities; using the BNN as a black-box (blue bar), the dDBC as a black-box (red bar), and the dDBC as an open-box (orange bar). Notice the logarithmic scale on the vertical axis.

These three computations of Shap scores were performed for sets of $20,40,60,80$, and 100 input entities, for all 13 features, and all input entities in the set. In all cases, using the uniform distribution over population of size $2^{13}$. Since the dDBC faithfully represents the BNN, we obtained exactly the same Shap scores under the modes of computation (a)-(c) above. The total computation times were compared. The results are shown in Figure 4 . Notice that these times are represented in logarithmic scale. For example, with the BNN, the computation time of all Shap scores for 100 input entities was 7.7 hrs , whereas with the open-box dDBC it was 4.2 min . We observe a huge gain in performance with the use of the efficient algorithm on the open-box dDBC. Those times do not show the one-time computation for the transformation of the BNN into the dDBC . If the latter was added, each red and orange bar would have an increase of 1.3 hrs. For reference, even considering this extra one-time computation, with the open-box approach on the dDBC we can still compute all of the Shap scores for 100 input entities in less time than with the BNN with just 20 input entities ${ }^{10}$

For the cases (a) and (b) above, i.e. computations with black-box models, the classification labels were first computed for all input entities in the population $\mathcal{E}$. Accordingly, when computing the Shap scores for a particular input entity $\mathbf{e}$, the labels for all the other entities related to it via a subset of features $S$ as specified by the game function were already precomputed. This allows to compute formula $\sqrt{1}$ much more efficiently ${ }^{11}$ The specialized algorithm for (c) does not require this precomputation. The difference in time between the BNN and the black-box dDBC, cases (a) and (b), is due the fact that BNNs allow some batch processing for the label precomputation; with the dDBC it has to be done one by one.

[^7]
## 5 Conclusions

We have showed in detail the practical use of logic-based knowledge compilation techniques in a real application scenario. Furthermore, we have applied them to the new and important problem of efficiently computing attribution scores for explainable ML. We have demonstrated the huge computational gain, by comparing Shap computation with a BNN classifier treated as an open-box vs. treating it as a black-box. The performance gain in Shap computation with the circuit exceeds by far both the compilation time and the Shap computation time for the BNN as a black-box classifier.

We emphasize that the effort invested in transforming the BNN into a dDBC is something we incur once. The resulting circuit can be used to obtain Shap scores multiple times, and for multiple input entities. Furthermore, the circuit can be used for other purposes, such as verification of general properties of the classifier [23, 11], and answering explanation queries about a classifier [3]. Despite the intrinsic complexity involved, there is much room for improving the algorithmic and implementation aspects of the BNN compilation. The same applies to the implementation of the efficient Shap computation algorithm.

We computed Shap scores using the uniform distribution on the entity population. There are a few issues to discuss in this regard. First, it is computationally costly to use it with a large number of features. One could use instead the empirical distribution associated to the dataset, as in [4] for black-box Shap computation. This would require appropriately modifying the applied algorithm, which is left for future work. Secondly, and more generally, the uniform distribution does not capture possible dependencies among features. The algorithm is still efficient with the product distribution, which also suffers from imposing feature independence (see [4] for a discussion of its empirical version and related issues). It would be interesting to explore to what extent other distributions could be used in combination with our efficient algorithm.

Independently from the algorithmic and implementation aspects of Shap computation, an important research problem is that of bringing domain knowledge or domain semantics into attribution scores and their computations, to obtain more meaningful and interpretable results. This additional knowledge could come, for example, in declarative terms, expressed as logical constraints. They could be used to appropriately modify the algorithm or the underlying distribution [5]. It is likely that domain knowledge can be more easily be brought into a score computation when it is done on a BC classifier.

In this work we have considered only binary NNs. It remains to be investigated to what extent our methods can be suitably modified for dealing with non-binary NNs.
