Abstract

We consider the dynamics and the interactions of multiple reinforcement learning optimal execution trading agents interacting with a reactive Agent-Based Model (ABM) of a financial market in event time. The model represents a market ecology with 3-trophic levels represented by: optimal execution learning agents, minimally intelligent liquidity takers, and fast electronic liquidity providers. The optimal execution agent classes include buying and selling agents that can either use a combination of limit orders and market orders, or only trade using market orders. The reward function explicitly balances trade execution slippage against the penalty of not executing the order timeously. This work demonstrates how multiple competing learning agents impact a minimally intelligent market simulation as functions of the number of agents, the size of agents' initial orders, and the state spaces used for learning. We use phase space plots to examine the dynamics of the ABM, when various specifications of learning agents are included. Further, we examine whether the inclusion of optimal execution agents that can learn is able to produce dynamics with the same complexity as empirical data. We find that the inclusion of optimal execution agents changes the stylised facts produced by ABM to conform more with empirical data, and are a necessary inclusion for ABMs investigating market micro-structure. However, including execution agents to chartist-fundamentalist-noise ABMs is insufficient to recover the complexity observed in empirical data.

1. Introduction

At high-frequency time scales, we can investigate how prices change at the level of individual trades revealing several remarkable micro-structural stylised facts [35, 22, 11, 4, 3, 38, 8, 7]. The most important of these stylised facts include the long-memory of order flows and absolute returns, the distribution of rare-events, and the power-law of price impact. Taken together, these stylised facts motivate a model for price dynamics based on order flow and liquidity provision, arising from the strategic behaviour of different classes of heterogeneous agents, operating at different time scales and under asymmetric information. These agents conceal private information to prevent adverse selection which limits the available liquidity, and has given rise to the notion of latent supply and demand for liquidity not reflected in the visible order-book. These micro-structural stylised facts are plausibly thought to arise from the interaction of latent supply and demand with revealed liquidity, facilitated by optimal execution agents. However, by definition, data pertaining to latent demand and supply is not publicly available, it is hidden, preventing a

detailed analysis into either top-down and bottom-up causation, or linkages, between the order execution process that reveals this liquidity and the market dynamics from historical market data.

Agent Based Models (ABMs) have been extensively used to explain subsets of various low-frequency stylised facts arising from the interactions of heterogeneous agents; most commonly chartists and fundamentalists within a minority game setting [9, 10, 32]. However, some micro-structural stylised facts can be directly attributed to the behaviour of optimal execution agents and isolating these features has received far less attention within the ABM literature. The execution of any parent order arising from latent demand incurs trading costs in the form of price impact. Optimal execution agents will try to minimise this impact, which arises from limited liquidity and incomplete information, through the use of strategic order-splitting. Here, a large parent order is split into smaller child orders to be sequentially executed. Empirically, order-splitting appears to be wide-spread in real markets, and is used to explain the observed persistence of order flow and the long-memory of the size of returns. Furthermore, it is now well-established that realised price impact is concave with a power-law relationship, which has been attributed to the transfer of latent liquidity to the visible limit order book in response to a change in price [14, 16]. In light of this,

how should optimal execution agents be defined in order to minimise costs and to simultaneously reproduce these stylised facts?

Firstly, it appears that realistic execution agents must also be able to use limit orders (LOs) to execute parent orders, in order to facilitate the transfer of latent demand and supply to the limit order book, and hence recover the concave price impact function. Next, we can distinguish between static and dynamic execution strategies. Markets are not automatically efficient in the sense of price predictability suggesting there is some form of *tatonnement*. Static strategies typically require some form of market efficiency in order to be optimal, *e.g.* consistency with linear price impact [29, 25, 16]. In contrast, the observed concavity of price impact [3, 20] provides both a normative and a positive argument for dynamic execution strategies that are aware of market conditions. Since a correct *a priori* specification of the data-generating process is unrealistic, it seems that some form of learning is necessary for dynamic strategies to be operational in practice. However, in the presence of many learning agents acting competitively, is learning still possible? This seems to depend on how market dynamics increase in complexity with the number of additional agents and the correlation between their payoffs [18, 39, 36].

In summary, the process that seems to dominate high-frequency phenomena appears to be the coupling between the low-frequency latent demand with the high-frequency mechanics, *i.e.* the market-microstructure, of continuous-time double auction markets in the presence of limited liquidity. We speculate that the role of learning and the choice of order types in optimal execution are important, if not fundamental, to this process. We are concerned about the role and nature of learning and how this could impact the stylised facts, and the market environment more broadly.

To explore this, we simulate how latent demand is revealed in a single stock financial market using an ABM to capture the market environment into which we introduce both single and many optimal execution agents that engage in learning. These agents each execute a single parent order in a market environment that also consists of (minimally intelligent) chartists, fundamentalists, and high frequency market makers. Model-free learning is incorporated using a simple (Multi-Agent) Reinforcement Learning specification. From these simulations, we examine how different model specifications affect stylised facts. We investigate whether the inclusion of the new agent-type, the execution agents with learning, to the traditional agent classes used to define the learning environment, can provide a more complete description of market ecology both in terms of stylised facts, but also by trying to recover the empirically measured market complexity. To do this, we view the ABMs as nonlinear dynamical systems and compare their complexity as measured by Grassberger-Procaccia Correlation Dimension plots.

However, our main contribution is to demonstrate how

different model specifications affect stylised facts. This yields several key findings. Firstly, we find that learning decreases the persistence in order flow, with some evidence that learning can also decrease the memory in the absolute returns. Second, we find that the persistence of order flow is (unsurprisingly) largely determined by the difference in the number of buying and selling agents. Third, we find that increasing the number of agents increases the persistence of order flow. Fourth, the ability to use LOs to execute a parent order results in lower price impact and faster decay in the size of absolute returns. This suggests that a good approach to optimal execution will always be a judicious combination of resting LOs, with market-orders (MOs) that enjoy immediate execution. Surprisingly, we did not find conclusive evidence that learning reduced price impact. Lastly, the inclusion of many execution agents endowed with learning, trading a single stock, is not able to recover the complexity observed in real-world data.

The rest of this paper is organised as follows. In section 2, we review the literature to motivate our investigation into optimal execution with learning. In section 3, we specify a novel learning agent that can post market and LOs to execute a parent order, and examine its learning dynamics (section 3.3). In section 4, we present the remaining results of our study, which includes the analysis of stylised facts 4.1, and an investigation into the market dynamics and complexity 4.5. Finally, in section 5, we conclude by summarising our study and indicating possible future directions of research.

2. Background and Motivation

2.1. Reinforcement Learning for Optimal Execution

An important question in formal models of learning is determining the conditions to allow for successful learning. Learning is said to be possible when, given a sufficient amount of data, the errors of the learners outputs can be made arbitrarily small. When it is difficult to show analytically that an algorithm can learn, the ability to learn is intimated from measuring performance on test data. In sequential decision problems, asymptotic convergence guarantees have been derived for many reinforcement learning algorithms such as Q-learning, under the assumption that the agent's environment is stationary [30]. Here, stationarity refers to state transition probabilities and the reward function. In financial markets, where the dynamics of the environment is changing, is learning possible?

Intuitively, we may guess that under a changing environment, a learning agent would have to continually relearn its policy to be optimal under the prevailing conditions. Thus, it would seem that asymptotic convergence may not be possible, but this need not be catastrophic to learning. Learning algorithms may still be able to out-perform rule-based counterparts; but inferring performance on static data may be misleading. Indeed, it was

shown that a simple learning agent could outperform a TWAP agent Dicks and Gebbie [13] where the learning dynamics of a simple RL execution agent in an ABM where non-stationary dynamics in the environment are primarily driven by the interactions of minimally intelligent agents did not have a policy that converged. Instead, the difference in policy over consecutive training periods appeared to converge. This work extends [13] by studying the learning and market dynamics that arise from many learning agents interacting within an environment that includes minimally intelligent agents.

Simulating multiple RL agents in an existing ABM of the LOB is a key long-term objective to investigate the effects of learning in a dynamic market environment, where each RL agent is attempting to learn the optimal trading strategy by continually adapting to each other and the foundational model. Interactions between minimally intelligent agents can produce nonlinear dynamics, but agents' decision rules are not changing over time, limiting the variation in the environmental dynamics. However, in the presence of multiple learning agents, the best policy of an agent changes in response to the changing environmental dynamics, which in turn changes with the other agent's policies [6]. Studying optimal execution in a MARL framework within an ABM can lead to a better understanding how increasing the number of RL agents affects the agents' ability to learn as well as how these affect the underlying ABM.

In multi-agent reinforcement learning, an important problem is the appropriate specification of learning goals, which typically involves a trade-off between stability and adaption [6]. The former is desirable for inferential purposes and establishing generalisation, but the latter is desirable for continual performance improvements. For example, learning stability can be established by specifying convergence to an optimal Nash equilibrium as a common learning goal. The combination of the two broad learning goals can be seen as having each agent converge to a stationary policy where each agent's policy is the best response to all the other agents' policies. Convergence to a Nash equilibria is easier to establish when agents are fully cooperative (agents have identical reward functions) or competitive (agents rewards are zero-sum), in comparison to when agents are trained independently without a common goal [5]. In the latter case, asymptotic performance guarantees of (single-agent) Q-learning may fail [40], but training agents independently still can work well in practice [42, 17].

2.2. Learning in Complex Multi-player Games

This work is further motivated by the study of learning dynamics in complex games [18, 39, 36], where complexity is measured in terms of the number of possible actions. In particular, Galla and Farmer [18] considers a two-player game, and show how the learning dynamics of an RL algorithm called experience-weighted attraction (EWA) are affected by the correlation between the player's

payoffs and the memory parameter of the learning algorithm. Galla and Farmer [18] finds that the learning dynamics of player's strategies can be separated into three different regimes. Namely, *i*) strategies can converge to a unique fixed point if agents have short memory, and correlation between the players payoffs becomes increasingly negative (ie. competitive), or *ii*) if correlations are negative but players have long memory, then learning dynamics can be chaotic or converge to limit cycles, and *iii*) if players have long memory and payoffs are positively correlated (ie. cooperative), then learning has a multiplicity of fixed points. In the second regime in particular, strategies are essentially random and learning is not possible. In two-player normal form games, a possible reason for this is that as games get more complicated and/or more competitive this causes best reply cycles to become dominant, which [36] shows to be a good predictor of the non-convergence of several learning algorithms. In games involving more than two players Sanders et al. [39] show that the parameter range in which learning converges to a fixed point becomes smaller as the number players increase. This implies that chaotic behaviour is characteristic of many-player games.

In summary, as games become more complex, and agents payoffs become increasingly independent, and the number of players increases, equilibrium becomes more unlikely. So, if normal form games are a good model for the games market participants play, and if these participants can be modelled reasonably well by learning algorithms, this body of work calls into question the common assumption of equilibrium in economics and finance. However, a key constraint related to the carrying capacity of real world markets is that of liquidity: without sufficient liquidity, trading decisions can not be made, compromising both the ability to learn and the profitability of the corresponding policy. Hence to understand how the scaling insights of many player games can impact financial markets one needs to include a broader ecosystem that captures these salient constraints: liquidity and the indirect cost of trading.

2.3. Market Ecology

The interactions of market participants can be viewed from an ecological perspective, forming a useful conceptual framework to develop ABMs to investigate disequilibrium price dynamics. Agent classes are specified in terms of strategies, analogous to "species" in ecological systems, which are rules describing how agents make trading decisions and hence govern their interactions [15]. Whilst market ecology is far from a formal theory of market functioning, two classification systems have seemed to have emerged in the literature: i.) Chartist-Fundamentalist-Noise (CFN) models and ii.) Liquidity-Provider (LP) and Liquidity-Taker (LT) models [2]. In both classification systems, agent interactions are intermediated by price.

Chartists determine trading behaviour purely on past performance, whereas fundamentalists determine trading behaviour based on current price relative to some subjective valuation. Chartists and fundamentalists have oppos-

ing effects on price dynamics, and their interaction is able to produce many early stylised facts observed in intraday and lower frequencies (mesoscale) including clustered volatility and fat tails in returns. In contrast, the liquidity provider and liquidity-taker classification is useful to explain microstructural stylised facts in terms of how information is processed into prices by agents operating at different timescales, whilst keeping prices unpredictable. In particular, liquidity-takers operating at low frequencies (particularly the fundamentalists) with large liquidity demands, can only trade incrementally owing to the limited available liquidity provided by higher frequency market makers. In between the large low-frequency liquidity takers and high-frequency market makers, are chartists acting at shorter time intervals acting on information contained in price changes.

To capture an ecology with limited liquidity and reasonably realistic market impact, we postulate a model in terms of 3-trophic levels defined respectively by three agents classes: learning agents, liquidity takers, and liquidity providers. This is similar to the thinking used in a 3-trophic level model of carnivore-herbivore-plant systems. Here, we have learning agents as the “carnivores”, or predators that engage in opportunistic behaviours which necessarily requires adaption and hence learning. We have the liquidity takers, both the fundamentalists and the trend-followers, as “foraging herbivores” since their activity is rule-based and hence “passive” in their consumption of liquidity. Liquidity, is the “food” provided by “plants” which are uninformed High-Frequency Traders (HFTs), or rather Electronic Liquidity Providers (ELPs). This suggests not only a financial market equivalent of a “food web” but also the inherent nonlinearity and feedbacks.

How trophic levels are defined in financial markets is necessarily contested, and can be fluid as markets change and adapt. However, this metaphor frames a narrative around how we are currently thinking about the role of learning agents within our financial market ecosystem – in particular, the relationship of strategic order-splitting to the latent order book in an environment with a highly constrained carrying capacity. We apparently do not need learning for the first two trophic levels of our system, since static mechanistic rule based responses to the market states seems to be sufficient to recover almost all of the necessary stylised facts of the environment [13]. Learning seems to only become important as a coupling mechanism between the visible market (the learning environment) and the latent order book, when one needs to find a mechanism to drive strategic order splitting that can be used to fine tune the observed balanced between order-flow persistence, price volatility and clustering, and the observed extreme events in the complete market, particularly when further tuning the parameters describing the environment cannot do so.

Whilst there are feedbacks between each class of agents in the different trophic levels, our framework suggests a hierarchy based on dependency. Although not a functioning

market, the presence of ELPs is sufficient for the existence of a persistent order-book, hence providing an environment for the other agent classes, and thus existing at the bottom of the hierarchy. In contrast, learning is situated in higher trophic levels [1], because the higher levels necessarily include adaption. However, learning agents cannot adapt to ELPs alone who just create noise. Thus, indicating the need for minimally intelligent agents at an intermediary level whose actions create learning opportunities. This picture in turn would suggest that a market made entirely of learning agents would not be feasible because of the extremely limited liquidity. The carrying capacity of the environment would be too low to support both the cost of learning, and then using it successfully, because other agents adapted similarly to the single learning agent with insufficient liquidity to take the necessary learning actions. This is speculative, but we think it is helpful in framing the overall thinking behind our specific model choices.

2.4. Limitations

One question surrounding the study of ABMs is determining whether simulated paths represent general agent and market behaviour or are particular to modelling choices. In our implementation, we address this by separating various sources of variation introduced in the modelling process. In particular, we have still retained the three-step approach for the development and calibration of the learning environment adopted in [27, 13]: 1. sensitivity analysis, 2. calibration with a minimal set of known and re-used seeds using the relationships between model and parameter variations found from the sensitivity analysis, and 3. simulation using the same restricted number of seeds using the calibrated parameters for the training environment. The number of random seeds is chosen to crudely optimise the compute times whilst providing relative stability of the parameters and a learning environment to faithfully capture the empirically measured environment. Many sample paths are simulated from each random seed to facilitate learning since including learning within an agent-based model imposes computational considerations that are at least an order of magnitude more onerous than a typical sensitivity analysis.

One of the drawbacks of ABMs is that they are computationally expensive to run, necessarily forcing pragmatic choices on the modeller. In this work, key sub-cases of the agent-based model were prudently chosen to explore the impact of both model and sample variations, whilst trying to prevent model and path variations that could confound our results. Since generating all possible combinations of parameters and paths is not computationally tractable, a subset must be pre-selected for simulation, which substantially restricts this type of simulation work.

Consequently, it may appear there is the possible danger of selective bias in the presented results, where possible sub-cases, parameters, and paths are chosen *a-priori* to support particular conclusion. However, owing to the non-linearity of the system and the inclusion of various sources

of noise, we do not know with any certainty the possible results corresponding to different parameter combinations, precluding the possibility of selective bias. However, conclusions from restricted results are never as robust as one would like, particularly when critiqued through the lens of linear statistical modelling techniques. Rather, our results are indicative and aimed to guide incremental model refinement to explain specific model features. One key lesson is that, although we can capture most of the key stylised facts, we are not able to capture the observed market complexity, but many of the narratives that emerge do make physical (or rather financial) sense.

3. Agent Specification and Learning

We investigate the interaction of different types of optimal execution agents within a pre-calibrated event-based minimally intelligent ABM, which forms a training environment. The minimally intelligent agents consist of chartists, fundamentalists, and liquidity providers. Their full specification, as well as details related to their learning dynamics, can be found in [13], which we do not restate here for the sake brevity. We study different cases, described in 2, where each case is defined by the number, type, and side (ie. buying or selling) of the agents, to determine how each of these characteristics affects the stylised facts.

The state space used for both agent classes corresponds to the smaller state space from Dicks and Gebbie [13], which is described in Table A1. Consequently, the results of this study are directly comparable with the results presented in Dicks and Gebbie [13]. Similarly, the agent actions for MOs as based on multiples of a TWAP strategy to provide an additional dimension to compare with work [13].

3.1. Actions

The set of execution agents investigated in this study include a minimally intelligent execution agent, characterised by a TWAP schedule consisting of MOs only, and two types of learning agents. We denote the first class of learning agents as “Type I” agents, also adopted in [13]. Type I agents have explicit order-splitting but only use MOs to interact with the market. Furthermore, in this study, we introduce a new class of agents, denoted “Type II” agents, which can trade with both MOs and LOs. This means that Type I agents cannot directly interact with each other in the model but are inter-mediated only by the liquidity providers. However, Type II agents can interact directly with each other and other agents as they use both LOs and MOs to trade.

Both type I and type II agent use trading schedules that are multiples of TWAP and order sizes following Dicks and Gebbie [13]. The action set of the Type I agents are given by $a_X = [0, 0.25, 0.5, 0.75, 1, 1.25, 1.5, 1.75, 2]$ giving a grid of actions from small orders to large orders as multiples of the TWAP strategy. For the Type II agents, MOs

are placed into the market at some rate of trading ν as a function of machine time, while the LOs will be placed into the order-book at a depth δ from the mid-price. The order sizes will be as before. Here the actions will be the placement depth at an activation is $a_\delta = [0.01, 1]$ (shallow or deep) and the rate of trading $a_\nu = 1/T[100, 10, 1]$ (fast, moderate or slow) as a multiple of the total session length.

3.2. Rewards

For the Type II agent, we specify a reward function that is symmetric between buying and selling agents, without resulting in agents learning degenerate policies. The reward function of the agent specified in Dicks and Gebbie [13] is suitable for profit maximisation on the sell-side only. Attempting to construct a symmetric reward function applicable to buying agents through cost minimisation results in a degenerate policy which minimises trading costs by not trading. Thus, some form of penalty needs to be included in a suitable reward function to encourage trading.

As in prior work [23, 13], we considered using Perold’s implementation shortfall [37], where the buying agent would try to minimise the difference between the Volume Weighted Average Price (VWAP) achieved using its strategy and the hypothetical VWAP it would receive if it traded the entire parent order at the initial price, with no price impact using an Immediate Execution (IE) strategy. However, in this case, the minimum implementation shortfall is negative, which can incentivise buying at higher prices. Conversely, if you aim to maximise the implementation shortfall, to try incentivise buying at lower prices, then you have the same problem arising from minimising the total cost, because the agent learns not to trade.

The aim is to formulate a reward function that is intuitive and minimises the cost on the buy side, maximises the profit on the sell side, and creates an incentive to trading. This can be achieved by a combination of the trader’s slippage and a penalty for not trading. For the n^{th} order in an episode the reward function for the ℓ^{th} learning agent:

$$R_{\ell,n} = \underbrace{\pm \ln \left(\frac{p_{\text{VWAP}}(\mathcal{X})}{p_{\text{VWAP}}(\mathcal{X} \setminus \mathcal{X}_\ell)} \right)}_{\text{slippage}} - \underbrace{\left(\frac{x_{\ell,n}}{v_n} \right) \lambda_r e^{\gamma_r t}}_{\text{penalty}}. \quad (1)$$

The first term is the *slippage*, and is positive for selling agents and negative for buying agents. By maximising this reward we aim to get higher prices when we sell, and lower prices when we buy. Here $p_{\text{VWAP}}(\mathcal{X})$ is the VWAP price received from the set $\mathcal{X} = \{x\}_{i=1}^n$ of all trades including the n^{th} trade submitted by the ℓ^{th} RL agent. The VWAP price found from all trades excluding all the trades submitted by the ℓ^{th} RL agent is $p_{\text{VWAP}}(\mathcal{X} \setminus \mathcal{X}_\ell)$. The difference between these two quantities measures the slippage between a given RL agent’s trades, and the trades made by the rest of the market (potentially including other RL agents).

The second term is the *penalty* term for not trading, which creates an incentive to trade whether on the buy

Table 1: Agents using strategic order splitting. Those engaged in learning their their respective rewards and actions are given with the state-space size on (n_t, n_I, n_S, n_v) . All the agent below engage in learning except for the minimally intelligent agent S

Agent type	Reward	State-space Size	\pm	Actions	
				Parent order	Order-type
Hendricks and Wilcox [23]	short-fall	5	Sell	multiple of AC	MO's
Dicks and Gebbie [13]	trading profit	5,10	Sell	multiple of TWAP	MO's
Type S^\pm	-	-	Buy/Sell	TWAP	MO's
Type I^\pm	slippage - penalty	5	Buy/Sell	multiple of TWAP	MO's
Type II^\pm	slippage - penalty	5	Buy/Sell	multiple of TWAP	MO's & LO's

or sell side. Here, the total time past in the simulation is t , the remaining inventory is $x_{\ell,n}$, and the total volume matched for the n^{th} order is v_n . The penalty increases exponentially as time increases, forcing the agents to learn to trade before the end of the simulation. The penalty is proportional to the inventory remaining and inversely proportional to the amount of volume matched for the last trade, ensuring that the penalty increases as the remaining inventory increases, and decreases as the amount traded by the n_{th} order increases. The agent will want to trade more when there is lots of inventory remaining. The penalty has two parameters: λ_r controls how much effect the penalty term has on the reward function, and γ_r controls the sensitivity to time.

Together, the slippage and penalty mean that the agents aim to minimise slippage and get the best prices relative to the rest of the market, while being incentivised to trade. The return function for the RL agent is the accumulated reward: $\sum_n R_n$. This will be maximised by all the RL agents.

3.3. Optimal Policies and Convergence

To visualise the convergence of the training of learning agents we plot the agent policy returns as a function of the training episodes in Figure 1. Here we have used 1000 training episodes. Figure 1b shows the return rewards for agent type I, where both buyers (+) and seller (-) are shown. Agents are taken from different model configuration sets *e.g.* the blue line is a lone buying agent (I^+) using only MOs, and has similar dynamics to the a lone selling agent (I^-) given in pink. This shows that the rewards appear to converge under training. Similarly, Figure 1b has the same plot but for agents of type II, these are agents that use both MOs and LOs. Again, we note reasonable evidence of convergence behaviour in the reward function over the 1000 training episodes for the ten different learning agent configurations. The TWAP agents (S^\pm) are included for comparison.

In Figure 2 we show the final buying and selling learning agents greedy policy after 1000 training episodes in the training environment [13] for Case 5 (the case which includes both type I^+ and I^- agents together in the environment). The five discrete inventory states increase bottom to top and the temporal states increase left to right across the episode. Within in each inventory and time

Case #	Types	#Agents	Parent order size
0	-	0	-
1	S^-	1	6% ADV
2	$5S^+$	5	$\frac{1}{5}$ (6 % ADV)
3	I^+	1	6% ADV
4	I^-	1	6% ADV
5	I^+, I^-	2	3 % ADV
6	II^+	1	6 % ADV
7	II^+, II^-	2	3 % ADV
8	II^+, I^-	2	3 % ADV
9	$5I^-$	5	$\frac{1}{5}$ (6% ADV)
10	$5II^+$	5	$\frac{1}{5}$ (6% ADV)
11	$5I^+, 5I^-$	10	$\frac{1}{10}$ (6% ADV)
12	$5II^+, 5II^-$	10	$\frac{1}{10}$ (6% ADV)

Table 2: Different combinations of agent engaging in strategic order splitting. The first case is the agent-based model without any learning agents – type 0. The minimally intelligent agents engaging in naive order splitting using a TWAP strategy are denoted as agents of type S . The agent types are either an acquisition agent (+), or a liquidation agent (-). The number of acquisition agents and liquidation agents are given for each case. The overall order size is in multiples of $X_0 = 6\%$ of ADV for all agent classes to ensure that the market has similar liquidity across all the cases considered. The learning agents are then either of class I or II. Here class I only use market-orders and class II use both market-orders and limit-orders (see Table 1). The state-space is of size 5 for all the learning agents.

state there are five spread and volume states, represented as heat maps. The specific actions are label as colour legend on the left and action “-1” represents the state has not been reached, and increasing aggression via the size label move bottom to top. Here only MOs are used. The learning agent with a mixture of MOs and LOs is given in the action space example for Case 6 in Figure 3.

In Figure 3 we have the final greedy policy for Case 6 (type II^-) learnt over 1000 training episodes in the ABM training environment. The five inventory states increase bottom to top, and the five temporal states left to right, from the first fifth of the training episode to the last fifth. Within each inventory and time combination a 5×5 heat map for the spread and volume state combinations is plot. The legend on the left provide the mapping from the number of actions taken for a particular combination to the action and represents the greedy actions taken in a particular state. The Case 4 agent is a combination of MOs and

Figure 1: The agent returns are given as a function of the training episodes. This demonstrates how the different agents rewards converge under training. In Figure 1a the return rewards for agent type I, both buyers (+) and seller (-) is shown. Type I agents only trade using market orders. 1b has the same plot but for agents of type II, these are agents that use both market orders and limit orders.

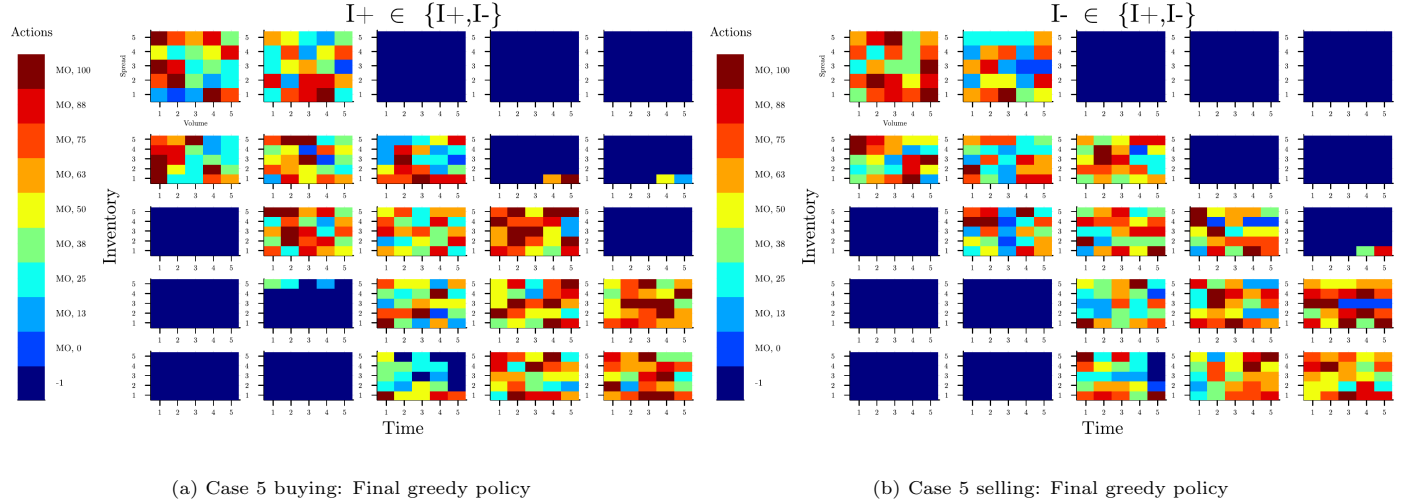

Figure 2: The final ϵ -greedy policy is shown for a type I agent example as a heat map. Here for Case 3 (see Table 2) with the buying agent in Figure 2a and the selling agent in 2b.

LOs actions with varying aggression.

4. Exploratory Data Analysis

The measured trade-and-quote (TAQ) data is a single 8 hour day of trading, on 08-07-2019, for a single Johannesburg Stock Exchange (JSE) dual-listed equity, Naspers (NPN.J) [28]. The data excludes all auctions. The simulated data similarly represents a single period comparable to 8 hour of trading on the basis of the average daily volume (ADV) where the ABM component was calibrated to the estimated moments. The method of simulated moments was used to calibrate the model for the base case (Case 0) and is described in prior work [27, 13].

4.1. Comparing Stylised Facts

Table 3 compares the moments for key configurations. The sample paths used to capture the model variations are comparable to those found in the calibration. The cases are ranked, left-to-right, on the micro-price fluctuation volatilities and the GPH, the measure of the long-range dependency. All the models have more extreme events than found in the real world data. None of the classes suggest evidence for a unit-root.

Multiple balanced learning agents (Case 5) increases the long-range dependencies (GPH) and mean-reversion (Hurst), possibly because of interactions. Conversely, Type II agents decrease long-range dependency whilst reducing volatility. We believe this occurs since allowing execution agents to post LOs introduces additional heterogeneity in the order flow and liquidity provision processes, reducing long range dependence, whilst the additional liquidity pro-

Figure 3: The final greedy policy example for a type II agent as shown for Case 4 (see Table 2) as a heat map.

vided by these agents reduces the occurrence of liquidity shocks, decreasing volatility. From the Hill estimators we see that Case 5 has less extreme events (a slower decay in the tail distribution exponent) than Case 1, which may suggest that balanced execution agents (*i.e.* equal number of buying and selling agents) more generally, reduces the tail effects.

4.2. Persistence of Orderflow

The ACF of trade-signs reflects the persistence in the direction of the MO flow¹. Due to potentially large sampling variation, analysis of a single path is not indicative of general behaviour. On the other hand, averaging sample ACFs tends to conceal interesting differences in the distribution of sample paths between the different cases. Thus, we consider average sample ACFs and the individual sample paths to explain the ABM behaviour, and discuss broad phenomena observed from their plots.

Firstly, as seen in Figure 6a, the average level of ACF reflects the number and (net) direction of the execution agents. The ABM was calibrated in an upward trending market, and hence the base case produces sample paths that are slightly more biased towards buying. Adding execution agents increases the persistence of the trade signs, and hence the ACF, simply by increasing the proportion of buys in the order flow. Conversely, including selling agents in the ABM results in an increase in activity in opposition to the original orderflow, thus decreasing the ACFs. Including both selling and buying agents produces ACFs that tend to lie between the ACFs of the buying and selling agents respectively.

However, as seen in Figure 6b, we believe the observed increases or decreases in ACF, largely reflect the bias of direction of order flow in the ABM. If the ABM was biased towards selling, we would observe the effects in the

opposite direction observed here. Nonetheless, we observe that the change in level from including agents of a given type become more pronounced with the number of agents, as these execution agents start to dominate the order flow over the other classes.

Secondly, as seen in Figure .9, following the inclusion of execution agents, the ABM produces, with greater frequency, sample paths where the cumulative direction of the order flow persists for very long periods. The corresponding sample ACFs are linear with very slow decay. This is especially evident in the minimally intelligent cases (TWAPs), where ACFs become increasingly linear with greater frequency as the number of agents increase. Surprisingly, the presence of sample paths with persistent cumulative order flow is also evident (although to a lesser degree) when the number of buying and selling agents are equal. However, the remaining sample paths may be non-linear with several changes in the direction of cumulative order flow with corresponding nonlinear ACFs, which can produce nonlinear behaviour in the average ACFs.

We observe that increasing the number of agents tends to decrease the rate of change of the ACF and is most evident at low lags (less than 1000 events). In the base case, the orderflow arises from the interaction of fundamentalists and chartists, which tends to have higher autocorrelations at shorter horizons, most likely due to minority game dynamics. In contrast, the order flow increasingly reflects the activity of execution agents as their numbers increase, which tends to result in linear slow decaying ACFs, and decrease the decay rate of ACF.

4.3. Price Impact

Price impact is defined as the instantaneous change to the mid-price following a trade, which depends on the shape of the orderbook at the time of trade. The greater the amount of liquidity, particularly at prices at and close to best quotes, the lower the price impact. Conversely, reducing the available liquidity will increase price impact.

Liquidity supply is dynamic and is reduced by liquidity taking agents (and order cancellations), and is increased by liquidity providing agents. Thus, differences between cases can be attributed to the differences in the trading and liquidity provision behaviour of the different agent classes. As with the analysis of tradesigns, the trading and liquidity provision behaviour is path-dependent and hence has a large degree of sampling variation, which we try to eliminate by analysing average price impact curves.

The clearest pattern that we observe is that cases with type 2 agents have lower price impact than Type 1 agents. Type 2 agents can use LOs in place of MOs to execute their parent orders, thereby reducing liquidity taking behaviour whilst increasing liquidity provision, both of which result in greater average available liquidity.

¹The ACFs are not on de-measured data because the data is ordinal.

Moment	Simulated								Estimated	
	Case 5:ABM + I [±]		Case 1:ABM + S ⁻		Case 0:ABM		Case 6:ABM + II ⁺		JSE:NPN.J

Table 3: Simulated moments (using the calibrated model for the environment) and estimated moments. These are the same used in prior work [13] and are briefly summarised here in Table A2. The estimated moments are from the market data [13]. The simulated moment sets are ordered on decreasing micro-price volatility (Std.) left to right.

Figure 4: Price impact plots for the twelve cases which include optimal execution agents. Left and right for buying and seller initiated. We see that the cases which include Type II agents (blue) have lower price impact than Type I agents. This suggests that using limit orders to take advantage of opportunities created by market flow and changes in the spread.

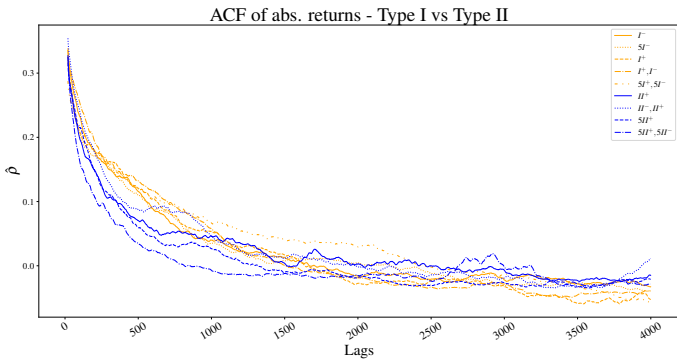

Figure 5: Absolute value auto-correlations plots comparing Type I (orange) and Type II (blue) cases. Type II agents suppress autocorrelations while agents type I agents have non-trivial autocorrelations in absolute value of the mid-price returns. This is indicative that the more complex Type II agents reduce regularity in potentially both the order flow, and the liquidity provision processes.

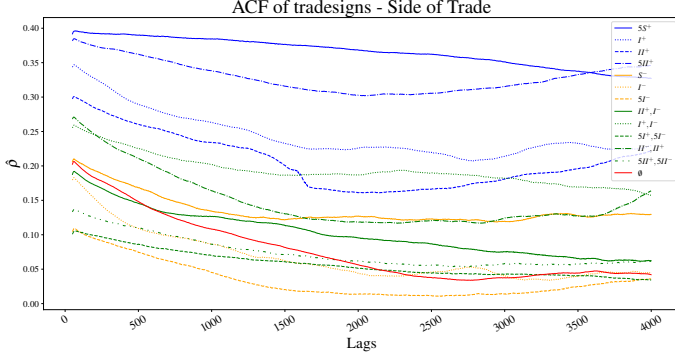

4.4. Memory in Absolute Returns

The ACF of absolute returns measures persistence in the size of returns calculated from micro-prices², reflecting the dynamics of the top of the order book. By definition, a change in the micro-price arises from a change in the top-of-book price and/or top-of-book volume. Changes in these quantities are due to events: a trade, a new limit order or a cancellation, and how these quantities change depend on the shape of the order book. The different event-types are mutually exclusive and have their own processes defined by volume, price, and relative frequency.

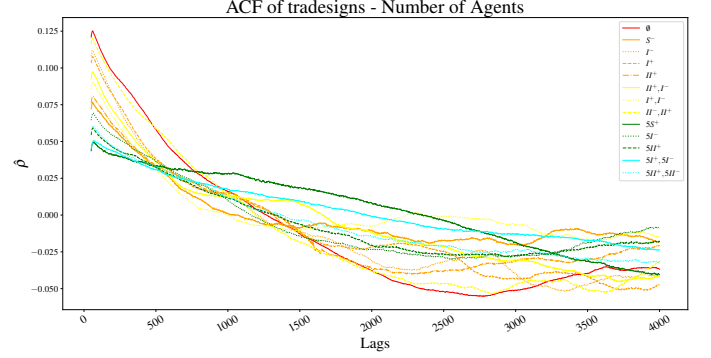

Thus, the ACF of absolute returns encapsulates the behaviour of a wider array of market variables, in comparison to the ACF of tradesigns and price impact curves, making any observed patterns remarkable and worthy of attention, but difficult to interpret.

Here, we observe two patterns which appear to support the hypothesis that the variation in liquidity demand in excess of liquidity determines the decay in the ACF of absolute returns. Firstly, the ACF decays at the slowest

²The ACF of the absolute returns uses demeaned data.

(a) ACF of tradesigns (not demeaned)

(b) ACF of tradesigns (demeaned)

Figure 6: Auto-correlation functions of tradesigns. Left and right for not demeaning and demeaning respectively. On the left, we observe that the level of the ACF reflects the imbalance in the number of execution that are buying vs selling. The level of the ACF increases with more buying agents (blue), is moderated by the including both buying and selling agents (green), and decreases by including selling agents only (orange). Note however, that directional changes in the ACF reflect may reflect that the base ABM (red) was calibrated in an upward trending market. On the right, we demean the ACF so that the imbalance in number of agents doesn't dominate the plot visually. We find that the increasing the number of agents (red is lowest, cyan is greatest) decreases the rate of decay of the ACF.

rate when five buying TWAP agents (Case 2) are added the base ABM, since this reduces variation in the volume and frequency of MOs. Furthermore, we see more generally that the ACF of type II agents decay faster than type I agents, because the ability to post LOs of varying size and depth introduces further variation in order flow and liquidity processes, which is temporally uncorrelated due changes in the market's state. However, limitations in the data prevented a convincing support or falsification of this hypothesis.

4.5. The missing complexity

Although we are able to recover many of the stylised facts (See Table A2 and Table 3) we are not able to fully recover sufficient model complexity relative to the measure real-world data. This is shown in Figure 8. The empirical data from the JSE test data is given with confidence intervals (red). The training environment is shown in black with confidence intervals. The learning agent configurations use the type labelling from Table 2. We notice that the none of model configurations are able to capture the full complexity of the real world data, and all have dimensions less than at least 2. The single agents tend to have dimensions slightly greater than that of the e-ABM, and the many agent configurations, slightly less. This is elaborated in Table 8b. Table 8b gives the relative differences of the model configurations. The agent case (first column), RL agents types (second column) and ΔD , the difference between fractal dimensions of the different configurations, and the ABM's fractal dimensions, as averaged across the embedding dimension (see Figure 8a) are sorted on the number of RL agents interacting with the ABM.

We estimate the correlation dimensions using the Grassberger-Procaccio algorithm [21]. This gives us a reasonable bound on the required phase space from the micro-price data. The resulting correlation dimension will be used as a proxy

for representation dimension of a particular model configuration *i.e* as a measure the model configurations relative complexity. We select the correlation time in machine-time by selecting the first minimum in the micro-price autocorrelations [24].

From Table 8b we can consider the relative differences in the model complexity measured at the higher embedding dimensions where there is the slowest increase in the estimated fractal dimension (the right of Figure 8a). In particular when focusing on the difference on the right of the inset of Figure 8a. Here we find that when single learning agents are combined with ABM they tend to increase the fractal dimension, and hence, the complexity of the model configuration. While adding multiple learning agents tends to decrease the fractal dimension – possibly because these tend to interact with each other and reduce the overall impact of adaption and learning in the combined market. However, it is important to realised that here the over-all total outstanding initial parent order volume has been keep the same, at $X_0=6\%$ of ADV (see Table 2). This means that the combined outstanding orders, the volume exposure (Vol. Exp.) for the multi (many) learning agents cases are *balanced* for cases 5,7,8,11 and 12, where the size of the buying position is the same as the selling position, zero. This is not the case for cases 1,2,3,4,6,9 and 10 where there is non-zero volume exposure, the volume exposure is *one-sided*. This suggests that increases in the fractal dimension may be explained in this model to be due to asymmetric liquidity demand. The extent to which the action state relationships are different across these cases can be seen in the appendices where the final greedy policies are compared for similar agent types.

5. Conclusion

Our expanded description of market ecology includes optimal execution agents, which is necessary to produce

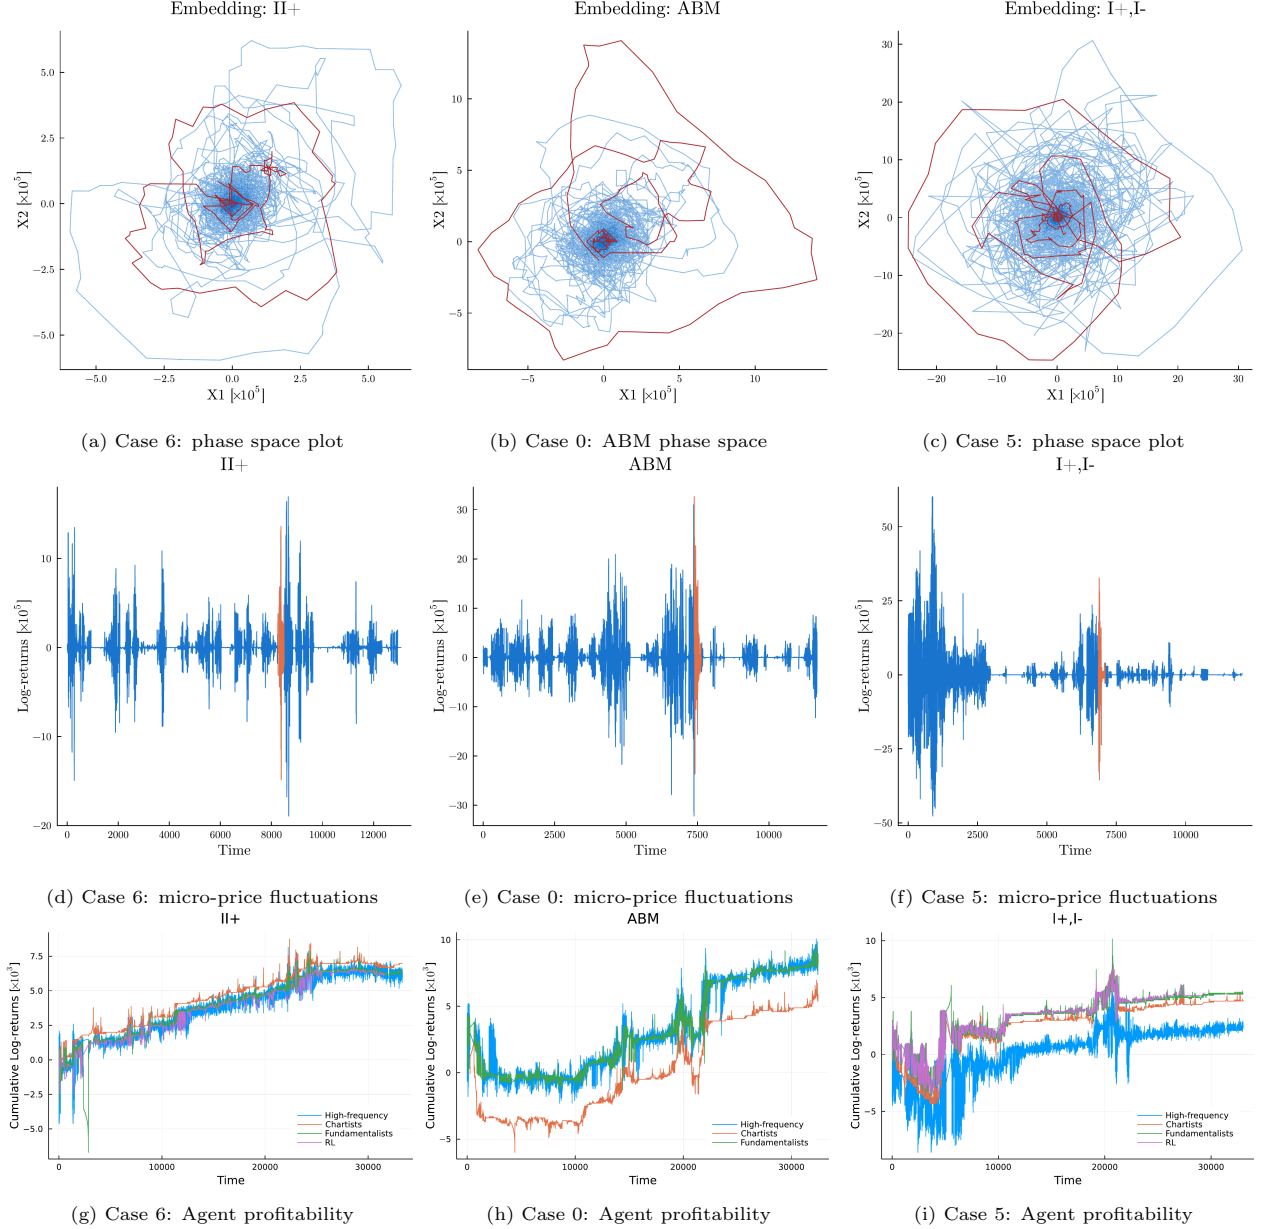

Figure 7: The phase space reconstruction plots using a 2-dimensional embedding, and a delay times $\tau = 10, 10$, and 6, respectively, for figures 7a, 7c and 7b. Segments, each of 250 points, are high-lighted in red and show the dynamics associated with large micro-price movements, and these associated time-series segments are given in second row of figures 7d, 7f and 7e. We notice that there is non-random structure to the dynamics with indications of quasi-periodic orbits. The plots are noticeable distorted relative to each other. With the single learning agent (Case 6) having the most extended phase-space, and the situation with both a buying and selling learning agent (Case 5) having the most concentrated dynamics. The lower row of plots are equivalent to “population” plots for the four different agent classes, the liquidity providers, the two classes of minimally intelligent liquidity takers, and the optimal execution agents where figures 7g, 7h and 7i plot the total running profit of the four agent classes.

stylised facts associated with order flow and the cost of trading. We further argue that learning is necessary because markets fail when the volume traded by a given agent exceeds the carrying capacity of the environment. However, having many agents attempting to learn simultaneously can result in complex non-stationary market dynamics, preventing successful learning for any agent.

The inclusion of execution agents to a minimally intelligent ABM introduces additional heterogeneity into the

observed order flow and liquidity provision processes. How these processes, and consequently the stylised facts, change depend on the specification of the optimal execution agents. In particular, we find that: *i*) persistence in order flow increases with the number of execution agents trading on a single side, *ii*) the realised cost of trading decreases when agents can submit LOs, and *iii*) increasing the complexity of trading agents introduce an additional source of variation into the price process. These findings suggest the

(a) The fractal (correlation) dimension as a function of the embedding dimension found using the Grassberger-Procaccio algorithm [21].

Case	Types	ΔD	# RL	Exp.	$\overline{\Delta D}$

8	I^+, I^-	-0.520			

(b) Comparing the complexity of different model configurations. The single agents tend to increase the difference relative to the training environment, and the many agent configurations reduce the difference.

Figure 8: Comparing the complexity of the different configurations. There complexity that is missing when compared to the real world data (red) relative the model distortions around the environment (black) introduce by the inclusion of learning agents. On the left (in Figure 8a) we have that triangles represent simulations with only either buy or sell side agents and the circles represent simulations with both buy and sell side agents, as well as the JSE and ABM.

necessity of including optimal execution agents in ABMs to recover empirical high-frequency stylised facts.

Furthermore, we find that learning introduces further variation into the order flow and liquidity processes, as agents make state-based decisions using a decision rule that adapts over time. This is demonstrated by the decrease in the level and persistence of autocorrelations. Surprisingly, we did not find that learning decreased the average cost of trading as reflected by the realised price impact functions. However, we still find evidence that learning is feasible since execution agents increase their performance over successive training periods. Although learning agents added complexity to the market's dynamics, this was insufficient to recover the complexity observed in empirical data.

In spite of the necessity of incorporating execution agents for a realistic ABM framework, neither execution agents or learning appears to be the dominant source of financial market complexity, at least when considered for a single stock in isolation from the broader market. Thus, as future work, we think it is worthwhile to consider the interaction of at least two markets, and investigate the emergence of correlations as the driver of the missing financial market complexity. This would allow for the investigation of a new agent class: multi-asset portfolio optimising agents, and how they are situated within the existing market ecology. In short, the bulk of the nonlinear dynamics, and complexity, in the single stock setting, seems to arise from the minimally intelligent agent dynamics, and it is this dynamic that provides the opportunity for learning.

Table A1: The best bid/ask volume (v_k) states are given, and the spread (s_k) states. Here the all provide the approximate probability of being in each states are based on the observed data at event k and the simulated historical distributions. Explain how the bid and ask volume states works. Let $\tau = T_0/n_T$, where T_0 is the total trading time for the RL agent and n_T is the number of time states. Let $i = X_0/n_V$, where X_0 is the total amount of inventory to be traded and n_V is the total number of volume states. The actions associated with these states are visualised in tables 2 and 3.

State	Inventory states		Prob.	Time states		Prob.	Volume states		Prob.	Spread states		Prob.
	Range			Range			Range			Range		
	$\cdot < x_k \leq \cdot$			$\cdot < t_k \leq \cdot$			$\cdot < v_k \leq \cdot$			$\cdot < s_k \leq \cdot$		
1	0	i	0.2	0	τ	0.2	31		0.2	0	1	0.6
2	i	2i	0.2	τ	2τ	0.2	31	266	0.2	1	2	0.123
3	2i	3i	0.2	2τ	3τ	0.2	266	1453	0.2	2	3	0.062
4	3i	4i	0.2	3τ	4τ	0.2	1453	5209	0.2	3	7	0.091
5	4i		0.2	4τ		0.2	5209	\cdot	0.2	7	\cdot	0.124

Table A2: The moments used to characterise the price paths. These are used in the sensitivity analysis to measure how changes in the parameters change the price paths, and they are used to calibrate the ABM to measured market data.

Moments	Description
Mean, Std.	The mean, μ , and standard deviation, σ , measure the shape of the log-return distribution.
KS	The Kolmogorov-Smirnov [33](KS) statistic is used to compare the maximum absolute difference between the CDFs of the empirical and simulated log-returns. This is used to test if the samples are drawn from the same distribution.
GPH	Geweke and Porter-Hudak [19] (GPH) provide an estimate for the fractional integration parameter $d \in [-0.5, 0.5]$ in absolute log-returns time series by estimating the memory parameter in the log-periodogram. This measures the long-range dependence in log-returns.
ADF	The Augmented Dickey-Fuller [12] (ADF) statistic tests for the presence of a unit root in the time series of the log-returns. The more negative the test statistic the less evidence there is for the presence of a unit root.
GARCH $\alpha + \beta$	The parameters of the GARCH(1,1) model provide a useful summary for the short-range dependence in the squared returns. Winker et al. [41] found that the sum of the parameters in the GARCH(1,1) model is a more robust statistic as compared to the individual parameters.
“Improved” Hill	The Hill Estimator (HE) is used to estimate the tail-index of a power-law distribution which can be used to infer the power-law behaviour in the tails of experimental distributions. Nuyts [34] proposed an “improved” Hill estimator to remedy the issues with the standard estimator.
Hurst (H)	The Hurst (H) exponent [26, 31] provides a measure of the long-memory of the log-returns. If $H \in [0, 1]$ is significantly far from 0.5 we have evidence that the log-returns do not follow a random walk. Furthermore, if $H \in [0, 0.5]$ then the process is said to be mean-reverting and if $H \in (0.5, 1]$ the process is said to be trending.

Figure .9: Sample ACFs of tradesigns with cumulative tradesigns plotted underneath, where the latter indicates the net direction of the order flow indicated by cumulating the tradesigns. Left is Case 1, a single selling TWAP agent. Right is Case 2, five buying TWAP agents. As the number of optimal execution agents increases, the cumulative order flow becomes increasingly uniform (bottom), leading to slowly decaying ACFs (top).
