(Dated: March 27, 2023)

We present a state-of-the-art prediction for cross sections of neutrino deeply inelastic scattering (DIS) from nucleon at high neutrino energies, E_ν , from 100 GeV to 1000 EeV (10^{12} GeV). Our calculations are based on the latest CT18 NNLO parton distribution functions (PDFs) and their associated uncertainties. In order to make predictions for the highest energies, we extrapolate the PDFs to small x according to several procedures and assumptions, thus affecting the uncertainties at ultra-high E_ν ; we quantify the uncertainties corresponding to these choices. Similarly, we quantify the uncertainties introduced by the nuclear corrections which are required to evaluate neutrino-nuclear cross sections for neutrino telescopes. These results can be applied to currently-running astrophysical neutrino observatories, such as IceCube, as well as various future experiments which have been proposed.

I. INTRODUCTION

Empirical information furnished by the deeply inelastic scattering (DIS) of high-energy neutrinos from nucleons and nuclei played an important role in establishing Quantum Chromodynamics (QCD) as the microscopic theory of strong interaction. Within this context, charged-current (CC) neutrino DIS (ν DIS) has the potential to be particularly enlightening in that it accesses unique combinations of quark-flavor currents inside QCD matter, having been measured in accelerator-based DIS experiments with neutrino energies up to $E_\nu \sim 300$ GeV (see Ref. [1] for an overview). In parallel with these accelerator-based experiments, which have played an invaluable role in understanding the hadronic and nuclear structure, considerable interest also attaches to neutrino measurements recorded at energies several orders of magnitude beyond those accessed in terrestrial experiments; conventionally, such measurements are designated as high-energy (HE, $10^3 < E_\nu < 10^8$ GeV) and ultra-high energy (UHE, $E_\nu > 10^8$ GeV). A significant share of the interest in HE and UHE neutrino processes derives from the fact that such measurements may possess sensitivity to a variety of beyond-the-standard model (BSM) scenarios, including non-standard interactions, leptoquarks, and the possibility of hidden extra dimensions (see, *e.g.*, Ref. [2] for a recent review). In addition, (U)HE astrophysical neutrinos can provide information constraining at least 6 of the 9 available neutrino flavor-oscillation channels, heightening their sensitivity to various BSM and non-standard interaction possibilities [2]. It is notable that high-energy neutrino measurements have motivations extending beyond fundamental high-energy physics (HEP) to particle astrophysics; this is due to the fact that the weakness of neutrinos' interactions with matter renders them ideal messengers for astronomy beyond the visible electromagnetic spectrum, possibly conveying information on the nature of their astrophysical sources related to the unsolved question regarding the origin of high-energy cosmic rays.

An array of experimental facilities, therefore, aims to measure neutrino cross sections at high energies. For example, the IceCube Neutrino Observatory is capable of detecting high-energy neutrinos with its unique instrumental volume of about 1 km^3 within the Antarctic ice sheet [3]. Other neutrino telescopes under development with complementary reach include IceCube-Gen2 [4], KM3NeT [5], Baikal-GVD [6], P-ONE [7], and TRIDENT [8]. The neutrino DIS cross sections are essential inputs to the modeling of the detection of high-energy neutrinos as well as their propagation through the earth, and directly impact the

extracted flux of astrophysical neutrinos with energies of about 10^4 GeV to 10^7 GeV [9, 10] as well as output of earth tomography [11]. We may expect the observed neutrino energies extended by a few orders of magnitudes due to large exposure from the next generation of neutrino telescopes. More interestingly, at IceCube one can also independently extract the total cross sections using earth absorption [9] or even differential cross sections in elasticity [12] in neutrino DIS though with large uncertainties. We also note the recently proposed FASER (ForwArd Search ExpeRiment) program [13, 14] as well as other Forward Physics Facilities (FPFs) [15, 16] at the LHC, which can potentially fill the gap between neutrino energies measured at IceCube and fixed-target experiments.

For all these reasons, a better understanding of ν DIS is also crucial for programs centered on neutrino telescopes and neutrino-based particle astrophysics. Ultimately, the ability of UHE neutrino measurements to impose stringent constraints on such scenarios depends on the current theoretical accuracy for predictions of the purely standard model neutrino-nucleon (-nucleus) interactions. Theoretical predictions on neutrino DIS rely on the theorem of QCD factorization [17] and thus the hard coefficient functions that can be calculated perturbatively and the parton distributions (PDFs) of nucleons and nuclei. For neutrino energies greater than 10^7 GeV, the corresponding DIS cross sections are potentially sensitive to QCD dynamics in the region of very small $x < 10^{-5}$. The PDFs at small x are only loosely constrained by experimental data from HERA [18] and LHC measurements in the forward region [19], which can lead to large uncertainties in theoretical predictions. Besides, the astrophysical neutrino DIS cross sections also depend on the effects of nuclear modifications since the neutrinos are colliding with nuclei inside water or the earth's crust rather than free nucleons.

In the current work, we present state-of-the-art predictions on total cross sections for neutrino DIS with neutrino energies up to 10^{12} GeV for both the charged-current (CC) and neutral-current (NC) interactions. We use the CT18 PDFs [20] as our baseline for the nucleon PDFs; these were fitted at next-to-next-to-leading order (NNLO) to a broad selection of the world's high-energy data, including the most recent LHC precision experiments. For the main NNLO calculations presented in this work, the hard coefficient functions are determined consistently in the S-ACOT- χ heavy-quark scheme [21], and are therefore based on a systematic evaluation of heavy-quark mass effects. It will be referred to as the ACOT scheme in this work. In addition, we explore approximate N3LO corrections using massless

Wilson coefficients for both neutral- and charged-current DIS structure functions [22–27]. Going beyond evaluations of free-nucleon cross sections, we also estimate nuclear effects and incorporate these into our analysis by considering recent nuclear PDF studies, specifically, EPPS21 [28] and nCTEQ15WZ [29]. The impact of higher-order corrections including small- x resummed corrections is also discussed.

Our predictions show the combined PDF-driven and theoretical uncertainties for ν DIS cross sections on nuclei to be several percent at high energies, increasing to a few tens of percent at ultra-high energies. Controlling these uncertainties, especially those at the highest neutrino energies, will require improved knowledge of free-nucleon PDFs in the extrapolated region of extremely small x as well as of nuclear corrections in the far-shadowing regime at similarly small x . We compare our cross-section predictions to those of CSMS [30], which are frequently used in IceCube publications, and discuss the implications of these comparisons for IceCube. In parallel, we briefly discuss some of the other calculations in the literature, such as GQRS [31], CTW [32], and BGR [33]. An alternative approach based on the color-dipole model [34] results in a growth of the neutrino cross section like $\ln^2 s$, with \sqrt{s} being the central-of-mass energy of the scattering process, in agreement with perturbative QCD predictions but with larger theoretical uncertainty.

The organization of the paper is as follows. Sec. II discusses the neutrino-nucleon cross section, which we calculate and compare for several assumptions with respect to the small- x PDF behavior. In Sec. III, we discuss the impact on the neutrino-nucleon DIS cross section deriving from the behavior and uncertainty of small- x PDFs, and the role of nuclear corrections in the corresponding cross sections on nuclei. We compare our results with other calculations and with existing cosmic neutrino data in Sec. IV before concluding in Sec. V. In addition, we provide more detailed discussion and supplementary material in several appendices. These provide practical neutrino cross section tables (App. A); a more detailed discussion of kinematics (App. B); estimates of neutrino Earth absorption (App. C); and comparative predictions of the neutrino-electron interaction and Glashow resonance (App. D).

FIG. 1. Feynman Diagram for neutrino-nucleon deep-inelastic scattering.

II. THE THEORETICAL FRAMEWORK

The charged-current (CC) or neutral-current (NC) process for the deep-inelastic scattering of a neutrino of flavor ℓ can be written as

$$\nu_\ell(k) + N(P) \longrightarrow \ell(k') + X(P + q) , \quad (1)$$

which we illustrate in Fig. 1. Here, the final-state lepton ℓ can either be a neutrino, ν_ℓ (corresponding to NC DIS), or a charged-lepton, ℓ^\pm (for CC scattering). The 4-momentum transfer is $q = k - k'$. N denotes a nucleon target, which can be a proton or neutron with mass m_N , while X represents the inclusive hadronic final state. The 4-momenta k , k' and P are indicated in Fig. 1. The familiar kinematic invariants are

$$\begin{aligned} s &= (k + P)^2 = m_N^2 + 2m_N E_\nu , \\ Q^2 &= -q^2 , \\ x &= \frac{Q^2}{2P \cdot q} = \frac{Q^2}{2m_N(E_\nu - E'_\nu)} , \\ y &= \frac{P \cdot q}{P \cdot k} = \frac{E_\nu - E'_\nu}{E_\nu} = \frac{Q^2}{2xm_N E_\nu} , \end{aligned} \quad (2)$$

where E_ν is the (initial) neutrino energy in the nucleon rest frame.

The inclusive DIS (anti)neutrino-nucleon cross section can be written as [35]

$$\frac{d^2\sigma^{\nu(\bar{\nu})}}{dx dy} = \frac{G_F^2 m_N E_\nu}{\pi(1 + Q^2/M_{W,Z}^2)^2} \left[\frac{y^2}{2} 2xF_1 + \left(1 - y - \frac{m_N xy}{2E_\nu} \right) F_2 \pm y \left(1 - \frac{y}{2} \right) xF_3 \right] . \quad (3)$$

Here F_i ($i = 1, 2, 3$) are the corresponding structure functions in the case of charged or neutral current scattering. The positive (negative) sign in the last term related to F_3 corresponds to the neutrino (antineutrino) scattering, as a result of spin correlation. We can

substitute the longitudinal structure function

$$F_L = F_2(1 + 4x^2 m_N^2/Q^2) - 2xF_1, \quad (4)$$

and obtain

$$\frac{d^2\sigma^{\nu(\bar{\nu})}}{dx dQ^2} = \frac{G_F^2}{4\pi x(1 + Q^2/M_{W,Z}^2)^2} [Y_+ F_2 - y^2 F_L \pm Y_- x F_3], \quad (5)$$

where $Y_{\pm} = 1 \pm (1 - y)^2$. At the leading order (LO), the neutrino CC structure functions can be written as

$$\begin{aligned} F_2^{\nu(W)} &= 2x \left(\sum_i d_i + \sum_j \bar{u}_j \right), & xF_3^{\nu(W)} &= 2x \left(\sum_i d_i - \sum_j \bar{u}_j \right), \\ F_2^{\bar{\nu}(W)} &= 2x \left(\sum_j u_j + \sum_i \bar{d}_i \right), & xF_3^{\bar{\nu}(W)} &= 2x \left(\sum_j u_j - \sum_i \bar{d}_i \right), \end{aligned} \quad (6)$$

where the index $i(j)$ runs over all the light $d(u)$ -type quarks. Similarly, the LO neutral-current structure functions are

$$F_2^{\nu,\bar{\nu}(Z)} = x \sum_i^{n_f} (a_i^2 + v_i^2)(q_i + \bar{q}_i), \quad xF_3^{\nu,\bar{\nu}(Z)} = x \sum_i^{n_f} a_i v_i (q_i - \bar{q}_i), \quad (7)$$

where $(a_i) v_i$ are the NC (axial) vector couplings for the quark q_i and i runs over all quarks in the n_f flavor number scheme. At the LO, the longitudinal structure functions are zeros, $F_L^i = 0$. In perturbative QCD, the structure functions in Eqs. (6) and (7) as well as F_L^i receive higher-order corrections, which is one main focus of this work.

In the isospin symmetric limit, the isoscalar $u(\bar{u})$ and $d(\bar{d})$ PDFs can be constructed in terms of the proton PDFs as

$$f_{u/I} = f_{d/I} = (f_{u/p} + f_{d/p})/2, \quad f_{\bar{u}/I} = f_{\bar{d}/I} = (f_{\bar{u}/p} + f_{\bar{d}/p})/2, \quad (8)$$

while other flavors are kept the same. Keep in mind the positive (negative) sign for neutrino (antineutrino) cross sections in Eq. (5). Together with the LO structure functions in Eqs. (6-7), we can see that the neutrino-isoscalar scattering cross sections are generally larger than the antineutrino ones, both for the CC and NC cases. In Sec. III A, we present the final, absolute isoscalar cross sections in Fig. 13 with related discussion; we note that the (anti)neutrino cross sections differ at the lower energies of the plotted range.

We point out that Eq. (5) above additionally assumes the high-energy (massless) limit, corresponding to $m_N = 0$, as is reasonable for (U)HE neutrino scattering. In the numerical calculations presented below, however, we implement the full expression in Eq. (3), though

FIG. 2. The kinematic (x, Q) ranges contributing to the inclusive neutrino DIS cross section for a given initial neutrino energy, E_ν . The vertical dashed lines represent the lower boundary in x for which each (nuclear) PDF group conventionally provides interpolation tables *by default*. This should not be misconstrued as the lowest value of x directly probed by the fitted data sets in each of these cases, which would generally lie at significantly higher x than that indicated.

the impact of the hadronic mass, m_N , is in general negligible. For NC DIS, higher-order EW corrections can be included through an “improved” scheme. (See Ref. [33] for details.) As implied by Eqs. (6-7), F_L and xF_3 are suppressed in comparison with F_2 , with respect to the contribution to Eq. (5); as such, the cross section can be approximated with a simplified form only involving F_2 as explored in Ref. [36]. For the sake of precision, however, we stay with the full expression given by Eq. (3) throughout this work.

A. Treatment of low- x and low- Q PDFs

The total cross section can be integrated in terms of the differential cross section in Eq. (3) over x and Q^2 . That is,

$$\sigma = \int_{Q_{\min}^2}^{2m_N E_\nu} dQ^2 N(Q^2) \int_{x_{\min}}^1 \frac{dx}{x} \mathcal{F}(x, Q^2). \quad (9)$$

where $x_{\min} = Q^2/(2m_N E_\nu)$. The specific functional forms of $N(Q^2)$ and $\mathcal{F}(x, Q^2)$ can be deduced directly from the structure functions F_i in terms of Eq. (3). In an experimental measurement, the neutrino DIS events are selected with a Q cut, such as $Q \geq Q_{\min} = 1$ GeV in MINERvA [37], which can be adopted here in Eq. (9).

In Fig. 2, we show the integrated kinematic (x, Q) region for a few representative neutrino energies, E_ν . We include two dashed horizontal lines corresponding to the CT18 starting scale, $Q_0 = 1.3$ GeV, and the upper bound of the Q grids in the LHAPDF format [38], $Q_{\text{up}} = 10^5$ GeV. In our practical treatment, the phase space below Q_0 and above Q_{up} can be obtained through either LHAPDF extrapolation(s) [38] or APFEL's backward/forward DGLAP evolution [39]. Fig. 2 plots several vertical lines indicating the lower x bounds for the corresponding PDF grids used in this work. The PDFs below these x bounds rely on the LHAPDF or APFEL extrapolation.

FIG. 3. The dependence of the neutrino-isoscalar nucleon charged-current (left) and neutral-current (right) DIS cross sections (σ) on the lower integration limits Q_{\min} , based on the CT18 NNLO PDFs. The upper integration limit is fixed by collision energy $Q_{\max} = \sqrt{2m_N E_\nu}$. σ_{\max} indicates the maximal cross section with $Q_{\min} = 1$ GeV.

In Fig. 3, we explore the dependence of neutrino-isoscalar nucleon charged- and neutral-current DIS cross sections on the choice of Q_{\min} in Eq. (10). We plot results for representative neutrino energies spanning the range $10^3 \sim 10^5$ GeV, where the dependence on Bjorken x is fully covered by the CT18 grids. The cross sections are normalized to the maximal result, σ_{\max} , where $Q_{\min} = 1$ GeV. The PDFs below $Q_0 = 1.3$ GeV are obtained with the APFEL's backward evolution [39]. The structure functions are calculated in the zero-mass variable-flavor-number (ZM-VFN) scheme at NNLO with CT18 PDFs. In order to define the charged-current DIS scattering consistently beyond the leading order, we take the maximum number of active quark flavors to be $n_f = 4$, similarly to Ref. [21]. The details

about the heavy-quark mass as well as the flavor number dependence are left to Sec. II C. In terms of Fig. 3, we see that the backward evolution region $Q \in [1, 1.3]$ GeV contributes at most approximately 0.8%(1.2%) to the (anti)neutrino cross sections, with this contribution peaking for $E_\nu = 10^3$ GeV. With increasing neutrino energy, this low- Q contribution quickly becomes negligible. A detailed exploration of the dependence of our calculation on Q_{\min} is presented in App. B. In the end, we find that the kinematic region around $Q \sim M_{W,Z}$ contributes most significantly to the total cross section, and we designate this *the important* (x, Q) *kinematics*, as investigated in App. B.

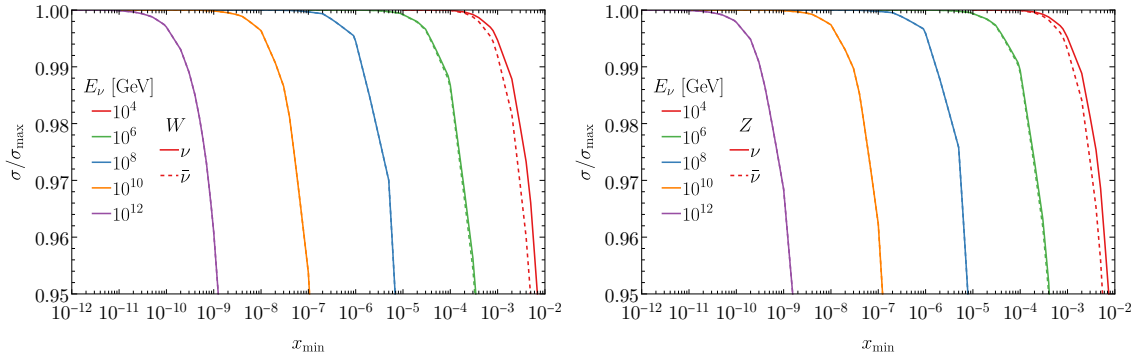

FIG. 4. Similar to Fig. 3, but for integration limit x_{\min} . The upper integration limit is fixed at $x_{\max} = 1$. σ_{\max} represents the maximal σ with $x_{\min} = Q_{\min}^2/(2m_N E_\nu)$.

With increasing neutrino energies, we see that the relevant values of x can fall below the region probed by existing data, and even below the x grid provided by different PDF groups, as indicated by the vertical lines in Fig. 2. At ultra-high neutrino energies, *e.g.*, $E_\nu > 10^9$ GeV, the kinematics will even cover a momentum fraction below the lowest x value provided by various PDF groups, such as $x_{\min} = 10^{-9}$ in CT18 [20]. In the CSMS calculation [30], two treatments for low x have been performed, based on (i) extrapolation or (ii) freeze-in, $f(x < x_{\min}, Q) = f(x_{\min}, Q)$. We have also explored another option in which we first extrapolate the provided LHAPDF grids to obtain PDFs below x_{\min} at the starting scale, Q_0 , and then evolve these to cover the whole phase space shown in Fig. 2; this option is denoted as the “Evolution” method below. In this approach, we first show the fraction of the extrapolated region $x < x_{\min}$ contributing to the total integrated cross section in Fig. 4. Similarly to the Q_{\min} case, we normalize the cross sections with different x_{\min} choices to the maximal scenario, where $x_{\min} = Q_{\min}^2/(2m_N E_\nu)$, for a few representative neutrino energies. We see that this extrapolation only contributes at most 3% for $E_\nu = 10^{12}$ GeV.

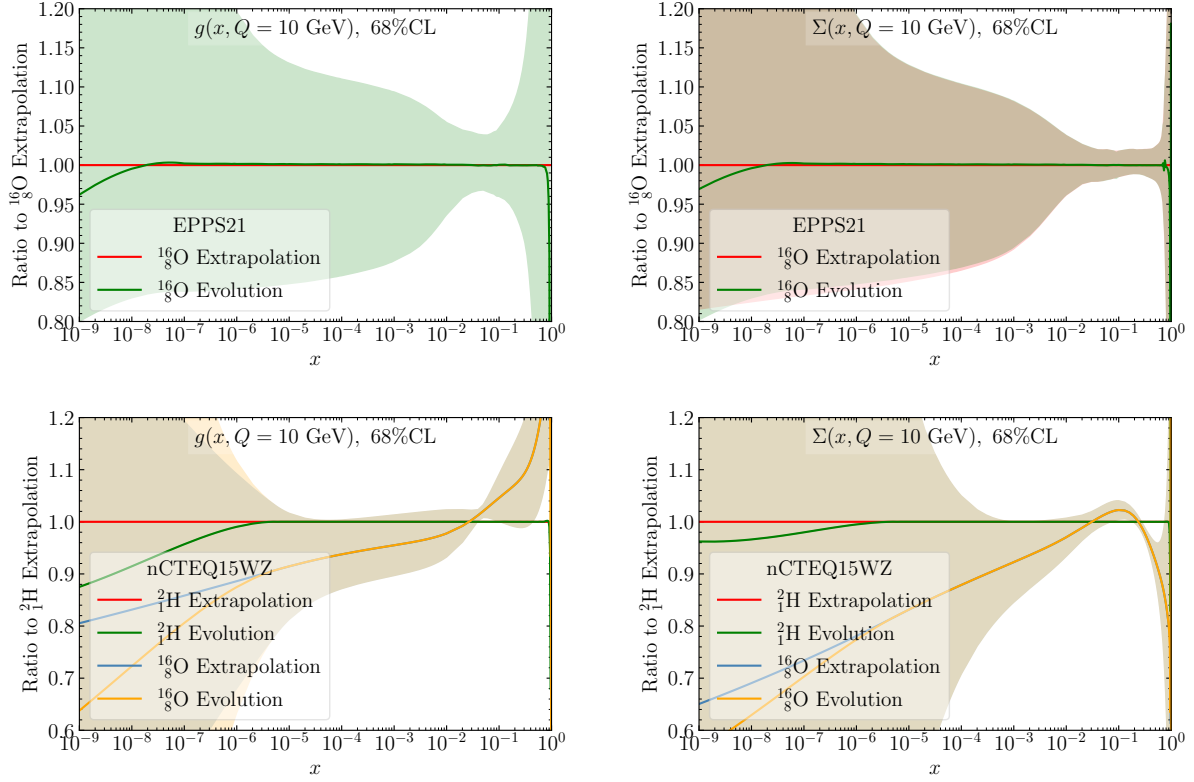

FIG. 5. Comparisons of the gluon (left) and flavor-singlet $\Sigma = \sum_i^{n_f} (q_i + \bar{q}_i)$ (right) PDFs at $Q = 10$ GeV for the nuclear ^{16}O with “extrapolation” and “evolution” of the EPPS21 (upper) and nCTEQ15WZ (lower) PDF grids.

For smaller energies, the extrapolation region $x < x_{\min} = 10^{-9}$ contributes negligibly to the total integrated cross section for CT18 PDFs. This result gives us confidence that the PDF grids provided in the CT18 global analysis [20] are sufficient to explore the neutrino cross section for neutrino energies reaching $E_\nu \lesssim 10^{12}$ GeV. Similarly to the Q_{\min} scan, we also explore the impact of the choice of x_{\min} in the full range $[Q_{\min}^2/(2m_N E_\nu), 1]$ in App. B, which shows the important (x, Q) kinematics around $x \sim M_{W,Z}^2/(2m_N E_\nu)$ and $Q \sim M_{W,Z}$.

We point out that the lower boundary in x of the interpolation grids typically provided by nuclear PDF fits tends to be higher than the corresponding value in CT18 or other free-proton analyses; it should be stressed that this feature reflects both conventions as well as the reality that high-energy data have not yet constrained A -dependent nuclear PDFs to as low x as HEP analyses of proton PDFs.¹ In Fig. 2, we indicate the lowest value in x reached by grids of the EPPS21 [28] and nCTEQ [29] nuclear PDFs, which we

¹ Here, A denotes the nucleon numbers of the scattered nuclei.

FIG. 6. Comparison of the neutrino-isoscalar charged (W) and neutral (Z) current DIS cross sections, obtained with the “extrapolation” and “evolution” methods for the CT18NNLO [20], EPPS21 [28], and nCTEQ15WZ [29] (n)PDFs.

examine below to study the possible role of nuclear effects in DIS cross sections on nuclei. It generally stands to reason that larger extrapolations over x will potentially introduce correspondingly larger uncertainties on the integrated neutrino DIS cross sections. In Fig. 5, we compare the gluon and flavor-singlet $\Sigma = \sum_i^{n_f} (q_i + \bar{q}_i)$ nuclear PDFs for ^{16}O at $Q = 10$ GeV based on the extrapolation and evolution approaches applied to EPPS21 (upper panels) and nCTEQ15WZ (lower panels). We see that the evolution and extrapolation methods agree exactly for the nuclear PDFs in those regions of x covered by interpolation grids, as shown. In contrast, at lower values of x below those covered by public grids (*i.e.*, in the extrapolation region) the evolution method can induce a small variation with respect to the LHAPDF extrapolation [38]. As a consequence, the induced neutrino-nucleus cross section normalized to the pure extrapolation is shown in Fig. 6. The corresponding variation for ultra-high energy neutrinos, with $E_\nu \gtrsim 10^8$ GeV, can be viewed as the uncertainty due to the low- x extrapolation. We see that the EPPS21 nuclear PDFs give a similar size for the extrapolation uncertainty in comparison with that based on CT18. For other PDFs, such as MSHT20 [40] or nCTEQ15WZ(SIH) [29], the extrapolation uncertainty can be larger. In addition, Fig. 6 also tells us the variation at low neutrino energy, such as $E_\nu \lesssim 10^3$ GeV, which results from the difference between the APFEL backward evolution approach and LHAPDF extrapolation below the DGLAP starting scale, *i.e.*, $1 < Q < Q_0 = 1.3$ GeV. We see that this variation at $E_\nu = 100$ GeV can be negligible for charged-current DIS, while $1\% \sim 3\%$ for the neutral current case.

Until this point, we have been able to include the relevant phase space in the inclusive neutrino scattering cross section as, in practice,

$$Q \in [Q_{\min}, \sqrt{2m_N E_\nu}] \quad \text{and} \quad x \in [Q^2/(2m_N E_\nu), 1], \quad (10)$$

demonstrated in Fig. 2. Based on this setup, we also show the Hessian correlation [41], dubbed as correlation cosine $\cos \phi$ between the neutrino-isoscalar cross sections and the gluon and flavor-singlet PDFs at $Q = 1.3$ and 100 GeV in Fig. 7 for charged-current DIS. Here, the neutrino and antineutrino cross sections are summed. We see that, at relatively low energy, a strong correlation appears in the singlet PDFs near $x \sim 10^{-2} - 10^{-1}$. With increasing energy, the sensitive momentum fraction x decreases accordingly, roughly scaling as $x \sim x_W = M_W^2/(2m_N E_\nu)$, which confirms the important kinematics as examined in App. B. Similar features have been found for the neutral-current DIS as well. When the neutrino energy goes above $E_\nu \gtrsim 10^9$ GeV, the largest sensitivity comes from the gluon PDFs, below the region $x \lesssim 10^{-4}$, reflecting the important contribution from the gluon partons. As also shown in Fig. 7, at $Q = 100$ GeV, far above the Q_0 scale, we also see a correlation with the flavor-singlet PDFs at $x < 10^{-4}$, reflecting the co-evolution of the singlet and gluon PDFs in the DGLAP evolution.

We point out that experiments usually require the invariant mass, W , of the recoil system to be in the perturbative region, *e.g.*, $W \geq W_0 = 2$ GeV as for MINERvA [37], in order to minimize the contributions from quasielastic scattering and the excitation of hadronic resonances. This W cut excludes a small region in the otherwise permissible phase space as shown in the lower-right corner of Fig. 2, since

$$x \leq \frac{Q^2}{W_0^2 - m_N^2 + Q^2} \leq 1 \quad (11)$$

for $W_0^2 \geq m_N^2$. However, the removal of this small region only negligibly affects the (anti)neutrino cross section, since PDFs in the high $x \rightarrow 1$ limit must rapidly vanish for reasons of momentum conservation as typically parametrized by assuming an overall $(1-x)^\beta$ (with $\beta > 0$) polynomial behavior. Therefore, we take the upper integration limit $x_{\max} = 1$ in Eq. (10) in practice.

FIG. 7. Correlation cosine angles between the neutrino-isoscalar charge-current cross sections (sum of neutrino and antineutrino) and the CT18 gluon (left) and flavor-singlet (right) PDFs at $Q = 1.3$ GeV (upper) and 100 GeV (lower). The color scale, indicated at the right of each panel, provides the value of $\cos \phi$; note that these scales differ slightly between the two panels.

B. Perturbative orders up to an approximate N3LO

In the demonstration above, we used the zero-mass scheme for structure functions at next-to-next-to-leading order (NNLO). In this section, we explore possible variations arising from performing the calculation at different orders in perturbation theory.

The CT18 global analysis is performed at both NLO and NNLO, with the corresponding error sets determined with the Hessian method [20]. Afterward, the leading order analysis has been released based on a few special considerations to improve the quality of fit [42].

FIG. 8. Comparison of the neutrino-isoscalar charged (W) and neutral (Z) current DIS cross-section ratios to their respective NNLO predictions, at different orders of QCD perturbation theory. The LO and NLO cross sections are calculated with the corresponding CT18 PDFs at LO [42] and NLO [20].

In Fig. 8, we show the CT18 predictions for the neutrino-isoscalar charged and neutral current DIS cross sections, normalized to the individual NNLO prediction. The LO [42] and NLO [20] PDFs are adopted with the same corresponding order of Wilson coefficients in the LO and NLO cross sections. Compared to NNLO, we see that the LO and NLO predictions are larger, and the increments become increasingly significant when $E_\nu > 10^7$ GeV. These differences are mainly driven by two factors: the strong coupling α_s at different orders and higher-order corrections to the structure functions. In the CT18LO analysis [42], the strong coupling is chosen to be a larger value, $\alpha_s(M_Z) = 0.135$ in order to compensate for the missing higher order corrections, especially for the Drell-Yan data. In the CT18 NLO fit, the strong coupling is determined as $\alpha_s(M_Z) = 0.118$, similar to the NNLO fit. However, when the scale Q runs down to lower values, which contribute to the majority of the total integrated neutrino-nucleon cross section as shown in Fig. 22 in App. B, the corresponding strong couplings are larger than that obtained at NNLO. On the other hand, the higher-order corrections contribute negatively to the structure functions. (See Fig. 11 of Ref. [43] for a specific example.) As a consequence, we obtain NNLO cross sections smaller than the LO and NLO ones, as shown in Fig. 8.

As we see above, the neutrino DIS cross section decreases as the perturbative order increases. A natural question one may ask is whether our result shows evidence of convergence in the perturbative expansion. Similarly to our previous work [21], we estimate an *approximate* N3LO contribution (denoted as N3LO') with the ZM N3LO structure functions

FIG. 9. The N3LO' ZM-VFN predictions to the (anti)neutrino-isoscalar charged (W) and neutral (Z) current DIS cross sections, with respect to the NNLO ones.

implemented in the `v1.2.0-struct-func-devel` version of HOPPET [22]. The resulting cross sections normalized to the NNLO ones are displayed in Fig. 9. We see that N3LO' corrections give a small decrease at low energy, while a slightly larger increase at high energy. The size of the difference is much smaller than that of the NNLO/NLO one as shown in Fig. 8. This result gives us confidence that, in terms of the perturbative expansion, our predictions are already showing strong evidence of convergence at NNLO. In the rest of this work, we will adopt the NNLO calculation as our baseline, with N3LO' corrections included as K -factors extracted from Fig. 9.

C. A general-mass variable-flavor-number scheme

Up to now, we have adopted the ZM-VFN scheme with CT18 PDFs, which include $n_f = 4$ parton flavors. One may wonder about the heavy-quark mass effects as well as the potential contribution from the third-generation quarks, especially when $\sqrt{s} \gg m_{b,t}^2$, which we will examine carefully in this subsection.

The heavy-quark mass corrections to NC DIS at NNLO have been obtained by several groups within corresponding general-mass schemes, such as the ACOT scheme employed in the CTEQ-TEA group [44], the FONLL scheme by the NNPDF group [45], and the optimal TR scheme in the MSHT group [46]. Recently, the complete mass corrections to CC DIS have been achieved up to NNLO [47]. The general-mass corrections to the structure functions have been implemented in the ACOT framework [21], which we will mainly rely

FIG. 10. The cross-section ratios of (anti)neutrino-isoscalar charged-current DIS in the General-Mass and Zero-Mass schemes (left) and different flavors (right).

on in this work.

In Fig. 10 (left), we show the charm mass correction to the (anti)neutrino cross sections, with the ACOT general-mass scheme normalized to the ZM-VFN scheme up to $n_f = 4$ flavors. At lower neutrino energies, *e.g.*, $E_\nu = 10^2$ GeV, the full charm-mass dependent structure functions reduce the antineutrino (neutrino) CC DIS cross section by about 2% (1%). In comparison, the massive corrections to the NC DIS cross section can be positive, mainly driven by an enhancement of the F_2 structure function at low scales, such as $Q \lesssim 2m_c$. (See Fig. 5 of Ref. [44] for details.) The size of the impact is smaller than that in the CC case, with 0.6% (0.3%) for antineutrino (neutrino) NC DIS cross sections, respectively. We remind the reader that the charm-mass corrections to antineutrino cross sections are always larger than the neutrino ones, mainly because of the relatively smaller absolute antineutrino cross section with respect to the analogous neutrino calculation.² Meanwhile, the mass effect vanishes very quickly with increasing neutrino energy. With $E_\nu \gtrsim 10^4$ GeV, the general-mass results are almost identical to those obtained in the ZM scheme. For this reason, we will assume the ZM-VFN scheme for the remainder of this work, with heavy-quark mass effects folded in via K -factors (GM/ZM ratios) extracted from Fig. 10 (left).

The CT18 PDFs adopt $n_f = 5$ as their default [20]. For $n_f \geq 5$, the CC scatterings involve the $gW^\pm \rightarrow t\bar{b}(\bar{t}b)$ partonic sub-processes beginning at NLO; these contain a collinear singularity in the $g \rightarrow b\bar{b}(t\bar{t})$ splittings in the zero-mass limit. The $g \rightarrow b\bar{b}$ collinear divergence can be absorbed into a redefinition of b -quark PDF. Similarly, we have to introduce t -quark

² We note that the apparent equality of the NC neutrino and antineutrino GM/ZM ratios near $E_\nu \sim 3$ TeV is an artificial smoothing effect due to numerical imprecision at the permille level.

PDF to absorb the $g \rightarrow t\bar{t}$ collinear divergence when the top quark becomes massless. For this reason, we take $n_f = 6$ to include the third-generation quarks in the zero-mass scheme beyond the leading order consistently. The $n_f = 6$ cross sections normalized to the $n_f = 4$ ones are shown in Fig. 10 (right). We remind that the $n_f = 4$ and $n_f = 6$ PDFs are obtained with the same CT18 parameterization as well as strong coupling at the starting scale Q_0 . In such a way, the light-flavor PDFs remain identical below the heavy-flavor mass. The difference only appears once the factorization scale crosses the corresponding partonic threshold when the heavy quarks become active.

In Fig. 10 (right), we see that the $n_f = 6$ scheme gives at most 6%(4%) larger cross sections at $E_\nu = 10^{12}$ GeV than the $n_f = 4$ ones for the CC (NC) DIS processes. For the NC scattering, the $n_f = 6$ enhancement from the contribution of b, t partons is identical at high (anti)neutrino energies. In comparison, at low energies the neutrino enhancement is slightly smaller than the antineutrino one, due to the correspondingly larger absolute NC cross section as mentioned before. Similarly, the larger neutrino CC cross section leads the corresponding $n_f = 6$ enhancement to be smaller than the antineutrino one at high energy.

Starting from this point, we will take $n_f = 6$ as the default to include the bottom and top parton's contribution in the rest of this work. Similarly to the charm mass effect as examined above, the top/bottom mass can slightly reduce the neutrino-nucleon cross section. However, considering the relatively small contribution from the third-general quark PDF even at extremely high energy, we can safely neglect the mass effect without a noticeable effect.

III. PDF UNCERTAINTIES: PROTON AND NUCLEAR PDFS AT LOW x

A. Small- x resummation

As we see in Sec. II A, the neutrino cross section in the ultrahigh-energy region is very sensitive to the PDFs, especially gluon, in the small x region. On general grounds, for Bjorken $x_B < 10^{-3}$ and momentum transfer Q around a few GeV, we would expect that the small- x logarithms will be enhanced, and eventually enter a partonic saturation phase as $x \rightarrow 0$. In the NNPDF [48] and xFitter [49] frameworks, a small- x logarithm has been resummed up to the next-to-leading level (NLLx) based on BFKL dynamics [50–55]. It is

found that the description of the low- x DIS data, especially data measured at HERA [18, 56], has been improved.

In this work, we have interfaced the HELL [57, 58] package with APFEL [39] to resum large $\sim \log(1/x)$ logarithmic corrections for parton evolution up to NNLx with matching to the NNLO DGLAP evolution; we dub the resulting distributions CT18sx [59]. The gluon and singlet PDFs compared to the nominal CT18 ones are displayed in Fig. 11. Small- x resummation enhances the gluon PDF but reduces singlet PDFs in the small- x region at low factorization scales. However, this small- x variation gradually dies out at larger scales, as can be observed by comparing the gluon PDF at $Q = 2$ GeV up to that at $Q = 100$ GeV. A similar effect can be obtained with an x -dependent DIS scale, motivated by the partonic saturation model [60].

Applying the correspondingly matched DIS Wilson coefficient functions provided by the HELL framework [57, 58], we explored the small- x resummed (anti)neutrino cross sections normalized to the NNLO fixed-order ones, as shown in Fig. 12. At a first sight, we see that the small- x resummed cross section is almost identical for the neutrino and antineutrino DIS cross sections. A closer examination reveals that at low neutrino energies ($E_\nu \lesssim 10^5$ GeV), the small- x resummation has no impact at all, as the corresponding kinematics only cover the intermediate to large x region, cf. Fig. 2. Starting around $E_\nu \sim 10^6$ GeV, we obtain a slight reduction of the resummed cross section, as a result of the smaller quark PDFs, indicated in Fig. 12. A turnover appears around $E_\nu \sim 10^8$ GeV, which roughly corresponds to $Q = M_W$ and $x = 10^{-5} \sim 10^{-4}$ according to the important (x, Q) kinematics, as explained in App. B. When the neutrino energy continues to increase above $E_\nu \gtrsim 10^{10}$ GeV, we get a cross-section *enhancement*, mainly driven by the enlarged gluon PDF in the extremely small- x region. When $E_\nu \sim 10^{12}$ GeV, the small- x resummed enhancement can be as large as 10%. Due to this reason, we will adopt the small- x resummed cross section in the main presentation of this work.

In Fig. 13, we display the final CT18 predictions on the neutrino-isoscalar scattering cross sections and the corresponding PDF uncertainties. Here, the impacts from the approximate N3LO' fixed-order corrections, the heavy-quark mass in the ACOT scheme up to $n_f = 6$ flavors, as well as the small- x resummation are all included. The specific numerical results are tabulated in Tab. I-II in App. A. In general, the charged current-cross sections are a few times larger than the neutral current ones. The high-energy neutrino and antineutrino cross

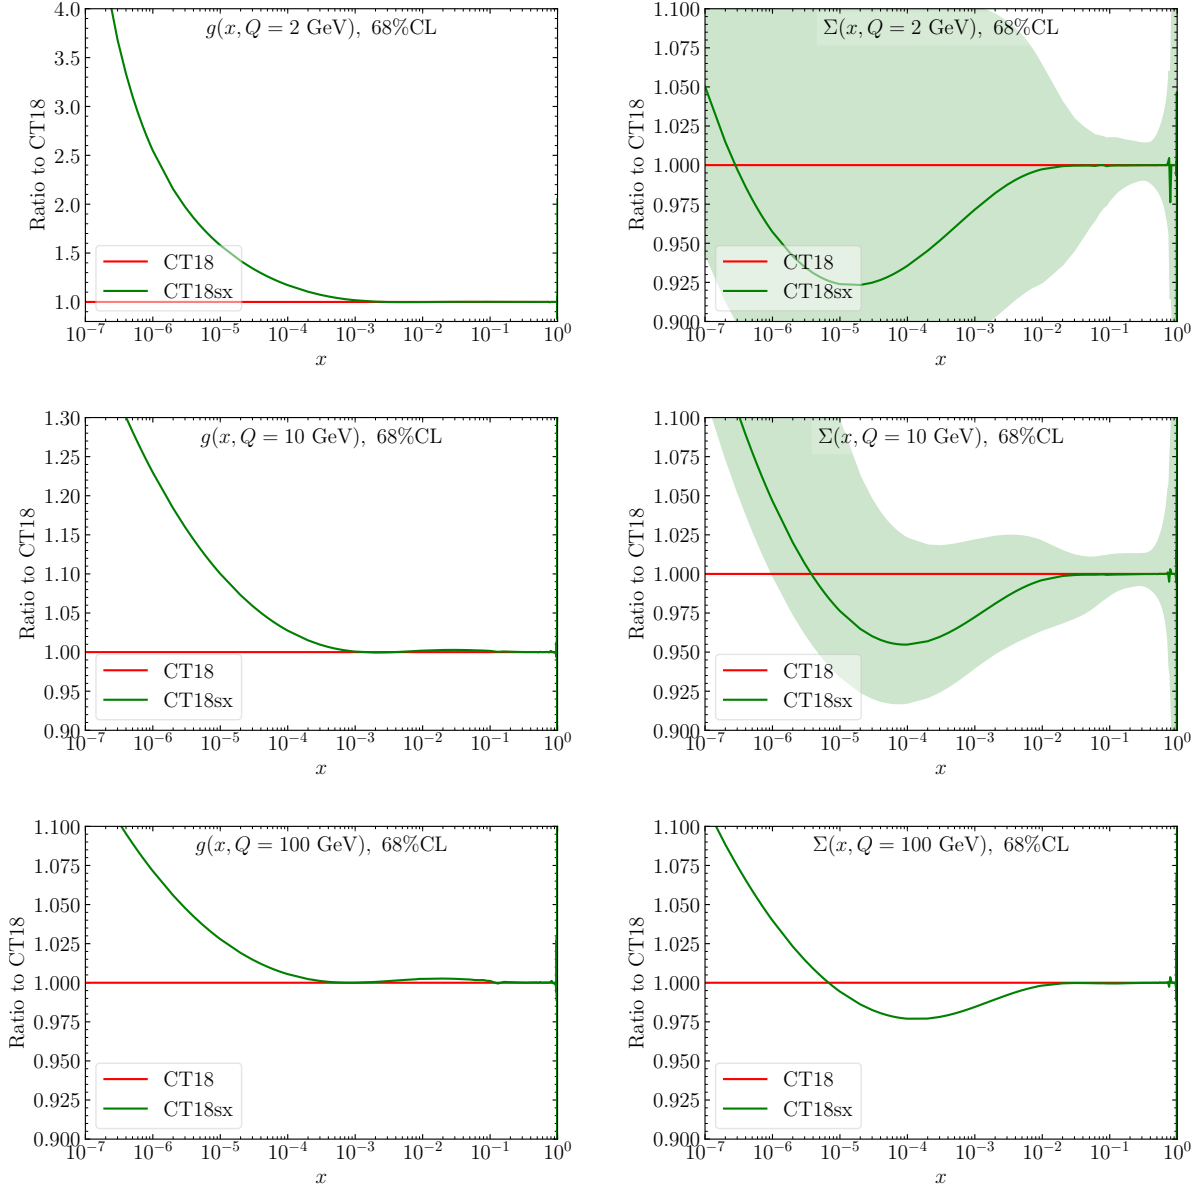

FIG. 11. The comparison of gluon and flavor-singlet PDFs for CT18 and CT18sx at the scales $Q = 2, 10, 100$ GeV, respectively.

sections converge as a result of the asymptotically identical quark and antiquark densities in the small- x region. At low (anti)neutrino energy, the neutrino cross sections are larger than the antineutrino ones, as a result of valence contribution to xF_3 at large x as indicated in Eqs. (6-7). The antineutrino DIS gives larger relative PDF uncertainty than the neutrino one, mainly as a result of the larger antiquark (*i.e.*, sea quark) uncertainty with respect to the quark (mainly valence) one in xF_3 .

FIG. 12. The (anti)neutrino-isoscalar cross sections for charged (W) and neutral (Z) current DIS, with small- x resummed up to next-to-leading logarithms (NLLx) with respect to NNLO predictions.

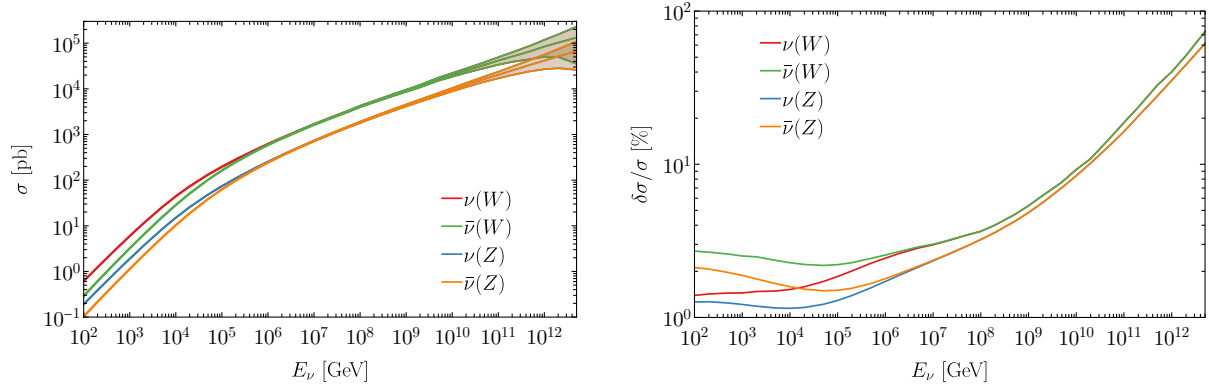

FIG. 13. (Left) The CT18 predictions for neutrino-isoscalar scattering cross sections σ ; and (right) the corresponding PDF uncertainties, $\delta\sigma/\sigma$.

B. Nuclear PDFs and uncertainties

Owing to the small magnitude of G_F , neutrino-scattering experiments have historically relied on nuclear targets to maximize the relevant cross sections. This has been true for terrestrial neutrino oscillation and DIS measurements, which typically involve heavy nuclei such as ^{40}Ar and ^{56}Fe . In the meantime, present or planned neutrino telescopes, including IceCube and KM3NeT, entail Cherenkov detection of the charged lepton from CC neutrino reactions with ice or water, such that the predominant nuclear interaction is with H_2O or the isoscalar nuclei O. In all such experiments, incident neutrinos resolve the partonic substructure of *nuclei* rather than of free nucleons; thus, such nuclear DIS events are subject to modifications, relative to scattering from free nucleons, due to the influence of the nuclear medium. The analogous nuclear parton distribution functions (nPDFs) relevant for nuclear

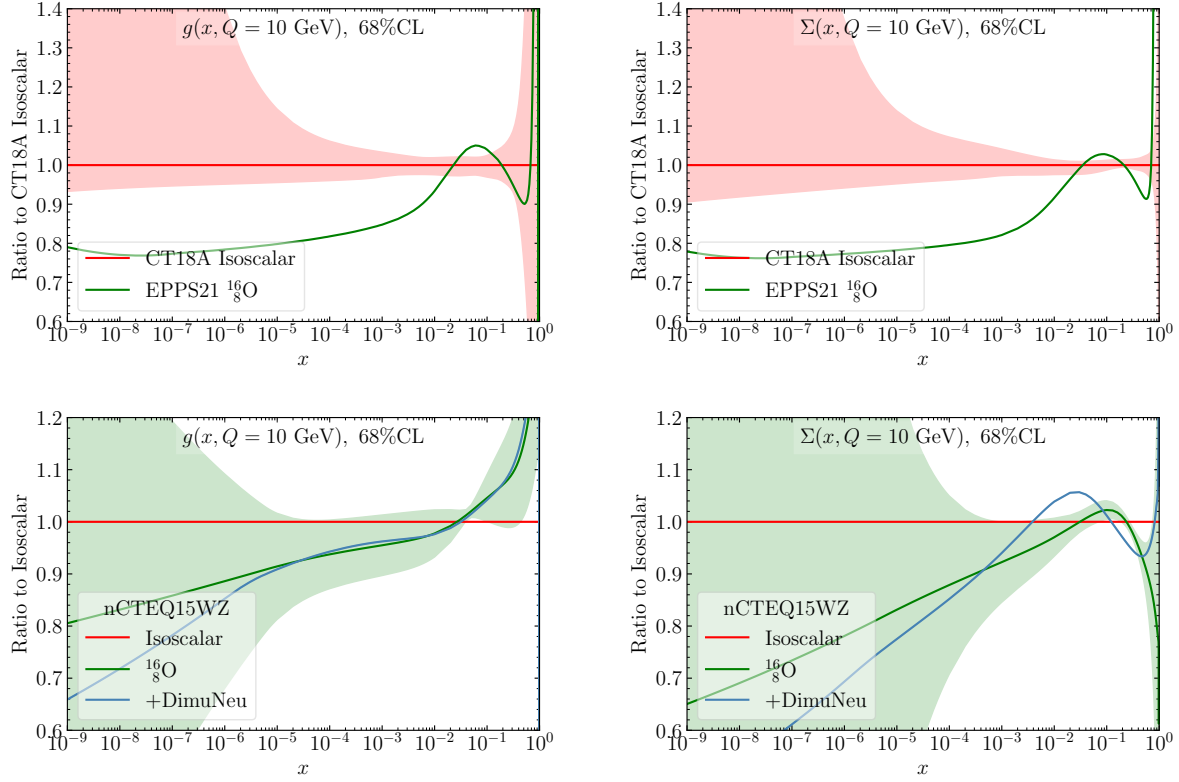

FIG. 14. Comparison of the gluon and flavor-singlet PDFs of ^{16}O at $Q = 10$ GeV, with the EPPS21 and nCTEQ15WZ nPDF sets. The low- x PDFs are obtained with the “extrapolation” method.

DIS must quantify the effects of nuclear binding on the free-nucleon PDFs — physics which is known to possess rich phenomenology from very low to high x . Much like the proton PDFs at very low x , nuclear PDFs remain essentially unconstrained for $x < 10^{-4}$, driving significant uncertainties which can in turn propagate to high-energy nuclear cross sections. This lack of constraints comes not only from the challenge, familiar from studies of proton PDFs, of probing QCD bound states at very high energies, but from the additional complication of gathering such information from a sufficient variety of nuclear species as to allow a detailed unfolding of the nPDFs’ A dependence; such knowledge is required to leverage the world’s nuclear data to improve nPDF predictions for specific nuclei like O relevant to IceCube.

In our present study of neutrino DIS at ultra-high energy, the prevailing nuclear corrections are those at very low x , where the nuclear medium produces a relative suppression of the nPDFs in a phenomenon known as *nuclear shadowing*, as shown in Fig. 14. In contrast, the mild enhancement of nuclear PDFs — so-called *anti-shadowing* — occurs at substantially larger $x \sim 0.1$ but remains incompletely determined, especially for neutrino scattering. As

a result, a sizable contribution to the full uncertainty in ultra-high energy neutrino-nuclear DIS cross section originates with the incomplete knowledge of the exact size of nPDFs and x dependence of the low- x nuclear shadowing corrections.

As these considerations are important in deriving realistic uncertainty estimates for the neutrino-nuclear cross section at very high energies, we consider two main scenarios for the nPDFs in this work. Specifically, in Fig. 14 we compare the gluon and flavor-singlet nPDFs for O based on two recent extractions: EPPS21 [28] and nCTEQ15WZ [29]. We remind the reader that the EPPS21 nPDFs start with the CT18A NLO fits of the free proton PDFs [20] and include the global nuclear data, fitting a nuclear correction factor, R , on top of this free-proton baseline. In contrast, the nCTEQ PDFs implement an alternative philosophy of fitting nPDFs which are directly parametrized with an explicit A dependence but yielding an assumed free-proton baseline as an $A = 1$ boundary condition of the parametrization. In either case, additional theoretical uncertainty comes from the longstanding issue of the applicability and limits of QCD factorization in nuclear DIS and the question of whether there may be differences between electromagnetic vs. weak interactions with the nuclear medium. Were there differences, these might be realized as distinct nuclear corrections to the DIS structure functions measured in the scattering of charged leptons vs. neutrinos from nuclear targets, including the degree to which (anti)shadowing corrections equally apply to such interactions at low x .

Since the behavior of nuclear corrections in neutrino scattering at low x may influence the high-energy neutrino-nuclear cross sections investigated in this study, we also consider an alternative nPDF scenario (dubbed as “DimuNeu”) based only on fits to neutrino data [61] as a means of cross-checking our primary calculations based on the recent nPDFs of EPPS21 [28] and nCTEQ15WZ [29]. We emphasize that the (heavy) nuclear corrections computed on the basis of nuclear PDFs as discussed above are in addition to the nonperturbative QCD considerations that are already present for free nucleons and arise from target mass effects and sub-leading terms in the twist expansion (so-called higher twist); notably, these effects have been explored for the proton and have analogous realizations for nuclei [62], but their impacts are generally limited to large x and modest values of Q^2 . For this reason, we do not give them special attention in this study, although they form a marginal contribution to the full neutrino-nuclear uncertainty.

An array of LHC measurements involving nuclei — including inclusive W and Z pro-

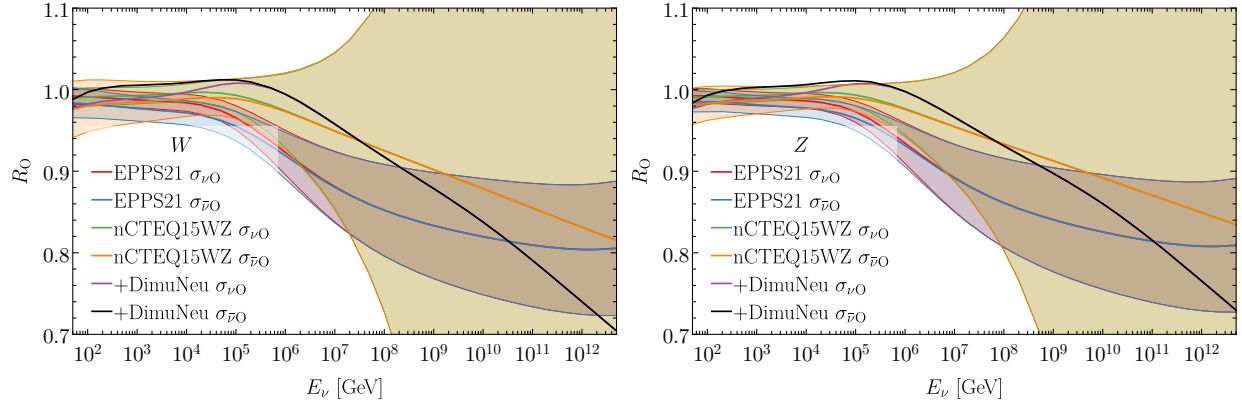

FIG. 15. The nuclear correction ratios, R_O defined in Eq. (12), of the neutrino-nuclear charged (left) and neutral (right) current DIS cross sections.

duction in p Pb collisions — have been recorded by the ALICE, ATLAS, CMS, and LHCb experiments [63–71]. Despite this progress, the current global data set constrains nPDFs only at somewhat higher values of $x \gtrsim 10^{-4}$ relative to free-proton analyses; that is, the lower bound in x of nPDF fits is considerably larger than the corresponding low- x frontier in modern proton PDF determinations, which are constrained by high-energy data down to $x \gtrsim 10^{-5}$. Given this present situation, we rely on extrapolations of existing nPDFs. We note that these polynomial extrapolations to small x are unavoidable on the grounds of numerical stability, despite the naive nature of the extension of interpolation grids to very small x based on parametrizations that have not been constrained by data to such low x ; again, we showed the extrapolated free-nucleon PDFs in Fig. 5 and the corresponding neutrino-nucleon cross sections in Fig. 6.

In the context of this behavior observed for the free-nucleon case, we present in Fig. 15 the nuclear corrections as the (anti)neutrino cross section ratios of nuclear to isoscalar scatterings

$$R_O = \frac{\sigma_{\nu(\bar{\nu})O}}{\sigma_{\nu(\bar{\nu})I}} , \quad (12)$$

with the corresponding nuclear PDF uncertainties, where O and I indicate the ^{16}O and isoscalar targets. We also collect associated numerical values in Tabs. I and II of App. A for the cross sections and nuclear corrections ratios R_O . As done for earlier plots, the left and right panels of Fig. 15 correspond to scattering mediated by W and Z exchange, respectively, and we show the nuclear correction ratio for both ν and $\bar{\nu}$ cross sections based on the EPPS21, nCTEQ15WZ, and the recent nCTEQ DimuNeu analysis. For the former

two analyses, the plotted error band represents the nPDF uncertainty obtained in those studies; for the DimuNeu calculations, in contrast, we simply display the best fit for the sake of comparison against EPPS21 and nCTEQ15WZ as baselines.

As can be seen in both panels of Fig. 15, the nuclear correction ratio is generally consistent with unity — up to nPDF uncertainties — at the lower energies that we plot (for $E_\nu \lesssim 10^4$ GeV), with little evidence of an enhancement above $R_O = 1$. Intriguingly, the E_ν dependence in the calculation based only on fits to neutrino data, DimuNeu, suggests a slight enhancement consistent with nuclear anti-shadowing for $E_\nu \sim 10^5$ – 10^6 GeV, although this behavior is within the 1σ error band determined in nCTEQ15WZ. However, EPPS21 reflects no such enhancement, suggesting a need to further investigate the presence of anti-shadowing in nPDFs for neutrino scattering. In all cases, with growing neutrino energy, the neutrino-nucleus cross section is increasingly suppressed relative to the free-nucleon cross section as nuclear shadowing becomes ever more significant at low x . In addition, the nuclear corrections at ultrahigh energy become universal in terms of flavor $\nu/\bar{\nu}$ as well as the charged/neutral current, much as we had observed for scattering from free nucleons. We see that in a large E_ν range, the nuclear uncertainty is the dominant one, until at an extremely high energy, such as 10^{12} GeV.

In the IceCube experiment, the high-energy neutrinos are scattered by ice/water. The mass-averaged structure functions of ice can be written as

$$F_i^{\text{H}_2\text{O}} = \frac{1}{2 + A}(2F_i^p + AF_i^{\text{O}}), \quad (13)$$

where $A = 16$ and $Z = N = 8$ for the O nucleus. Correspondingly, the averaged-nucleon cross section can be expressed as

$$\sigma_{\nu\text{H}_2\text{O}} = \frac{1}{2 + A}(2\sigma_{\nu p} + A\sigma_{\nu\text{O}}). \quad (14)$$

We show the neutrino-proton DIS cross sections as well as the (anti-)neutrino cross-section ratios of proton to isoscalar $R_{p/I}$ in the upper panels of Fig. 16. In the low energy region, the charged-current DIS gives smaller (larger) cross sections for (anti-)neutrino-proton scattering than isoscalar scattering. This can be understood in terms of the leading partonic subprocesses

$$\nu + d \rightarrow \ell^- + u, \quad \bar{\nu} + u \rightarrow \ell^+ + d. \quad (15)$$

In terms of its valence content, the free proton contains fewer down but more up quarks than

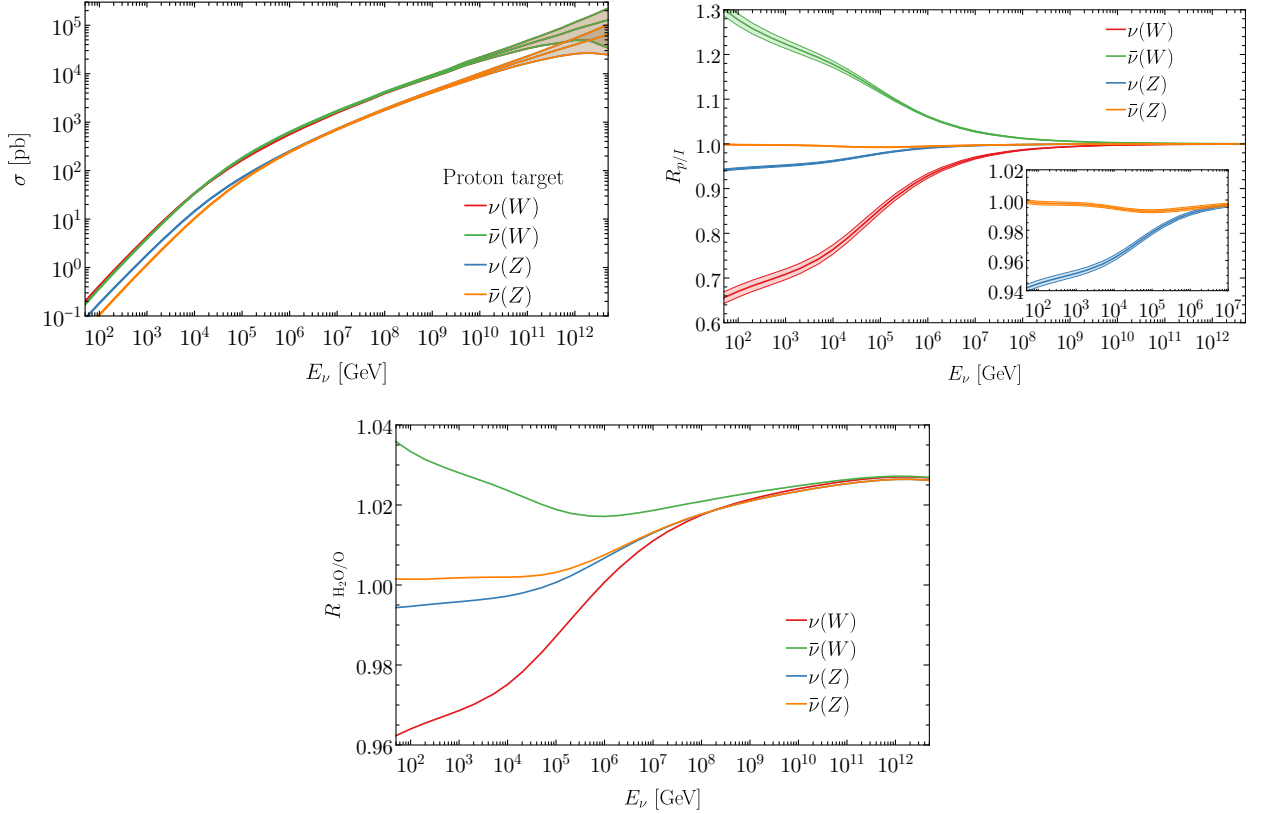

FIG. 16. The neutrino-proton DIS cross-section (upper left), and the cross-section ratios of proton to isoscalar (upper right), and the ratio of H_2O to O nuclei (lower). The bands in the upper right plot indicate proton Hessian uncertainties of CT18 PDFs.

the isoscalar nucleon, leading to a corresponding difference in the CC DIS cross sections. The neutral-current scattering gives $R_{p/I}^{\bar{\nu}(Z)} \sim 1$, which is resulted from an accidental numerical cancellation between the spin correlation (*i.e.*, in the minus sign) and the F_3 difference in Eq. (5). A similar accidental cancellation happens to the CC scattering of the proton target, which gives almost identical cross sections for neutrino and antineutrino. In contrast, $R_{p/I}^{\nu(Z)} \lesssim 1$, as a result of the accumulation of both effects. We also notice that the proton PDF uncertainty is largely canceled in this ratio, especially in the ultrahigh-energy limit, which is slightly more pronounced in the NC current case than the CC one.

In the right panel of Fig. 16, we show the averaged neutrino-water cross section normalized to the oxygen nucleus as

$$R_{\text{H}_2\text{O}/\text{O}} = \frac{2\sigma_{\nu p} + A\sigma_{\nu O}}{(2 + A)\sigma_{\nu O}}. \quad (16)$$

The corresponding numerical values are listed in Tabs. I and II in App. A. Taking the

universal nuclear correction in the high-energy limit to be $R_O \sim 0.81$ [cf. Eq. (12) and Fig. 15 based on EPPS21], we determine that the averaged molecular water-to-oxygen ratio approaches a constant $R_{\text{H}_2\text{O}/\text{O}} \sim 1.026$ at high energy, as shown in Fig. 16. The final H_2O -averaged cross section can then be obtained with

$$\sigma_{\nu\text{H}_2\text{O}} = \sigma_{\nu I} R_O R_{\text{H}_2\text{O}/\text{O}} , \quad (17)$$

with the corresponding uncertainty propagated as

$$\frac{\delta\sigma_{\nu\text{H}_2\text{O}}}{\sigma_{\nu\text{H}_2\text{O}}} = \sqrt{\left(\frac{\delta\sigma_{\nu I}}{\sigma_{\nu I}}\right)^2 + \left(\frac{A}{2+A} \frac{\delta R_O}{R_O}\right)^2} . \quad (18)$$

IV. PREDICTIONS FOR NEUTRINO SCATTERING EXPERIMENTS

So far, we have explained our theoretical calculation of the (anti)neutrino-nucleus scattering in great detail, including both the cross section on free nucleons as well as nuclear corrections. Our predicted cross sections, tabulated in Tab. I-II in App. A, can be directly compared to experimental measurements, both current and future. Here we mainly focus on the IceCube experiment [10] and the proposed future IceCube-Gen2 [72]. We will comment on the collider neutrino energy gap filled by the FASER ν experiment [73] at the LHC as well.

A. Comparisons with CSMS and other calculations

For the IceCube measurements [9, 10], the calculation of Cooper-Sarkar, Mertsch, and Sarkar (CSMS) [30] has been adopted for both neutrino-flux calibrations as well the comparison with the experimental measurement. In addition, a number of similar calculations exist in the literature, such as the Gandhi, Quigg, Reno, and Sarcevic (GQRS) [31], Connolly, Thorne, and Waters (CTW) [32], as well as Bertone, Gauld, and Rojo (BGR) [33]. Similar to our framework, all these calculations adopt the structure-function approach, but with different schemes at different orders, as well as different PDFs. Both the GQRS and CTW took the LO structure functions, while PDFs are based on CTEQ4M [74] and MSTW08 [75], respectively. The CSMS calculation is performed with the Thorne-Roberts scheme [76, 77] at NLO with the HERAPDF1.5 PDFs [78]. The BGR calculation is the most closed one to our framework, with the heavy-flavor structure function in the FONLL scheme up to $n_f = 6$

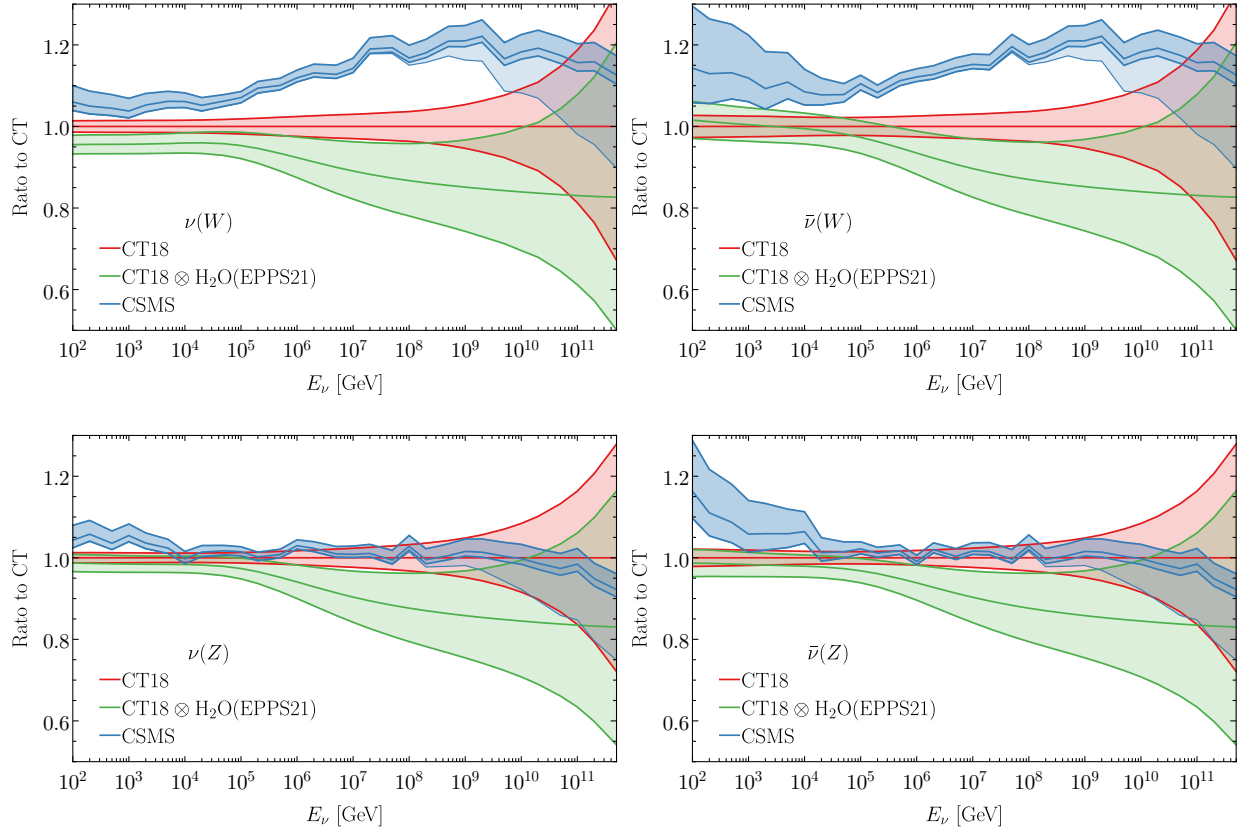

FIG. 17. Comparison of the neutrino-isoscalar cross sections with the existing calculations between the CT18 and CSMS [30], for the CC (upper) and NC (lower) scattering processes.

flavors [45] together with the small- x resummation [48] included. In this work, we have gone beyond in two aspects. We have included the complete heavy-quark effect up to NNLO in the ACOT scheme [21]. It turns out the heavy-flavor effect is negligible at an ultrahigh energy, while a negative 2% when $E_\nu \sim 100$ GeV, as examined in Sec. II. We also extend our calculation up to approximate N3LO, with zero-mass Wilson coefficient functions.

In this work, we are mainly targeting a state-of-art prediction for the high-energy neutrino cross section measured at IceCube. In Fig. 17, we compare our calculation with the CSMS result — the theoretical prediction adopted in IceCube [9, 10], with our numerical results tabulated in App. A. Compared to the free-nucleon (isoscalar) CT18 predictions, the CSMS calculation gives overall larger cross sections for charged-current DIS, while the neutral-current cross section is in good agreement. The larger CC cross section can be understood in terms of the corresponding larger small- x PDFs, as shown in Fig. 18. Relative to the free-isoscalar cross section, the H₂O nucleon-averaged calculation receives a negative nuclear

FIG. 18. The comparison of gluon and flavor-singlet PDFs at $Q = 10$ GeV between the CT18 NNLO and HERAPDF1.5 NLO PDFs.

correction as examined in Sec. III B.

The HERAPDF1.5 PDFs, adopted in the CSMS calculation, give smaller PDF error bands, reflecting the different criteria adopted in two sets. In addition, CSMS realized that member 9 of HERAPDF1.5 gives the largest deviation of neutrino cross sections from the central set, shown as the lower boundary line in Fig. 17. This particular member was argued to be excluded when quantifying PDF uncertainty in Ref. [30] as it gives negative gluon at low x and low Q . However, it has been shown that negative PDFs should be acceptable as long as the physical observables, such as cross section, remain positive [79]. In comparison, HERAPDF adopts the $\Delta\chi^2 = 1$ criterion in generating its 68% confidence level (CL) Hessian eigenvector sets, while CT18 takes $\Delta\chi^2 = 100$ for the 90% CL uncertainty in order to capture variations in the non-perturbative parameterization forms, selection of data sets as well as the variation of theoretical setups [80, 81]. The 68% CL error band is obtained by dividing the 90% CL one by a factor of 1.645. We remind that HERAPDF also released VAR sets, in order to capture variations of some theoretical parameters, such as strong coupling, heavy-quark mass, evolution starting scale, etc [78]. In Fig. 18, we also show the error band including the HERAPDF15VAR set, which indicates its comparable uncertainty with the CT18 prediction.

B. IceCube high-energy neutrino measurements

The IceCube Collaboration has observed high-energy astrophysical neutrinos since 2013 [82]. Two measurements of neutrino-nucleon cross sections have been reported. In

Ref. [9], the Earth absorption cross section is analyzed for energies between 6.3 TeV and 980 TeV, by using the upward-going neutrino-induced muons with 10784 events. In Ref. [10], neutrino cross sections including all three neutrino flavors were reported for neutrino energies from 60 TeV to 10 PeV, based on the 60 high-energy starting events (HESE) with 7.5 years of data. We also note that IceCube has recently reported the measurement of a possible Glashow resonance event [83], providing further motivation to quantify the neutrino-nucleon cross section at corresponding kinematics so as to understand backgrounds to neutrino-electron scattering. We discuss this aspect in further detail in App. D.

In Fig. 19, we show the CT18 and CSMS predictions for the neutrino charged-current DIS cross sections, compared with IceCube data. In the earth absorption (up-going muon) case, the neutrino and antineutrino cross section was flux weighted as

$$\sigma_{\nu,\text{wgt}} = \frac{\Phi_{\nu}\sigma_{\nu} + \Phi_{\bar{\nu}}\sigma_{\bar{\nu}}}{\Phi_{\nu} + \Phi_{\bar{\nu}}}, \quad (19)$$

with the corresponding flux ratio $\Phi_{\nu}/\Phi_{\bar{\nu}}$ taken from Refs. [84, 85]. Similarly to the IceCube analysis, nuclear corrections are not included in this comparison due to the complication of the Earth's nuclear abundance. In the all-flavor HESE cross section, the average of neutrino and antineutrino CC DIS events was reported. We include the data with both Bayesian and Frequentist analyses [10]. A previous analysis based on 33 events [86] has been superseded and is not shown here. Our theoretical predictions with and without nuclear corrections based on the H₂O nucleon average are provided in this case.

We include the CSMS predictions as well, which were used in the IceCube analysis. The difference between our predictions and CSMS, including relative uncertainties, can be inferred from Fig. 17. Both the CSMS and CT18 (both with and without nuclear effects estimated according to EPPS21) predictions provide good descriptions of the IceCube data, considering the large experimental uncertainty, while the CT18 incorporates more comprehensive effects, as detailed in Sec. II-III. In comparison with CSMS NLO calculation, the CT18 baseline is at NNLO, which receives negative a few percent corrections at low (anti)neutrino energy, with size growing up to 20% when $E_{\nu} = 10^{12}$ GeV. The approximate N3LO contribution has been estimated with the zero-mass structure functions, which can give 2% corrections for CC DIS and 4% to NC DIS. The heavy-quark mass effect has been examined with the recently developed ACOT scheme at the NNLO [21, 47], which turns out to be -2% at low (anti)neutrino energy around $E_{\nu} \sim 100$ GeV and diminishes very quickly

with energy increasing. The quark flavors have been included up to $n_f = 6$, and top quarks can contribute 2 – 4% to the total cross section when $E_\nu = 10^{12}$ GeV. In addition, we have also included the small- x resummation based on the BFKL matched to the DGLAP evolution, which enhances the neutrino cross section up to 20% at high (anti)neutrino energy. Finally, based on nuclear PDF sets, EPPS21 and nCTEQ15WZ, we have estimated the nuclear corrections up to be negative -20% as a result of the nuclear shadowing effect. The comparison between the CT18 and CSMS results can be found in Sec. IV A.

FIG. 19. Comparison of the theoretical predictions of charged-current neutrino cross sections with the IceCube measurements [9, 10]. In the left panel for measurements with up-going muon neutrinos [9], the neutrino and antineutrino cross sections are weighted with flux as Eq. (19). In the right panel for the HESE sample, the neutrino and antineutrino cross sections are averaged, with both Bayesian and Frequentist analyses shown here [10]. The CT18 error bands indicate the PDF uncertainty, while the H₂O averaged band combines the EPPS21 nuclear uncertainty in terms of Eq. (18).

As shown in Fig. 19, the experimental uncertainties are overwhelming in comparison with the theoretical ones, both driven by the statistic errors and the complicated systematics, such as the neutrino flux and the earth model. Therefore, a better understanding of systematics as well as higher statistics will be critical in future measurements. IceCube Collaboration has proposed a significant upgrade of the IceCube Antarctic neutrino observatory, to be called IceCube-Gen2 [72]. Two distinct features of Gen2, (i) a larger (by a factor of 10) volume of the ice Cherenkov detector and (ii) an additional shallow radio array to detect higher-energy neutrinos with $E_\nu > 10^{11}$ GeV, will provide better measurements for the neutrino cross sections. Our theoretical predictions apply to IceCube-Gen2 as well.

Neutral-current (NC) cross sections. One goal of the IceCube Collaboration is to measure the flux of cosmic neutrinos as a function of neutrino energy [87]. The IceCube Ob-

servatory uses Cherenkov radiation to detect charged particles as a proxy for UHE neutrinos. High-energy neutrinos that undergo charged current (CC) interactions in the detector create high-energy charged leptons, which radiate Cherenkov light. Obviously, the theoretical CC cross section is important for interpreting the IceCube Observatory results.

The theoretical *neutral current* (NC) cross section is also important because the IceCube Collaboration uses *the absorption of neutrinos by the Earth* to estimate the flux of neutrinos incident on the Earth. Neutrinos incident on the Earth from the Northern Hemisphere must pass through a fraction of the Earth, dependent on their direction, before reaching the IceCube Observatory at the South Pole. As they travel through the Earth, some neutrinos will be absorbed or scattered by interacting with matter, including both CC and NC interactions. In such a way, a better determination of the NC cross section will play a role in the earth absorption rate, as discussed further in App. C.

C. Accelerator neutrinos and the energy gap

In Fig. 20 (left), we compare our theoretical predictions for the neutrino-isoscalar charged current cross section in comparison with the data measured at accelerator experiments, such as NuTeV [88], CCFR [89] and NOMAD [90]. We remind the reader that the NOMAD has released only the neutrino rather than antineutrino CC inclusive cross sections so far [90]. Due to the complication of different target materials used in different experiments, we don't include nuclear corrections here, which deserve future dedicated studies. In general, we see that these three experiments give consistent results for both the neutrino and antineutrino beams. In comparison, our theoretical calculations give a good description of the high-energy data. The low-energy predictions are smaller than the experimental measurements. This behavior was already noticed in our previous work [21], which indicates the importance of missing contributions from other nuclear scattering processes, such as quasi-elastic scattering and the hadronic resonance production, which dominate at the neutrino-nuclear cross section at low energies [35].

In Fig. 20 (right), we show the averaged (anti)neutrino-isoscalar charged-current cross section divided by the (anti)neutrino energy $\sigma(E_\nu)/E_\nu$. We also include the cross section measured by the NuTeV Collaboration, as one of the highest energies reached for accelerator neutrinos [88]. The “energy gap” between the NuTeV ($\lesssim 360$ GeV) and the IceCube data (\gtrsim

FIG. 20. Left: The CT18 predictions for the neutrino-isoscalar charged-current cross sections divided by the (anti)neutrino energy, σ/E_ν , in comparison with data measured at accelerator-based experiments [88–90]. Right: The CT18 prediction of the averaged neutrino-isoscalar charged-current cross sections divided by neutrino energy in the energy gap ($360 \text{ GeV} \lesssim E_\nu \lesssim 6 \text{ TeV}$), which can be measured by the FASER and other FPFs at the LHC [15, 16]. We included cross sections below 360 GeV measured by NuTeV [88] and above 6.3 (60) TeV by IceCube upgoing $\bar{\nu}_\mu$ [9] (HESE Bayesian [10]) analyzes.

6 TeV) can be bridged by ongoing and future measurements at the LHC, such as the FASER (ForwArd Search ExpeRiment) [91] as well as other Forward Physics Facilities (FPFs) [15, 16]. Meanwhile, though yet to reach 3σ statistical significance, the first detection of neutrinos at the LHC was claimed by the FASER Collaboration in 2021 [92]. The maximum neutrino energy produced at the LHC can potentially reach the order of 10 TeV. As an optimistic consequence, the energy gap can be completely closed by these experiments. Our theoretical cross section is also shown as the red line in Fig. 20 (right), which provides state-of-the-art predictions for the neutrino scattering measured at these FPFs [15, 16].

V. CONCLUSIONS

In this work, we have presented up-to-date theory calculations for neutrino-nucleon deeply-inelastic scattering (DIS) mediated by both charged- and neutral-current interactions over a wide range of neutrino energies, spanning $E_\nu \sim 50 \text{ GeV}$ up to 10^{12} GeV . We have also generalized these results to neutrino DIS from nuclei by estimating high-energy nuclear corrections to interactions with free (isoscalar) nucleons. As is typical, we separate the cross section into a (weak) leptonic tensor as well as a corresponding hadronic tensor. This latter quantity may be expanded in a complete basis of allowed Lorentz structures,

such that folded into the hadronic tensor are the structure functions of the target nucleon or nucleus; these in turn can be computed according to well-established QCD factorization theorems that facilitate the separation of short-distance matrix elements, which are now calculable to high perturbative order (at present, N3LO'), from the nonperturbative parton distribution functions (PDFs) of the nucleon or nucleus. On the basis of this formalism, we predict neutrino DIS cross sections, leveraging recent developments in QCD perturbation theory and the most current PDF determinations provided by global QCD analyses, which systematically unfold the PDFs from diverse high-energy data taken at collider and fixed-target experiments. This work, therefore, provides the current best theoretical description for both accelerator-based neutrino experiments at higher energies, as well as astrophysical neutrino telescopes, which can potentially observe events in the ultra-high energy regime.

Using the recent CT18 NNLO proton PDFs [20] together with the Wilson coefficients calculated up to N3LO', which includes the exact NNLO heavy-parton mass effect [21, 47] and N3LO contribution with zero-mass partons [22], we carefully examine each of the stages of the neutrino-nucleon DIS cross section calculation. As the total neutrino cross sections involve broad integrations over the (x, Q) phase space, knowledge of the structure functions, including those at low scales, is a prerequisite. In the low- Q region, below the starting scale of the CT18 PDFs ($Q_0 = 1.3$ GeV), we have explored the impact on the total DIS cross section of taking either LHAPDF extrapolation [38] or APFEL backward evolution [39] to lower Q . We find that the dependence on this selection produces approximately percent-level variations in the cross section at neutrino energies of $E_\nu = 10^3$ GeV; at larger values of E_ν , this difference quickly vanishes. On the other hand, as the neutrino energy enters the ultra-high energy region, $E_\nu > 10^8$ GeV, the cross section increasingly gains contributions from very small parton momentum fractions, $x \ll 1$, extending the dependence of the cross section to values of x which have not been directly probed experimentally, and potentially even beyond the lower x bounds of available PDF interpolation grids. We have quantified the contribution(s) from this low- x extrapolation region, which ultimately amounts to $\sim 3\%$ of the total cross section at $E_\nu = 10^{12}$ GeV. The corresponding uncertainty is quantified with the LHAPDF extrapolation and APFEL extrapolation together with evolution, which is found to be at most 1% for CT18 NNLO. This uncertainty is larger for other PDF sets, such as the nCTEQ15WZ nuclear PDFs [29], due to a larger extrapolation region from a larger x value. Furthermore, we have identified the important (x, Q) kinematics, which is

around $(x, Q) \sim (M_{W,Z}^2/(2m_N E_\nu), M_{W,Z})$, based on separate scans of integration limits x_{\min} and Q_{\min} as well as the joint two-dimensional scan.

We have also explored higher-order effects by comparing the LO, NLO, and NNLO calculations implemented alongside the corresponding CT18 PDFs consistently determined at the same orders. These corrections up to NNLO are generally negative, about a few percent at low neutrino energies, but increasing to 20% percent at $E_\nu = 10^{12}$ GeV. The missing higher-order effect is estimated with zero-mass N3LO Wilson coefficients together with NNLO PDFs and found to be 2% for CC DIS, and 4% for NC DIS. We have also investigated heavy-quark effects using the recent NNLO ACOT calculation for CC DIS [21], which we find to be at most 2% for $E_\nu = 10^2$ GeV before rapidly becoming negligible at higher energies. Moreover, the contribution from the third quark generation is examined within a variable-flavor-number scheme. We find that the bottom quark and top quarks contribute negligibly at low (anti)neutrino energy when $E_\nu < 10^6$ GeV. With increasing (anti)neutrino energy, each can contribute at most $\sim 2-4\%$ for $E_\nu = 10^{12}$ GeV. As the small- x phase space contribution becomes important with increasing neutrino energy, we have included small- x resummation effects based on the BFKL evolution using the HELL [57, 58] framework interfaced to APFEL [39], finding the associated effect can be as large as 10% for $E_\nu = 10^{12}$ GeV. Moreover, effects of nuclear corrections were estimated using two of the latest nuclear PDF extractions, EPPS21 [28] and nCTEQ15WZ [29]. For example, if we base our default nuclear correction estimates on EPPS21, we obtain a negative shift in the neutrino-oxygen cross section relative to isoscalar (free-nucleon) scattering up to -20% when $E_\nu \gtrsim 10^{10}$ GeV, a result of the nuclear shadowing effect at small x . We also find the uncertainties associated with these nuclear-medium effects, especially the low- x shadowing, to be particularly sizable and an important limitation to the precision of ultra-high energy neutrino-nuclear scattering predictions.

We have compared our predictions to those obtained in the CSMS model [30], which is based on an NLO QCD calculation using HERAPDF1.5 PDFs. While our calculation agrees with CSMS for NC DIS, our results are $\sim 10-20\%$ smaller for CC DIS. This difference is a consequence of two primary factors: the negative NNLO corrections including in our calculation as well as the (comparatively) smaller gluon PDF obtained by CT18 in the small- x region relative to HERAPDF1.5. We also provide the PDF uncertainty based on the Hessian eigenvector sets [80]. It is found to be a few percent at intermediate high energy when

$E_\nu \lesssim 10^7$ GeV, which grows up to $60\% \sim 70\%$ at $E_\nu = 10^{12}$ GeV. Our PDF uncertainties are generally larger than the CSMS result, mainly because of different uncertainty criteria. In the CT18 PDFs, the 90% CL Hessian eigenvector sets are determined by a 100-unit increase, $\Delta\chi^2 = 100$, in the global χ^2 (out of a total global $\chi^2 \approx 4300$); this extended tolerance captures the full PDF error stemming from tensions among fitted data as well as uncertainties from the non-perturbative parameterization and other QCD parameters [80, 81]. In comparison, HERAPDF assumes a $\Delta\chi^2 = 1$ criteria to determine its error bands at the 68% CL, while other QCD parameter uncertainties are quantified by corresponding VAR sets [78], which are comparable with the CT18 ones.

In addition to other theoretical calculations, we have also compared our results to existing measurements, including the high-energy events at IceCube as well as the accelerator-based neutrino experiments. Our theoretical predictions give a good description of the IceCube results, both for the earth absorption cross sections [9] and the so-called high-energy starting events [10]. Compared to the theoretical calculations, current experimental uncertainties are much larger, driven by complicated systematics as well as limited statistics. As for the accelerator neutrino cross sections [88–90], our theoretical calculations agree well with the high-energy tails with $E_\nu \gtrsim 250$ GeV but under-predict the data at more modest energies, indicating the importance of missing contributions from low-energy nuclear processes like quasi-elastic scattering and resonance production, which are beyond the scope of this work. In between the accelerator neutrinos and the IceCube telescope, an energy gap exists for $360 \text{ GeV} \lesssim E_\nu \lesssim 6 \text{ TeV}$, which may potentially be filled by the ongoing and future FASER [14] as well as other Forward Physics Facilities [15, 16] experiments at the LHC.

A number of improvements upon the present work can be pursued in the future. For instance, very recently, approximate N3LO PDFs have been released based on the global analysis of the MSHT group [93]. A complete N3LO PDF set is needed to obtain the full N3LO contribution. As we have seen, theoretical uncertainties increase significantly with neutrino energy, mainly induced by the large free-nucleon and nuclear PDF uncertainties in the small- x region. Constraining small- x PDFs, especially the gluon PDF, better can greatly enhance the accuracy of high-energy theory predictions. This might be furthered by incorporating LHCb data on the forward production of D and B mesons [94, 95] into global QCD analyses of PDFs. In addition, obtaining improved theoretical control over gluon saturation effects at small x [96], further investigating the systematics of PDF extrapolation

to low x , and pursuing studies of nuclear PDF issues related to shadowing at $x \ll 1$ would all be invaluable to next-generation precision for neutrino-nuclear scattering.

ACKNOWLEDGMENTS

We would like to thank Valerio Bertone for the helpful instruction about the BGR calculation and Donna Naples for providing the NuTeV data. We also thank Faiq Muzakka, Fred Olness, and the larger nCTEQ collaboration for providing grid files corresponding to the recent DimuNeu nPDF fit as well as for useful discussions related to neutrino-nuclear interactions, and Tyce DeYoung for reading part of this manuscript as well as a few useful comments. The work of JG is sponsored by the National Natural Science Foundation of China under Grant No.12275173 and No.11835005. The work of TJH was supported by the U.S. Department of Energy under contract DE-AC02-06CH11357. The work of CPY is supported by the U.S. National Science Foundation under Grant No. PHY-2013791. CPY is also grateful for the support from the Wu-Ki Tung endowed chair in particle physics.

Appendix A: Neutrino cross sections

As explained in the Sec. II and III, we collect our theoretical predictions for the neutrino charged-current and neutral-current deep inelastic scattering cross sections in Tabs. I and II. The second column of Tabs. I-II corresponds to the neutrino-isoscalar cross sections $\sigma_{\nu I}$ based on the CT18 NNLO PDFs, including the heavy-quark mass effect with the ACOT scheme, parton flavors up to $n_f = 6$, approximate N3LO corrections (N3LO') with massless Wilson coefficient functions, as well as the small- x resummation, which are detailed in Sec. IIB, IIC and IIIA. The third column indicates the CT18 proton PDF uncertainty quantified with the traditional Hessian error method at 68% confidence level (CL) [80]. In the fourth ($R_{\nu O}$) and fifth columns, we present the nuclear corrections to the isoscalar target O and the corresponding uncertainty, based on the EPPS21 nuclear PDF sets [28], explored in Sec. IIIB. The sixth column ($R_{\text{H}_2\text{O}/\text{O}}$) denotes the water (H_2O) nucleon-averaged ratio

defined in Eq. (16). The final neutrino-water cross section can be obtained with Eq. (17) and uncertainty with Eq. (18). The antineutrino cross sections follow after as another block in Tabs. I-II.

TABLE I. Charged current neutrino-isoscalar scattering cross sections $\sigma_{\nu(\bar{\nu})I}$, calculated with the CT18 PDFs with flavor up to $n_f = 6$, approximate N3LO corrections (N3LO'), as well as small- x resummed up to next-to-leading logarithmic level (NLLx). The $\delta\sigma_{\nu(\bar{\nu})I}$ column indicates the isoscalar uncertainty from proton PDFs at 68% CL, while the nuclear correction as cross-section ratios of O to isoscalar targets $R_{\nu(\bar{\nu})O}$ are obtained with EPPS21 and uncertainty folded in $\delta R_{\nu(\bar{\nu})O}$. The water cross section ratios $R_{\text{H}_2\text{O}/\text{O}}$ are defined in Eq. (16), with the final cross section propagated with Eq. (17) and uncertainty with Eq. (18).

TABLE II. Similar to Tab. I, but for the neutral current case.

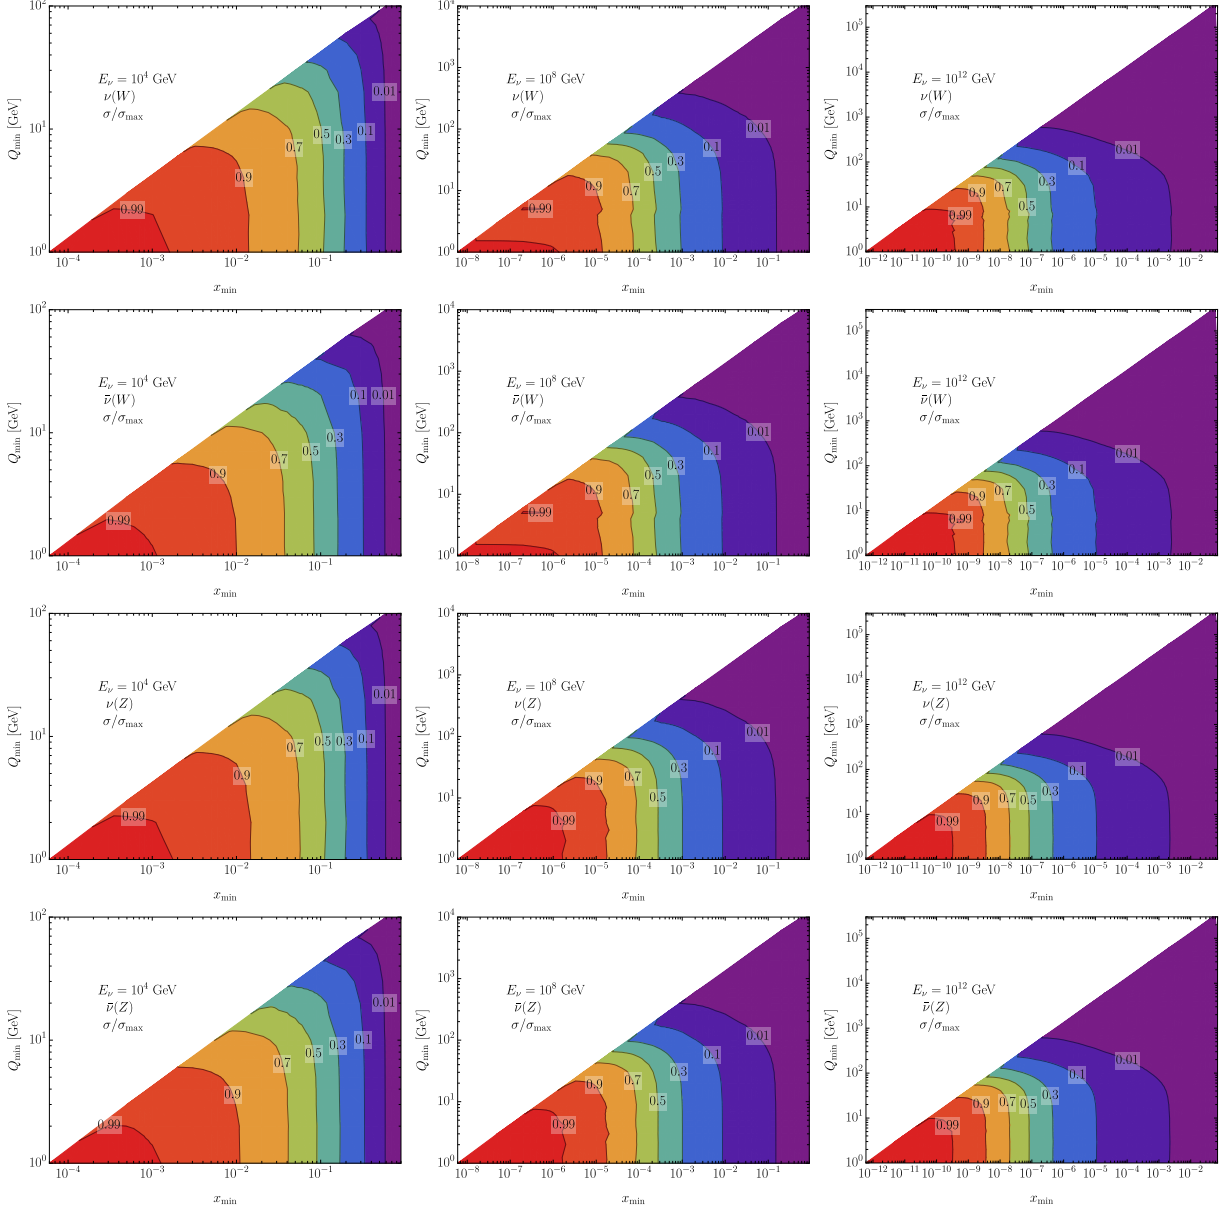

FIG. 21. The ratio contours of neutrino-isoscalar DIS cross sections with variations of integration limits (x_{\min}, Q_{\min}) , with respect to the maximal one with $x_{\min} = \frac{Q^2}{2m_N E_\nu}$ and $Q_{\min} = 1$ GeV.

Appendix B: The important (x, Q) kinematics

In Sec. II A, we have performed the two separate scans over x_{\min} and Q_{\min} in the low- x and low- Q region. We found the extrapolation region only makes up to a percent level for the total cross sections. These scans can be extended to higher x and larger Q values, which can give us an idea of the integration contribution from various kinematic (x, Q) regions. A more transparent and direct way can come from a joint two-dimensional scan of x_{\min} and

FIG. 22. Similar to Fig. 3, but with an extended Q_{\min} scan, as a projection of Fig. 21 to the Q_{\min} direction with $x_{\min} = Q_{\min}^2/(2m_N E_\nu)$.

Q_{\min} . Therefore, we perform the integration of Eq. (9) in the trapezoid region,

$$Q \in [Q_{\min}, \sqrt{2m_N E_\nu}], x \in [\max(x_{\min}, Q^2/(2m_N E_\nu)), 1]. \quad (\text{B1})$$

With a few representative energies, we show the percentage of the total cross section as contours plots in Fig. 21. The projections to one-dimensional x_{\min} and Q_{\min} directions are plotted in Figs. 22-23, similar to Figs. 3-4. We found that the integrated cross sections decreases drastically around $Q_{\min} \sim M_{W,Z}$ and $x \sim x_{W,Z} = M_{W,Z}^2/(2m_N E_\nu)$. It indicates that a large part of the total cross section comes from the integration around the region $(x, Q) \sim (M_{W,Z}^2/(2m_N E_\nu), M_{W,Z})$, which we call the *important* (x, Q) *kinematics*. This can be understood naturally in terms of the integration in Eq. (3). On one side in the asymptotic limit $Q \gg M_{W,Z}$, the integrand dies away quickly due to the suppression from the prefactor, $1/(1 + Q^2/M_{W,Z}^2)^2$. That is, the large- Q region does not contribute much to the total cross section in the integration. Conversely, for $Q \ll M_{W,Z}$, the prefactor becomes a constant; in that case, the integration is mainly driven by the region with large structure functions. In comparison with F_2 , F_L and F_3 are generally small. Due to the DGLAP evolution effect, F_2 generally increases with the scale, Q^2 , which can be seen in some simplistic parametric forms, such as those of Refs. [97–99]. Consequently, the weight contribution to the cross-section integration grows with energy Q , which is explored in Ref. [36] and leads to the Froissart bound [75, 100].

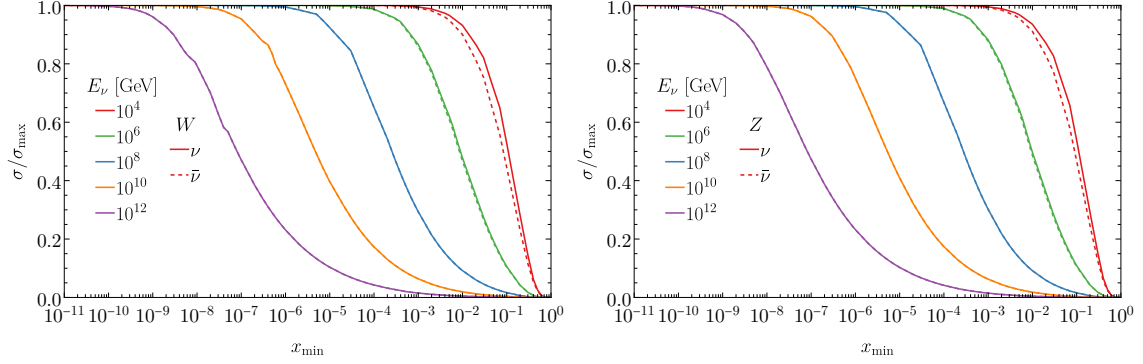

FIG. 23. Similar to Fig. 4, but with an extended x_{\min} scan as a projection of Fig. 21 to the x_{\min} direction.

Appendix C: The Earth absorption

The neutrinos measured at the IceCube can come from both the northern and southern skies. The neutrinos from the northern sky need to pass through the whole earth before arriving at the IceCube detectors located at the geographic South Pole. As a result, the upward-going events, proportional to the neutrino arrival flux with the zenith angle $\theta \in [90^\circ, 180^\circ]$, are subject to the Earth's absorption rate, which in turn depends on neutrino scattering cross sections. The IceCube collaboration has taken the CSMS calculation [30] in the corresponding experimental simulation and event analyses, for the neutrino DIS cross sections based on up-going muon neutrinos [9] and the high-energy starting events (HESE) sample [10].

Recall that high-energy neutrinos detected at IceCube mainly come from atmospheric and astrophysical resources [102, 103]. Based on the simplest single-power-law flux model, the neutrino flux can be parameterized as

$$\Phi_\nu(E_\nu) = \phi \cdot \left(\frac{E_\nu}{100 \text{ TeV}} \right)^{-\gamma}, \quad (\text{C1})$$

where ϕ indicates the value at $E_\nu = 100 \text{ TeV}$, and γ is the power law spectral index, with both fitted from astrophysical data [102, 103]. The event rate of upward-going neutrino-induced muons observed in the IceCube observatory can be written as

$$N_{\nu(\bar{\nu})}(E_\nu, \theta) \sim \sigma_{\nu(\bar{\nu})}^W(E_\nu) \Phi_\nu(E_\nu) \mathcal{P}_{\text{trans}}(E_\nu, \theta). \quad (\text{C2})$$

Here $\sigma_{\nu(\bar{\nu})}^W(E_\nu)$ is the charged-current cross section of the (anti)neutrino scattered with the IceCube material, such as H_2O . $\mathcal{P}_{\text{trans}}(E_\nu, \theta)$ denotes the neutrino's transmission (or survival)

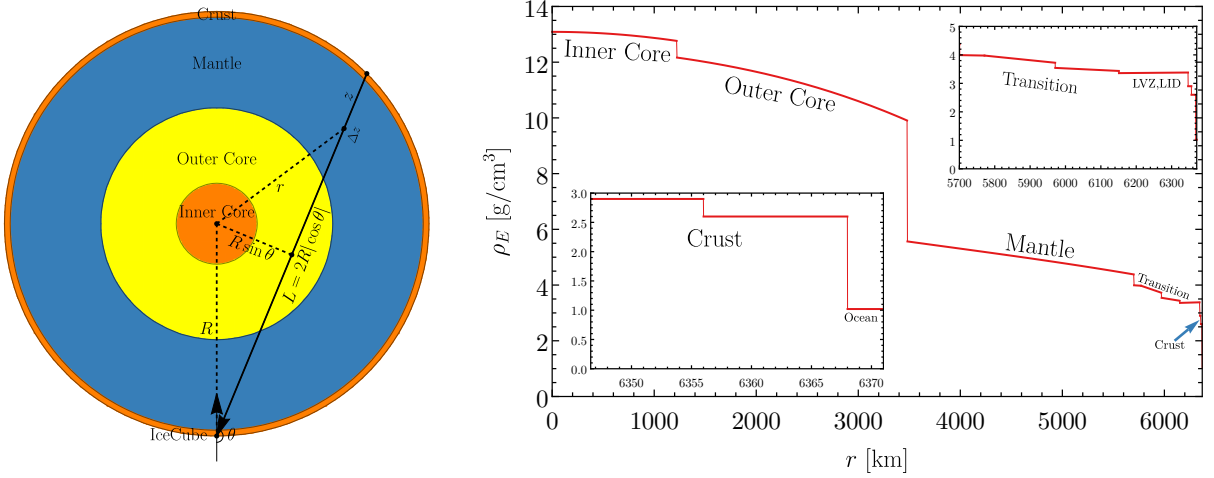

FIG. 24. (Left) A schematic path for neutrino traveling through the chord in the direction of zenith angle θ . The Earth's internal structure is assumed to be spherical symmetric, with density (right) taken from the Preliminary Reference Earth Model (PREM) [101].

probability when passing through the earth in the direction of zenith angle θ . For neutrino travels through the path of chord $z \in [0, L = 2R|\cos \theta|]$ as shown in Fig. 24 (left), the transmission probability can be obtained in terms of

$$P_{\text{trans}}(E_\nu, \theta) = \prod_{\Delta z} P_{\alpha\alpha}(E_\nu, \Delta z) \exp\{-\Delta z/\lambda(r, E_\nu)\}. \quad (\text{C3})$$

$P_{\alpha\alpha}(E_\nu, \Delta z)$ is the oscillation probability of neutrino flavor $\alpha = e, \mu, \tau$. Also, $\lambda(r, E_\nu) = \frac{1}{n_N(r)\sigma_{\nu(\bar{\nu})}(E_\nu)}$ is the mean-free path, which depends on the earth's nucleon density $n_N(r) = \rho_E(r)/m_N$ at a distance to the earth center as

$$r = \sqrt{(R \sin \theta)^2 + (R|\cos \theta| - z)^2} = \sqrt{R^2 + z^2 + 2Rz \cos \theta}, \quad (\text{C4})$$

as well as the absorption cross section $\sigma_{\nu(\bar{\nu})}(E_\nu) = \sigma_{\nu(\bar{\nu})}^W(E_\nu) + \sigma_{\nu(\bar{\nu})}^Z(E_\nu)$, including both NC and CC scatterings. In principle, the neutrino-electron scattering should be included as well. However, the corresponding cross section is generally two or three magnitudes smaller than the nuclear-nucleon one, with an exception around the Glashow resonance region. (See App. D for its details.) Therefore, we can safely neglect it in this estimation. Moreover, we consider the earth's isotopic constituents as isoscalars and neglect the nuclear effect, which in principle can be included when knowing the earth's element abundances [104]. Furthermore, the NC interactions, as well as the τ decays in ν_τ CC scattering, will “regenerate” neutrinos

FIG. 25. The neutrino (left) and antineutrino (right) transmission probability $\mathcal{P}_{\text{trans}}$ when passing the Earth, based on the CT18 and CSMS predictions for neutrino-isoscalar charged- and neutral-current DIS cross sections. The small thin bands correspond to the CT18 PDF variation.

with lower energies, which is not considered here. Integrating out the exponent in Eq. (C3) ends up with [105]

$$\mathcal{P}_{\text{trans}}(E_\nu, \theta) = P_{\alpha\alpha}(E_\nu, L) \exp\{-X(\theta)\sigma(E_\nu)\}, \quad (\text{C5})$$

where

$$P_{\alpha\alpha}(E_\nu, L) = 1 - \sin^2 2\theta_{\alpha\alpha} \sin^2 \frac{\Delta m_{\alpha\alpha}^2 L}{4E_\nu} \simeq 1 \quad (\text{C6})$$

when $E_\nu \gtrsim 1$ TeV [1], and

$$X(\theta) = \int_0^{L=2R|\cos\theta|} dz \rho_E(\sqrt{R^2 + z^2 + 2Rz \cos\theta})/m_N. \quad (\text{C7})$$

Here, $\rho_E(r)$ is the earth matter density, which can be assumed to be spherically symmetric from the Preliminary Reference Earth Model (PREM) [101], as shown in Fig. 24 (right).

Knowing the neutrino cross sections from the CT18 and CSMS predictions, we can calculate the transmission probability, with results shown in Fig. 25, with the CSMS one agreeing with the IceCube simulation quite well [9]. However, we note that as shown in Fig. 17, the CT18 prediction yields a smaller cross section than the CSMS one by about 10 percent, hence giving a larger transmission probability. Consequently, from Eq. (C2), for a given number of observed event $N_{\nu(\bar{\nu})}$, the CT18 predictions would give a smaller product of $\sigma_{\nu(\bar{\nu})}^W \Phi_\nu(E_\nu)$ as compared to the CSMS prediction. This would have an entangled impact on the final measured cross section as well as other parameters, such as ϕ , γ obtained by the IceCube analysis [9, 106].

Assuming a well-determined astrophysical neutrino flux, the IceCube Observatory may

FIG. 26. Feynman diagrams for the neutrino-electron scattering.

measure the neutrino cross section *without* being affected by the earth's absorption. In another word, neutrino events *from the Southern Sky* could be used to determine the neutrino cross section in better systematics if enough statistics, due to the advantage of being free from the earth model of the nuclear isotopic abundance, density, and other parameters. However, this method faces a disadvantage due to a large background of cosmic-ray muon events in the ice Cherenkov detector as well as lower statistics. A more complete work remains to be done with experimental simulations.

Appendix D: Neutrino-electron scatterings and the Glashow Resonance

In addition to scattering from QCD matter as explored above, neutrinos can also interact with electrons, as representative diagrams shown in Fig. 26. Different from neutrino-nucleon scattering, which involves nonperturbative parton structures, neutrino-electron scattering is fully perturbative in terms of the EW interaction. We show the corresponding cross sections compared with the (anti)neutrino-nucleon DIS cross section without nuclear corrections in Fig. 27. The detailed description of the (anti)neutrino-nucleon cross section can be found in Sec. III A. Generally speaking, the (anti)neutrino-electron cross sections are two or three magnitudes smaller than the neutrino-nucleon ones.

Similar to nucleon ones, neutrino-electron scatterings involve both the charged and neutral current interactions mediated by W and Z bosons. The neutral-current couplings are smaller than the charged-current ones, which explains the smaller cross sections for the processes $\nu_\mu e^- \xrightarrow{Z} \nu_\mu e^-$ and $\bar{\nu}_\mu e^- \xrightarrow{Z} \bar{\nu}_\mu e^-$ than $\nu_e e^- \xrightarrow{W,Z} \nu_e e^-$ and $\nu_\mu e^- \xrightarrow{W} \nu_e \mu^-$. For sole NC scatterings, $\nu_\mu e^- \xrightarrow{Z} \nu_\mu e^-$ is more-or-less the same for $\bar{\nu}_\mu e^- \xrightarrow{Z} \bar{\nu}_\mu e^-$ due to the same coupling, while the minor difference is originated from the spin correlation. In comparison, $\nu_e e^- \xrightarrow{W,Z} \nu_e e^-$ gives a smaller (larger) cross section than $\nu_\mu e^- \xrightarrow{W} \nu_e \mu^-$ when

FIG. 27. Comparison of the neutrino-electron and neutrino-isoscalar DIS scattering cross sections. The neutrino-isoscalar cross section is directly taken from the CT18 predictions without nuclear corrections.

$E_\nu \lesssim 10^8$ GeV ($E_\nu \gtrsim 10^8$ GeV), as a result of the destructive (constructive) interference between CC and NC interactions. The tau-neutrino cross sections behave more-or-less the same as the muonic ones, with only a minor correction from the heavier tau mass whenever a final-state tau lepton shows up.

Distinct from scattering off nucleons, a new process emerges in the form of s -channel Glashow resonance [107] production, depicted in Fig. 26 (right). The corresponding cross section can be written as [108]

$$\sigma_{W(s\text{-ch})} = 24\pi\Gamma_W^2 \mathcal{B}(W^- \rightarrow e^- \bar{\nu}_e) \mathcal{B}(W^- \rightarrow f \bar{f}') \frac{s/M_W^2}{(s - M_W^2)^2 + (M_W \Gamma_W)^2}, \quad (\text{D1})$$

where $\mathcal{B}(W^- \rightarrow f \bar{f}')$ is the corresponding decay branch fraction. Here, W bosons can subsequently decay into leptons as well as hadronic final states. The resonance peak appears at

$$s = 2m_e E_\nu = M_W^2 \implies E_\nu = \frac{M_W^2}{2m_e} \simeq 6.32 \times 10^6 \text{ GeV}. \quad (\text{D2})$$

In comparison with other resonance decay channels, the $\bar{\nu}_e e^- \xrightarrow{W(s\text{-ch}), Z} \bar{\nu}_e e^-$ scattering also involves the neutral-current interaction, via the t -channel Z -mediated diagram also shown in

Fig. 26, which dominates the high-energy tail. In contrast, the $\bar{\nu}_e e^- \xrightarrow{W(s\text{-ch})} \bar{\nu}_\mu \mu^-$ scattering involves only the CC interactions via s -channel diagram, resulting in a suppressed cross section at high neutrino energies. In the IceCube measurement, one Glashow resonance event was reported around the neutrino energy $E_\nu = (6.05 \pm 0.72) \times 10^6$ GeV [83]. When neutrinos pass the earth, the neutrino-electron scattering will contribute to the earth's absorption. However, in comparison with the neutrino-nucleon (or -nucleus) cross sections shown in Fig. 19, the neutrino-electron process is generally much smaller, being negligible for most scenarios.
