# MoS<sub>2</sub>/MoO<sub>3</sub> Heterojunction: Dual Role of the Type II set-up and Band Gap Modulation of MoS<sub>2</sub> upon Lithium-Ion Intercalation

#### Abstract:

In recent times photorechargeable metal ion batteries have garnered significant attention but the atomistic details of the mechanism of the charging process is still unknown.  $MOS_2/MOO_y$ , a type II semiconductor heterostructure, has been shown to function as photocathode where during discharge the lithium ion (Li-ion) intercalation happens mostly in  $MOS_2$  layers. Photoexposure leads to exciton formation and the type II set-up is supposed to generate spatially separated and longer-lived charge carriers. The Li intercalated  $MOS_2$  is known to undergo a phase transition from the semiconducting (2H) to a metallic (1T') phase. Hence, the proposal of exciton formation and its separation in  $Li_xMOS_2$  during photocharging needs closer inspection. In this study, with the help of density functional theory (DFT) based studies that is aptly supported by experimental data, it is shown that  $Li_xMOS_2/MOO_3$  forms a type II heterostructure where the underlying band gap of  $Li_xMOS_2$  is exposed due to dispersion of electron density onto  $MOO_3$  upto a certain value of x. Further studies show that the type II arrangement is lost prior to the phase transition. In order to investigate the electronic structure and the phase transition upon lithiation in the explicit heterostructure, we introduced two unconventional computational schemes. The presence of the band gap and the ensuing type II arrangement in  $Li_xMOS_2/MOO_3$  upto a certain concentration of the intercalated Li-ion justifies the possibility of the photocharging process. We believe that the general concepts explored in this study will be important in the rational design of type II heterostructures that can behave as photo-cathode materials in Li-ion batteries.

Keywords: Solar Battery; Density Functional Theory; Type-II Heterostructure, Phase Transition; Band Gap Change

Due to the structural stability and reversible lithium ion (Li ion) intercalation/de-intercalation abilities, layered materials like LiNi<sub>x</sub>Mn<sub>y</sub>Co<sub>z</sub> have been widely used in Li ion batteries as cathode where they exhibit large capacity and high voltage discharge plateau, sometimes at the expense of the electronic band gap.<sup>[1-4]</sup> In contrast, studies on the photo-cathode materials with a band gap commensurate with the frequency of light in the visible region, have been significantly low. <sup>[5-7]</sup> Traditionally, a type II heterojunction has been employed for photosensing and photocatalytic applications in order to efficiently separate the charge carriers that are generated upon photo-excitation.<sup>[8-12]</sup> The efficiency of the type II set-up is critically dependent on the alignment of the band edges of the two materials that ensures proper dispersion of the excited electron on the conduction band (CB) of the material with the higher band edges to the CB of the other material.<sup>[8,9,13]</sup> Hence, for a type II heterojunction to act as a photocathode, the bands of the two materials need to remain properly aligned *during the full discharge cycle of the battery*. In this study we investigate the changes in the electronic band structure of MoS<sub>2</sub> upon lithiation in a type II set-up with MoO<sub>3</sub> that has been recently demonstrated in a photochargeable Li ion battery.<sup>[8]</sup>

Bulk MoS<sub>2</sub> in 2H phase (with 2 layers of hexagonal lattice stacked in AB fashion) displays an indirect band gap of ~ 1.3 eV while the 1T' phase (monolayer of distorted octahedral phase) is found to be metallic.<sup>[14-16]</sup> The computed band structure of monolayer 1H-MoS<sub>2</sub> displays a direct band gap of ~ 1.65 eV while there is a small indirect band gap in 1T' monolayer.<sup>[14]</sup> The band gap of layered MoS<sub>2</sub> can be engineered by chemical doping<sup>[17]</sup> or employing external stimulus.<sup>[18]</sup> Previous studies indicate that upon lithiation, MoS<sub>2</sub> becomes metallic irrespective of the initial phase (Figure S1).<sup>[19,20]</sup> The metallization questions the photocharging mechanism, where exciton formation has to happen upon the absorption of light in the lithiated MoS<sub>2</sub> (Li<sub>x</sub>MoS<sub>2</sub>).<sup>[8]</sup>

In order to understand the electronic structure of the  $MoS_2$  (bilayer)<sup>[21]</sup>/MoO<sub>3</sub> (bulk) heterostructure, one needs to align the band edges between the two materials. The alignment requires computation of the valence band maxima (VBM) of the two materials relative to the vacuum in addition to their band gaps, which invariably involves calculation of band edges for a slab of finite number of layers. Incidentally, previous density functional theory (DFT)<sup>[22]</sup> calculations indicated that layered  $MoS_2/MoO_3$ combination forms a type III heterojunction if PBE functional<sup>[23]</sup> is employed.<sup>[24]</sup> In order to avoid this pitfall, we employed an artificial layering scheme (henceforth termed as 'uL') for  $MoO_3$  to obtain the desired type II band alignment (Figure 1a,b). Alternatively, one can employ the natural layering for  $MoO_3$  and still obtain a type-II alignment by computing the band gaps with a more accurate hybrid functional (HSEO6) while using PBE+U+D3<sup>[25,26]</sup> for all the other relevant quantities to estimate the valence band offset (VBO) (see SI for details).

In Figure 1(c,d), two different type-II band alignments between bulk MoO<sub>3</sub> and bilayer 2H-MoS<sub>2</sub> are shown, employing either the natural layering (and gap from HSE06) or the uL layering for MoO<sub>3</sub>.<sup>[27,28]</sup> The corresponding alignments for Li<sub>x</sub>MoS<sub>2</sub> with varying x, along with an estimate of the number of electrons that is present in the CB of Li<sub>x</sub>MoS<sub>2</sub>, are shown in Figure 2. As can be seen, the number of electrons is equal to the number of Li-ions that are added to the system. These electrons in the CB of Li<sub>x</sub>MoS<sub>2</sub> make this system metallic albeit the presence of an underlying band gap. In addition, it is clear from the graph(s) (Figure 2) that this underlying band gap decreases with increase in the lithium ion concentration due to dramatic stabilization of the conduction band minimum (CBM) while the changes in the VBM is comparatively smaller. Ultimately, the type II character is lost and hence, there cannot be any efficient photo-excitation beyond that point (x = 0.33, Figure 2a; x = 0.25, Figure 2b). In order to understand the origin of the lowering of the CBM, we have plotted the corresponding projected density of states (PDOS, Figure S3) where the total DOS is projected separately onto the two MoS<sub>2</sub> layers. The upper MoS<sub>2</sub> layer, where the Li ions are being added, shows a steady metallization whereas the band edges of the lower layer do not change appreciably. These plots indicate that the reduction in the underlying band gap is caused by the presence of Li induced gap states near the CB edges.

We hypothesize that for lithium ion composition less than 0.25 (Figure 2b), the electron density in the CB of Li<sub>x</sub>MoS<sub>2</sub> will be transferred to the CB of MoO<sub>3</sub>, thus exposing the underlying band gap and hence, the system can be amenable to photo-excitation. In order to investigate the electron distribution in lithiated MoS<sub>2</sub> in conjunction with MoO<sub>3</sub>, we set-up an explicit heterostructure composed of MoS<sub>2</sub> and MoO<sub>3</sub> (SI, Figure S4). Here we show that the type II alignment can be achieved in the explicit heterostructure with the uL scheme for MoO<sub>3</sub> as opposed to chemical modifications <sup>[24]</sup> of the natural layering. Note that this artificial scheme is employed only to understand the electron density distribution in a type II setting. The structure of the supercell and the corresponding PDOS are shown in Figure 3. The corresponding structure and PDOS of a representative lithiated MoS<sub>2</sub> system (Li<sub>2</sub>Mo<sub>40</sub>S<sub>80</sub>) in conjunction with MoO<sub>3</sub> (Mo<sub>48</sub>O<sub>144</sub> in the supercell) are provided in Figure S5. Integration of the DOS shows that two electrons are present in the combined conduction band of the heterostructure. Resolving the DOS onto PDOS and integrating it reveals that 1.12 electrons are transferred from the CB of lithiated MoS<sub>2</sub> to the CB of MoO<sub>3</sub>.

While monolayer 1H-MoS<sub>2</sub> is more stable than 1T'-MoS<sub>2</sub>,<sup>[14,20]</sup> the stability order switches upon Li-ion intercalation beyond a certain Li ion concentration as shown in Figure S6.<sup>[14]</sup> We wanted to investigate whether the transition point changes in a type-II set-up. This aspect is very important because if the structure transitions to the metallic phase at a very low concentration of lithium then the whole argument regarding lithium induced band gap modulation of the H-phase becomes inconsequential towards the photo-cathode behavior. Moreover, previous studies have shown that the phase stability can change depending on the number of electrons present in the system.<sup>[14]</sup> Computing the energy of the two phases in an explicit heterojunction set-up, however, is not practically feasible since there is a significant lattice parameter mismatch between the 1T'-MoS<sub>2</sub> and MoO<sub>3</sub> structures.

In order to mimic the effect of the  $MoO_3$  layers, we introduced a hypothetical layer of electronegative fluorine atoms on top of the lithiated  $MoS_2$  surface (Figure S7) to extract electron density from the CB of lithiated  $MoS_2$  in either phase without affecting the band edges (Figure S8). The amount of charge extracted by the fluorine sheet, obtained by integrating the differential PDOS, varies from 0.92e to 1.64e as the number of Li-ions is increased from 1 to 6 in a simulation cell with 12 units of  $MoS_2$  (Table S1). The corresponding PDOS plots are shown in Figure S9. Using this set-up, we can compute the effect of the charge density extraction on the phase transition between the 2H- and the 1T'- phases upon lithiation. As shown in Figure 4, the transition point is shifted towards higher lithium composition.

In order to experimentally investigate the effects of lithiation in the metallization and phase transition of monolayer (1H) MoS<sub>2</sub>, we have systematically studied lithiation/delithiation using *in situ* Raman spectroscopy [details in the supporting information]. As shown in Figure 5a, pristine MoS<sub>2</sub> exhibits two prominent peaks at ~383 cm<sup>-1</sup> and ~402 cm<sup>-1</sup>, which correspond to the E<sup>1</sup><sub>2g</sub> and A<sub>1g</sub> vibration modes of monolayer 1H-MoS<sub>2</sub>, respectively.<sup>[29]</sup> On the other hand, the metallic 1T' phase is characterized by J1 and J2 modes centered at ~154 cm<sup>-1</sup> and ~225 cm<sup>-1</sup>. <sup>[30,31]</sup> The evolution of the vibrational modes of the 1H phase at different stages of charging is shown in Figure 5b. We performed UV-VIS absorption for pristine MoS<sub>2</sub> and Li<sub>x</sub>MoS<sub>2</sub> (discharged till 1V). As shown in Figure S11, pristine MoS<sub>2</sub> shows absorption peaks at 660 nm, 610 nm, and 434 nm corresponding to A, B, and C exciton of 1H MoS<sub>2</sub>,<sup>[32]</sup> whereas Li<sub>x</sub>MoS<sub>2</sub> does not show any absorption peak but higher absorption in the entire spectral range, indicating metallization upon lithiation. To understand the metallization of the 1H-phase upon lithiation, we performed *in situ* photoluminescence (PL) studies (Figure 6). The drastic decrease in intensity upon lowering the discharge voltage indicates decrease in efficiency of charge transfer from MoS<sub>2</sub> (lithiated) to MoO<sub>3</sub> and the shift in frequency to longer wavelengths imply decreasing band gap. Subsequent disappearance of photoluminescence below 2.95 V (during discharge) suggests disappearance of the type II character and phase transition to the 1T'-phase, which is also corroborated by the appearance of J1 and J2 peaks at that voltage in the Raman spectra. Additional graphs at different stages of charging / discharging are provided in the SI.

In this communication, we have explored the changes in the electronic band structure of  $MoS_2$  upon lithiation in a type II heterojunction set-up with  $MoO_3$ . Our results suggest that (1) the type II arrangement exposes the underlying band gap of the otherwise metallic Li<sub>x</sub> $MoS_2$  and (2) the band gap of 2H/1H-phase of Li<sub>x</sub> $MoS_2$  reduces upon increasing x and eventually the type II band alignment is lost (~ x > 0.25). The loss of the type II character would suppress the photo-cathode behavior since the photoexcited electron-hole pair cannot be separated efficiently anymore. Computationally, the transition from the 2H/1H phase to the 1T' phase is found to occur after the loss of the type II character. We believe that the dual role of the type II set-up (exposure of the underlying band gap and efficient formation of charge separated excitons upon photoexcitation) is a general phenomenon. On the other hand, the current study suggests that one should also consider the band structure modulation upon Li-ion intercalation as an important gauge for an ideal photocathode material.

Figures

Figure 1: Unit cell for (a) conventional layering and (b) uL scheme. Band alignment between bilayer  $2H-MoS_2$  and bulk  $MoO_3$  where VBO is computed with PBE+U whereas the band gap is computed either with HSE06 for the conventional layering of  $MoO_3$  (c) or with PBE+U for the uL scheme of  $MoO_3$  (d).

Figure 2. Band edges of  $Li_xMOS_2$  for different values of x with the computational schemes shown in figures 1c and 1d, respectively. The type-II character is lost for x > 0.33 and x > 0.25 in the two cases respectively.

Figure 3. Left: Supercell for 2H-MoS<sub>2</sub>/MoO<sub>3</sub> (uL) heterostructure Right: Corresponding PDOS resolved into Mo (MoS<sub>2</sub>, black), Mo (MoO<sub>3</sub>, blue), S (yellow), O (red) density of states.

Figure 4. Phase transition with or without the hypothetical F6 sheet.

Figure 5. The *in situ* Raman spectra of monolayer based electrodes during Lithiation/delithiation (with Lithium metal as the other electrode) at different voltage vs Li/Li\*. (a) Initial (pristine) MoS<sub>2</sub> monolayer (Open circuit voltage: 2.8V), 1st discharge (dchg, 0.01 mAcm<sup>-2</sup>) at 2.2V and after over charging (chg) till 3.4V. (b) The spectra taken during the electrochemical charging at different charging potentials.

Figure 6: The *in situ* photoluminescence (PL) of  $MoS_2$  monolayer based electrodes at different discharging voltages vs Li/Li<sup>+</sup>: (a) during discharging from charged state at 3.45 V till 2.35 V (inset PL curve shows discharge state from 2.85V to 2.35V). (b) During charging from discharged state 1.90 V to 3.45V.

#### **Computational Details:**

Our calculations employed density functional theory (DFT) in conjuncion with PBE functional<sup>1</sup> as implemented in Vienna ab-initio simulation package (VASP)<sup>2</sup> with a plane wave basis set within the projector augmented plane-wave method (PAW)<sup>3</sup>. For all the MoS<sub>2</sub> calculations a kinetic energy cutoff for plane-waves was set to be 360 eV, while a cutoff of 500 eV was used for MoO<sub>3</sub> and MoO<sub>3</sub>/MoS<sub>2</sub> heterostructure calculations. The energy and force convergence criteria were set to be  $10^{-4}$  eV and 0.02 eV Å<sup>-1</sup> respectively. We employed a gamma centered Monkhorst scheme of grid density 0.025 in each direction for all the calculations. We have used a Hubbard U parameter of 5.0 eV for both MoS<sub>2</sub> and MoO<sub>3</sub>.<sup>4,5</sup> For all multi layered systems DFT+U was combined with the disperson correction (D3) by Grimme et.al<sup>6</sup> to account for long range interactions. We relaxed the bulk and multi-layered geometry using PBE+U+D3 for MoS<sub>2</sub>. Additionaly HSE06 functional was used to compute the band gaps for a few systems as specified in the manuscript.

Figure S1: (a) Band structure of monolayer of 1H-MoS<sub>2</sub> computed with a periodic hexagonal cell with the lateral dimensions of 12.648 Å (16 Mo and 32 S atoms) employing PBE+U functional (b) Computed band structure of monolayer of 1H-Li<sub>0.1875</sub>MoS<sub>2</sub>

Figure S2. (a) Band gap is computed with HSE06 while the valence band offset computed with PBE+U within the uL scheme for  $MoO_3$ . (b) Change in band edges of lithiated  $MoS_2$  as a function of Li-ion concentration. The type II alignment is lost for Li-ion concentration (x) less than 0.083

Figure S3. PDOS of lithiated  $MoS_2$  for different concentration of Li-ion. The upper  $MoS_2$  layer ( $MoS_2(u)$ ) where the Li ions are added shows gradual metallization whereas the band edges of the bottom layer remains more or less unaffected. The analysis has been done with the PBE+U+D3 results.

# MoS<sub>2</sub>/MoO<sub>3</sub> Band-offset

We used planar averaged Hartree potential to compute the offset between MoO<sub>3</sub> and MoS<sub>2</sub>. The valence band maxima (VBM) of bi-layer MoS<sub>2</sub>(2L) is computed with HSE06 functional relative to its macroscopic average, which in turn is referenced to the vacuum level in a slab calculation. For bulk MoO<sub>3</sub> calculations (with HSE06), the VBM is referenced to the vacuum level using the following protocol. We first computed the electronic structure of multi-layered slabs of MoO<sub>3</sub> [010] in conjunction with vacuum in addition to the bulk MoO<sub>3</sub>. The lateral dimensions of the slab and the bulk simulation cells are kept the same while the geometry was relaxed in both cases. Central layers in the slab are supposed to represent the bulk and using the macroscopic average of this region one can reference the VBM of the bulk to the vacuum.<sup>7-8</sup> We can then compute the valence band offset (VBO) between the two materials. The simplified formula for the above method is given below

$$VBO = \overline{VBM}_{2MoS_2} + \overline{V}_{2MoS_2-vac} - (VBM_{MoO_3} - \overline{V}_{MoO_3} + \overline{V}_{MoO_3} - \overline{V}_{vac})$$
  
=  $\overline{VBM}_{2MoS_2} + \overline{V}_{2MoS_2-vac} - (\overline{VBM}_{MoO_3} + \overline{V}_{MoO_3-vac})$   
 $\overline{V}_x$  = macroscopic average;  
 $\overline{V}_{x-vac}$  = macroscopic average of the bulk referenced to the vacuum;  
 $\overline{VBM}_x$  = VBM with respect to the macroscopic average

The conduction band offset is simply obtained by adding the band-gap to the VBM. However, PBE is known to underestimate the band gap, and therefore the experimental/HSE06 band gap can be combined with the above VBO for band alignment.<sup>8,9</sup>

Figure S8. Left :PDOS of  $Li_{0.083}MoS_2 + F6$  sheet; Right: PDOS of  $Li_{0.083}MoS_2$ 

System	Charge Extracted by F-sheet
Li1M012S24/F6	0.920 e
$Li_2Mo_{12}S_{24}/F_6$	0.635 e
Li <sub>3</sub> Mo <sub>12</sub> S <sub>24</sub> /F <sub>6</sub>	1.601 e
Li4M012S24/F6	1.400 e
Li5M012S24/F6	1.321 e
Li <sub>6</sub> Mo <sub>12</sub> S <sub>24</sub> /F <sub>6</sub>	1.641 e

Table S1. Number of electrons extracted by the F6 sheet for different Li-ion concentrations

Integration of PDOS upto fermi level does not add up to total electrons in the system. To accurately compute the electron occupation number integration of total DOS has to be used. Incidentally, the PDOS of F and  $Li_1Mo_{12}S_{24}$  (upto the Fermi level) do not overlap in  $Li_1Mo_{12}S_{24}/F_6$  heterojunction. Therefore, the PDOS can be used to determine the integration limits and total DOS can be used to compute the electron occupations in flourine and  $Li_1Mo_{12}S_{24}$ . To compute electron occupations in  $Li_xMo_{12}S_{24}/F_6$  for x > 1, we compute the integral of PDOS for F upto fermi level for these systems. This integral is then compared with PDOS integral for F in  $Li_1Mo_{12}S_{24}/F_6$ , the difference is used to determine the charge extracted by flourine.

# **Experimental Methods:**

The growth procedure for  $MoS_2$  monolayer synthesis involved the use of chemical vapor deposition (CVD) method. A two-zone furnace was employed for the growth, following a method previously discussed. Only  $MoO_3$  and sulfur were used as precursors, and a small amount of NaCl was added to aid metal decomposition at lower temperatures. The process involved keeping sulfur at 210°C in Zone I and placing  $MoO_3$  at 710°C in Zone II, as indicated in the schematic diagram. The experiment was conducted in the presence of 190 sccm  $N_2$ , which acted as the carrier gas. Upon completion of the growth, the furnace was rapidly cooled to room temperature to prevent further multilayer growth.

### **Characterization:**

The Renishaw Invia Raman spectroscopy was used to obtain in-situ and ex-situ Raman spectra and photoluminescence (PL) spectra. The analysis was conducted using a 532 nm exciton laser with a 20x objective. The laser power was optimized to prevent overheating and improve the noise to signal ratio of the data.

## **Electrochemical measurements:**

Electrochemical measurements in this study were carried out using a single-channel Bio-logic potentiostat (SP-200). The electrochemical discharge measurements during the lithiation of monolayer MoS<sub>2</sub> were performed using a two-electrode battery setup consisting of an ITO-coated quartz electrode (25 mm  $\times$  25 mm) as the working electrode, lithium metal as the other electrode, and LiPF<sub>6</sub> in EC/EMC as the electrolyte. Prior to transferring the MoS<sub>2</sub> onto the ITO-coated quartz electrode, the electrode was thoroughly cleaned by washing it with soap and then with DI water and iso-propanol several times. The MoS<sub>2</sub> was first spin-coated moS<sub>2</sub> was then transferred to water to remove KOH and subsequently transferred to the ITO-coated quartz electrode. The electrode was further cleaned with acetone after drying

Figure S10. Schematic diagram of the  $MoS_2$  growth by the CVD method. Sulfur is placed in Zone I whereas a mixture of  $MoO_3$  and NaCl in Zone II. The  $MoS_2$  on Si/SiO<sub>2</sub> is clearly seen in the optical image where the lateral size of the crystal is around 100-200  $\mu$ m.
