Abstract

The organic spacer cation plays a crucial role in determining the exciton fine structure in two-dimensional (2D) perovskites. Here, we use low-temperature magneto-optical spectroscopy to gain insight into the influence of the organic spacer on dark excitons in Ruddlesden–Popper (RP) perovskites. We show that by using modest magnetic field strengths (<1.5 T), the spin-forbidden dark-exciton state can be identified and its emission properties significantly modulated through the application of in-plane magnetic fields, up to temperatures of 15 K. At low temperatures, an increase in collected photoluminescence efficiency of $>30\%$ is demonstrated, signifying the critical role of the dark exciton state for light-emitting applications of 2D perovskites. The exciton fine structure and the degree of magnetic-field-induced mixing are significantly impacted by the choice of organic spacer cation, with 4-methoxyphenylethylammonium

(MeO-PEA) showing the largest effect due to larger bright–dark exciton splitting. Our results suggest that dark excitons preferentially form biexcitons depending on the choice of spacer. We distinguish between interior (bulk) and surface dark-exciton emission, showing that bright–dark exciton splitting differs between the interior and surface. Our results emphasise the significance of the organic spacer cation in controlling the exciton fine structure in 2D perovskites and have important implications for the development of optoelectronic technology based on 2D perovskites.

Introduction

Two-dimensional (2D) perovskites have attracted significant attention in recent years due to their unique optoelectronic and structural properties. These materials consist of inorganic perovskite layers separated by organic cations which provide criteria that violate the Goldschmidt tolerance factor, forming natural quantum wells of varying thicknesses.^{1–4} Unlike their three-dimensional (3D) counterparts, 2D perovskites exhibit strong excitonic effects due to quantum confinement and reduced dielectric screening caused by the mismatch in dielectric constant between the inorganic sheets and organic spacers.^{1–5}

2D perovskites have shown promise for optoelectronic applications, including solar cells,^{6–10} light-emitting diodes,^{11–15} and lasers.^{16–18} The incorporation of 2D perovskites has led to the demonstration of solar cells with enhanced stability,^{6–10} including solar cells with an operational lifetime exceeding one year.¹⁹ However, a comprehensive understanding of their electronic and optical properties is currently lacking, despite being crucial for further advancements in these technologies.

The increased quantum and dielectric confinement produced by the structure of 2D perovskites leads to a large exciton binding energy (E_B) in the range of 150–750 meV.^{3,4,20–24} These values of E_B are substantially greater than those of bulk 3D perovskites and even 3D-perovskite nanocrystals, resulting in the dominance of excitons as the photoexcited species at room temperature. They exhibit a rich exciton fine structure due to mechanisms such

as the electron–hole exchange interaction and crystal field splitting, which remove the degeneracy of the exciton states, allowing them to be discerned via methods such as optical spectroscopy.^{25–28}

Ruddlesden–Popper (RP) phase 2D perovskites have the general formula $A_{n+1}B_nX_{3n+1}$, where A is often an organic cation, B is a transition metal and X is a halide anion. The most commonly studied composition is phenylethylammonium (phenethylammonium, PEA) lead iodide ((PEA)₂PbI₄), characterised by single layers (n=1) of lead iodide octahedra separated by interlayers comprised of the bulky PEA cation. The choice of organic cation spacer has been demonstrated to affect dielectric environment, distortion angles of perovskite octahedral units, bandgap energy, effective mass of carriers, and exciton–phonon coupling.^{29–31} Recently, functionalisation of the PEA cation has been investigated, where for example, a methoxy group is used to produce 4-methoxyphenylethylammonium (MeO-PEA). MeO-PEA cations have been utilised as an additive for 3D-perovskite based solar cells to improve passivation^{32,33} and also in quasi-2D perovskite solar cells for improved ambient stability.³⁴

Several studies have utilised magneto-optical spectroscopy to gain insight into the nature of the exciton fine structure of 2D perovskites, often using large magnetic fields (> 50 T) to selectively manipulate exciton states according to their dipole orientation, hence modifying their optical characteristics.^{25–27,35–40} Here, we show that applying a comparatively modest in-plane magnetic field (< 1.5 T) significantly increases the photoluminescence intensity of 2D perovskite thin films in the family of $A_2\text{PbI}_4$ at low temperatures (Figure 1), where the choice of cation, A , has a substantial impact on this effect. We use these observations to gain insight into the exciton fine structure of 2D perovskites, revealing the role and behaviour of bright exciton, dark exciton and biexciton energy states in relation to the spacer cation used.

Figure 1: **Mechanism of magnetic-field-induced photoluminescence brightening at low temperature.** Following non-resonant photoexcitation, the dark exciton state, which also can form biexcitons, is preferentially populated at low temperatures. When an in-plane magnetic field is applied, oscillator strength is transferred from bright exciton states to the more highly populated dark state (represented by the line thickness) and the overall radiative emission intensity is increased.

Results and discussion

We firstly produced the following RP phase perovskites: $(\text{PEA})_2\text{PbI}_4$, $(\text{MeO-PEA})_2\text{PbI}_4$, $(\text{BA})_2\text{PbI}_4$, and $(\text{OA})_2\text{PbI}_4$, where PEA is phenylethylammonium, MeO-PEA is PEA with a methoxy functional group (4-methoxyphenylethylammonium), BA is *n*-butylammonium, and OA is *n*-octylammonium. Films with a thickness of $\sim 350\text{--}400$ nm were obtained by spin coating the precursor solutions onto quartz substrates using the procedure described in the experimental section. Characterisation results of the 2D perovskite thin films are shown in Figure 2. We performed X-ray diffraction (XRD) on the samples (Figure 2A–D), with results showing typical patterns for the 2D ($n=1$) RP phase perovskite structure shown in Figure 2E. UV-visible absorption spectroscopy (room temperature) shows that the samples have a sharp optical transition around 2.4 eV, indicative of materials with a large exciton binding energy (Figure 2F).

To investigate the nature of the exciton fine structure in 2D perovskite thin films we first carried out measurements of steady-state photoluminescence in the temperature range of 2.4–300 K, as shown in Figure 3. At room temperature, all samples exhibit a broad emission with a linewidth (full-width at half maximum) of ~ 1 eV, with a slightly different peak emission energy for each spacer cation. Upon cooling the sample from room temperature, the emission for all compositions undergoes a slight redshift, however, the most notable feature is an abrupt shift of the emission energy at ~ 245 K in $(\text{BA})_2\text{PbI}_4$ and at $\sim 210\text{--}215$ K in $(\text{OA})_2\text{PbI}_4$. In general, such features are often observed at temperatures where structural phase changes occur,^{41,42} and in the 2D RP phase perovskites studied, this has been attributed to a change in relative alignment of PbI_4 octahedra, caused by ordering of weakly interacting alkylammonium chains.^{3,43–46} This is not observed in $(\text{PEA})_2\text{PbI}_4$ or $(\text{MeO-PEA})_2\text{PbI}_4$, due to the phenylethylammonium chains being shorter and less flexible than *n*-butylammonium and *n*-octylammonium.^{3,44}

On further decreasing temperature below ~ 200 K, the $(\text{BA})_2\text{PbI}_4$ and $(\text{OA})_2\text{PbI}_4$ samples exhibit an emission band between 2.38–2.42 eV, which undergoes a slight redshift as the

(E) Inverse integrated intensity ($1/I(T)$) of the biexciton emission versus inverse temperature ($1/T$) for (PEA)₂PbI₄, fitted with equation 1. The biexciton binding energy is estimated from the activation energy for dissociation. F) Bright-dark exciton splitting, Δ_{B-D} as a function of temperature, comparing (PEA)₂PbI₄ and (BA)₂PbI₄.

temperature is decreased. In the $(\text{BA})_2\text{PbI}_4$ thin film, this emission is narrower and persists down to low temperatures, whereas in $(\text{OA})_2\text{PbI}_4$ the emission is undetectable below ~ 40 K. In $(\text{OA})_2\text{PbI}_4$, it is likely that the origin of this emission is due to a persistence of the higher-temperature phase with distorted PbI_4 octahedra, since the lineshape is consistent at temperatures above and below the transition temperature of the phase change. On cooling further, the spectrum eventually fully transitions to that of the low temperature phase.

For the low-energy emission in $(\text{BA})_2\text{PbI}_4$, similar features have been observed previously and were attributed to emission from the interior, in contrast to the surface emission which was assigned to the high energy peak.^{47,48} Several other studies report origins such as magnetic dipole emission from self-trapped excitons,⁴⁹ the effect of strain induced by cation stacking,⁵⁰ and interactions of the lead iodide interlayers.⁵¹ Regardless of the physical mechanism responsible, it is clear from the previous literature that the emission source can be separated into interior and surface emission.^{47,48}

For $(\text{PEA})_2\text{PbI}_4$ at low temperatures, three optical transitions can be easily distinguished, which themselves are known to be multi-component (Figure S2).^{25–28} Four primary exciton states have previously been identified: a 'dark' exciton state in the singlet spin configuration with zero angular momentum ($J = 0$) and three optically active ('bright') states with $J = 1$, which in general are split by exchange interaction. In 2D perovskites, these bright states are typically split into states with in-plane and out-of-plane dipole moments due to their alternating layered structure having a broken symmetry perpendicular to the axis of the stacking.^{25,26,52,53}

To avoid potential error from fitting a non-unique set of transitions, we separate the observed emission into three main components: we attribute the highest energy peak to emission from the bright exciton transitions (BX), the intermediate energy peak to the spin-forbidden dark exciton transition (DX), and the lowest energy peak to a biexciton transition (XX) (Figure S2).^{25–27,54–56} We fitted the sum of three Gaussian functions (see supporting information) to the data obtained for each composition and found that these fit the data

well over the temperature range 4–200 K, with additional transitions present in (BA)₂PbI₄ and (OA)₂PbI₄ as discussed in more detail below (Figures S2–S4). For (MeO–PEA)₂PbI₄, the addition of a low-energy tail overlapping with the XX transition (Figures 3B and S5) means that the spectrum does not fit well with three, or even four Gaussian transitions due to the asymmetry introduced. This suggests that (MeO–PEA)₂PbI₄ has additional disorder or a defect state which is not present in (PEA)₂PbI₄, but may share the same origin of the lower energy shoulder in the BA and OA compositions (Figures S3 and S4).

A biexciton is the simplest type of multiexciton state, formed from two excitons and typically observed at higher excitation intensities. These states have an energy which is lower than the single-exciton state, separated by the biexciton binding energy. Relaxation to the singly excited state can occur through the photon emission (radiative) or via non-radiative Auger processes. The presence of photoexcited biexcitons in 2D RP phase perovskites has been the subject of debate^{39,54–56} but despite this, evidence has been produced that suggests biexcitons in (PEA)₂PbI₄ persist at room temperature,⁵⁴ and the biexciton binding energy has been previously determined to be 39–49 meV.^{54–56} By extracting and fitting the temperature-dependent intensity of the biexciton emission, we can estimate the biexciton binding energy as an ‘activation energy’ for dissociation by using the following exponential equation^{24,57,58} (see supporting information for details),

$$1/I(T) = A + B e^{\frac{-E_B}{T k_B}}, \quad (1)$$

where A is the inverse of the photoluminescence intensity at 0 K, $(1/I(0))$, and B is the ratio of the biexciton dissociation rate to the emission rate, k_{dis}/k_r .

We applied this fitting process to the data in the temperature range of 30–200 K for (PEA)₂PbI₄, where the intensity decreases monotonically and smoothly (Figure S1–S3). The result of this fitting is shown in Figure 3E, and a value of 36.47 ± 2.18 meV is obtained for E_B , which is slightly lower than the range of 39–49 meV determined in prior work.^{54,55} We note that this method has several limitations: for example, it does not account for a binding

energy which varies with temperature (ignoring possible phase changes) and assumes that the phonon-assisted dissociation is the dominant mechanism competing with emission when increasing temperature. A very similar value of activation energy (36.7 meV) was previously determined in $(\text{PEA})_2\text{SnI}_4$ and attributed to the activation energy for thermal re-excitation from lower energy states, proposed to originate from bound excitons or shallow defects.³⁹ This prior work could therefore indicate a similar biexciton binding energy in $(\text{PEA})_2\text{SnI}_4$, but we do not completely rule out the possibility of the XX-assigned transition being due to emission from such singly-excited states.

To provide further insight into the photophysics of the exciton states discussed, we performed photoluminescence measurements at low temperatures with a magnetic field applied parallel to the plane of the substrate and interlayers, perpendicular to the direction of the excitation beam (Voigt configuration), as described in the experimental section.

Figure 4 shows the photoluminescence spectrum as a function of magnetic field at a temperature of 2.4 K for the different spacer cations used. At this temperature, the total integrated intensity increases monotonically with increasing magnetic field for all compositions. This can be almost directly translated to an increase in photoluminescence quantum yield (PLQY) within the collection scheme used, since the change in absorption under applied fields of < 1.5 T has been previously found to be negligible.²⁵

This effect is much more pronounced in PEA and MeO-PEA, with $> 30\%$ enhancement of integrated total photoluminescence intensity (Figures 4A, B, E and F). PEA-based 2D perovskites have been the most successfully utilised compositions for optoelectronic devices such as solar cells and LEDs,^{7-9,15} which alludes to a potential link between observed dark-exciton brightening and performance of materials. For the other cations, BA (Figure 4C and G) and OA (Figure 4D and H), the detectable total photoluminescence enhancement is limited to a very narrow region of the emission and overall is very small ($< 1\%$). Nonetheless, the modulation of the photoluminescence is significant enough to be identified using the simple detection method used (see experimental section) and can be spectrally resolved,

offering important insights into the origin of the emission.

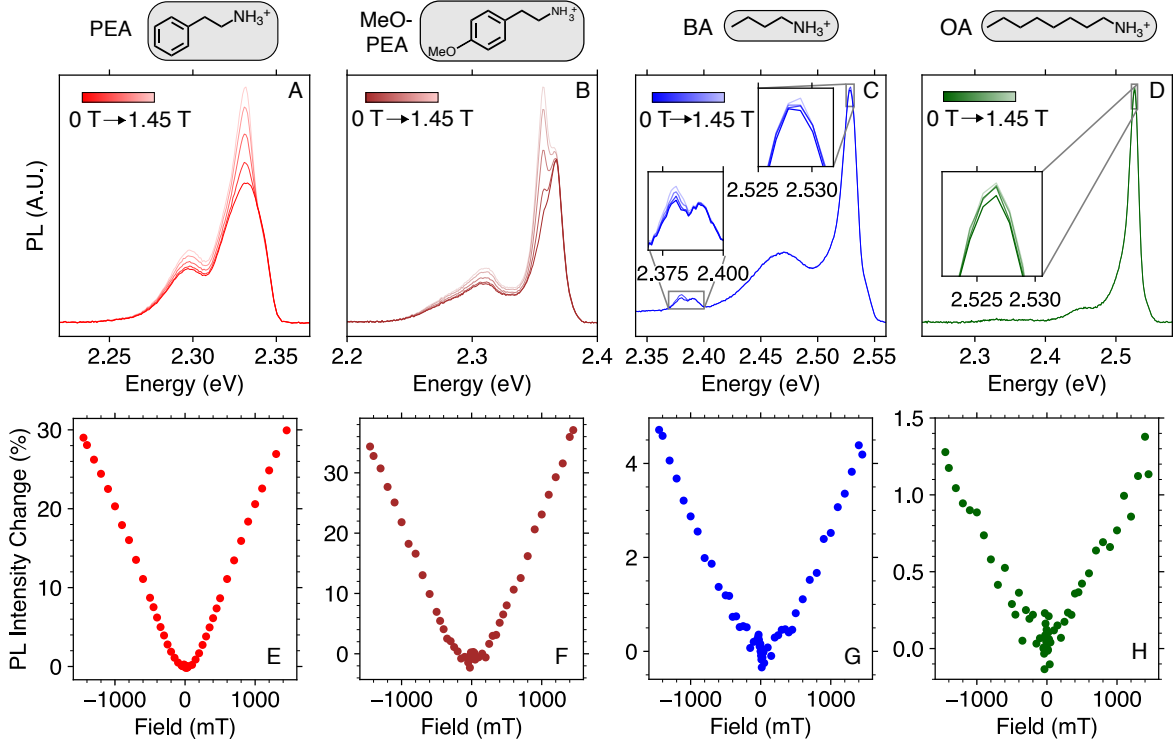

Figure 4: **Photoluminescence of 2D perovskite thin films at 2.4 K in the presence of an in-plane magnetic field.** Low temperature, magnetic-field dependent photoluminescence spectra for (A) $(\text{PEA})_2\text{PbI}_4$, (B) $(\text{MeO-PEA})_2\text{PbI}_4$, (C) $(\text{BA})_2\text{PbI}_4$, (D) $(\text{OA})_2\text{PbI}_4$. The corresponding change in photoluminescence intensity across regions where change is detected for (E) $(\text{PEA})_2\text{PbI}_4$ (2.27–2.35 eV), (F) $(\text{MeO-PEA})_2\text{PbI}_4$ (2.27–2.4 eV) (G), $(\text{BA})_2\text{PbI}_4$ (2.37–2.40 eV and 2.50–2.53), and (H) $(\text{OA})_2\text{PbI}_4$ (2.50–2.53 eV).

Dyksik *et al.* describe the magnetic field effects observed in 2D RP perovskites as mixing of dark and bright states caused by the in-plane magnetic field breaking the crystal field symmetry, which results in a transfer of oscillator strength and population.²⁵ At low temperatures, the lower-energy dark exciton state has a higher probability of occupation than the bright exciton states following non-resonant photoexcitation and subsequent thermal relaxation. Therefore, a transfer of oscillator strength to the dark exciton state would increase the total photoluminescence quantum yield if the population difference is large enough, despite the dark-exciton radiative emission being spin-forbidden. This should result in a decrease of magnetic-field-induced photoluminescence brightening with increasing

temperature, which explains why the magnetic field effect was not detectable above 2.4 K in $(\text{BA})_2\text{PbI}_4$ and $(\text{OA})_2\text{PbI}_4$, and the total enhancement decreases with temperature up to 15 K in $(\text{PEA})_2\text{PbI}_4$ and $(\text{MeO-PEA})_2\text{PbI}_4$, beyond which the effect was found to diminish (Figures S7 and S8). At higher temperatures, the reduction in oscillator strength of the bright exciton out-competes the dark-exciton brightening at low fields due to the smaller difference in population at these temperatures. Hence, the integrated photoluminescence is actually reduced between 0–0.5 T at temperatures 10 and 15 K, beyond which it starts to increase again to $> +10\%$ at 1.45 T (Figure S9).

An increase in photoluminescence in $(\text{BA})_2\text{PbI}_4$ and $(\text{OA})_2\text{PbI}_4$ is observed in the region of the highest intensity peak, attributed to bright-exciton emission (Figures 4C and D). This increase is likely indicative of lower bright–dark exciton splitting in these compositions (Figure 3F), rendering these states too close in energy to distinguish in terms of magnetic-field brightening. Fitting the low-temperature photoluminescence spectra to multiple contributions exemplifies this, with the main peak of the data fitting well to two transitions (bright and dark excitons) closer together in energy for $(\text{BA})_2\text{PbI}_4$ and $(\text{OA})_2\text{PbI}_4$ (Figure S3 and S4). From this analysis, the bright–dark splitting is estimated to be ~ 7 meV for $(\text{OA})_2\text{PbI}_4$ and $(\text{BA})_2\text{PbI}_4$, compared to ~ 12 – 14 meV for $(\text{PEA})_2\text{PbI}_4$ and $(\text{MeO-PEA})_2\text{PbI}_4$. This corroborates with a reduced magnetic-field effect in $(\text{OA})_2\text{PbI}_4$ and $(\text{BA})_2\text{PbI}_4$ compared to $(\text{PEA})_2\text{PbI}_4$, since the energy difference between the bright and dark exciton states is half the size, and hence the population difference is smaller.

Figure 5A illustrates this relationship between the observed dark-exciton brightening and the size of the bright–dark energy splitting. The difference in population is likely to depart significantly from one based purely on Boltzmann-like statistics, since non-thermalised (‘hot’) photoluminescence is known to occur in these materials, reducing the proportion of excitons that fully relax to the dark exciton state following non-resonant excitation.^{25,39}

The diamagnetic coefficient in 2D perovskites containing an aromatic spacer, such as PEA, is larger compared to layered perovskites of the same thickness containing an aliphatic

spacer. This is because the exciton wavefunction in layered perovskites with an aromatic spacer extends over a larger spatial area due to a smaller dielectric mismatch between the well and the barrier, compared to 2D perovskites with aliphatic spacers.^{4,35} This should result in a larger exchange interaction between the electron and hole, increasing the bright–dark exciton splitting in (PEA)₂PbI₄ and (MeO–PEA)₂PbI₄ compared with the other two compositions, in agreement with our observations.

In the temperature-dependent photoluminescence data, (Figure 3A–C and Figures S2–S3) the dark and bright exciton states seem to abruptly split further on increasing temperature beyond 20 K, with the apparent dark exciton state shifting to a lower energy, while the bright exciton emission energy is almost unchanged. This is accompanied by a concurrent increase in intensity of both the dark and biexciton states. We find that these results are repeatable and have been observed in previous studies, with the process responsible for the abrupt energy shift remaining unclear.³⁹ The correlated increase in intensity with energy shift can be again explained via Boltzmann statistics, where the reduction in energy of the dark exciton results in a larger population, promoting radiative emission. As the temperature is further increased, the relative intensity from the biexciton and dark exciton decreases, as expected when thermal energy is supplied to the system. Interestingly, the shift at 20 K coincides with the temperature above which no magnetic field effects can be observed, suggesting that the low-temperature regime plays a crucial role in the dark-exciton brightening.

The photoluminescence spectrum of (BA)₂PbI₄ at low temperatures exhibits two additional peaks at lower energy, which are not observed in the spectra of the other compositions (Figure 3C and 4C). As discussed above, it is possible that the emission is from the interior of crystal domains.^{47,48} In this case, the two lower energy peaks observed likely originate from dark and bright exciton states of the interior separated by ~ 10 meV, where the lower energy dark-exciton emission is brightened by the in-plane magnetic field. The bright–dark exciton splitting of the interior domains is larger than that of the surface, such that the brightening of the dark state can be distinguished, unlike the emission from the surface due

to its lower bright–dark exciton splitting.

As mentioned, above temperatures of 2.4 K, the photoluminescence change with magnetic field was undetectable in $(\text{BA})_2\text{PbI}_4$ and $(\text{OA})_2\text{PbI}_4$. In $(\text{PEA})_2\text{PbI}_4$ and $(\text{MeO-PEA})_2\text{PbI}_4$ however, the change in photoluminescence with magnetic field can be observed up to temperatures of 15 K (Figures S7 and S8). Figure 5 shows the magnetic-field-dependent photoluminescence for $(\text{PEA})_2\text{PbI}_4$ at 6 K. At this temperature we were able to resolve the transitions more clearly due to the larger bright–dark splitting compared with 2.4 K, which aids with our confidence in the multi-component fitting (supporting information). We show how the integrated intensity of each component changes as a function of magnetic field by again fitting the sum of three Gaussian functions to the photoluminescence spectrum (Figure 5B). At each temperature, we first fit the zero-field data as a reference to obtain initial parameters, then fix the widths of the Gaussian components before fitting the field-dependent data, setting the amplitude and position as free parameters. As the applied magnetic field increases, the dark-exciton and biexciton emission intensities increase, whereas the bright-exciton emission decreases (Figure 5C), in agreement with previous reports.^{25–27}

In CsPbI_3 nanocrystals, previous photon correlation measurements indicate that the dark-exciton ground state favours the creation of biexcitons at low temperatures.⁵⁹ If this is also the case for $(\text{PEA})_2\text{PbI}_4$, it would explain the correlation of the magnetic-field brightening observed for the dark exciton and biexciton transitions at 6 K (Figure 5C) and it is less likely that only dark excitons form bound states or are preferentially trapped by shallow defects. These factors, combined with the simultaneous increase in emission of the two transitions at ~ 20 K discussed above provides compelling evidence that biexcitons are formed from dark excitons in $(\text{PEA})_2\text{PbI}_4$ and $(\text{MeO-PEA})_2\text{PbI}_4$, as they are in CsPbI_3 nanocrystals.

At first glance, this interpretation appears to contradict the centre-energy positions of the emission peaks observed, since the difference in energy between the biexciton and dark exciton emission ranges from ~ 25 meV at 4 K, to ~ 18 meV at 120 K (Figure S2). However,

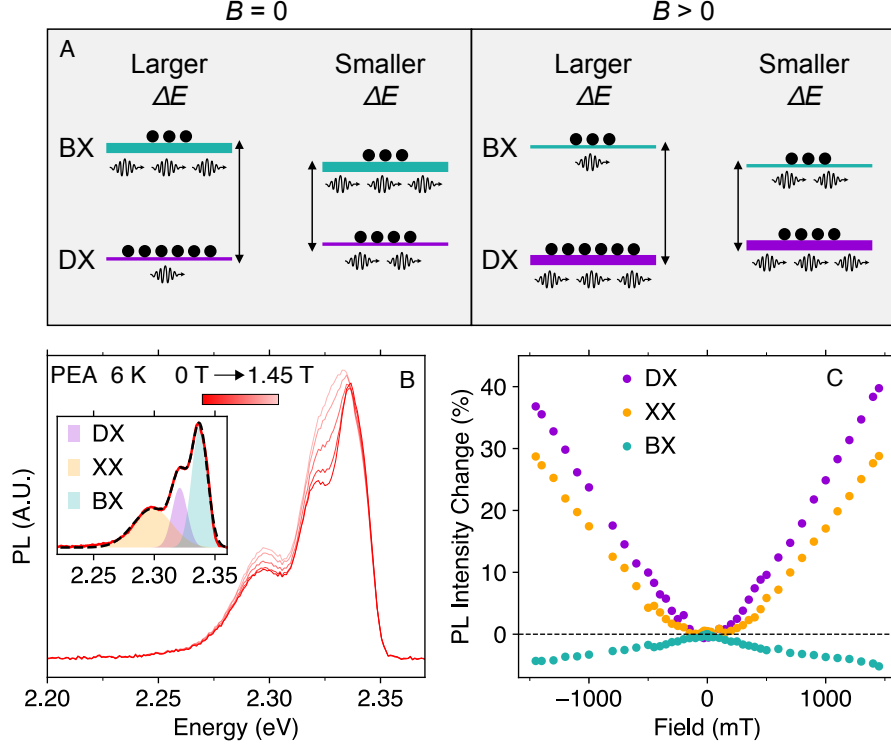

Figure 5: **Response of individual exciton transitions to an applied in-plane magnetic field.** (A) Schematic showing the effect of bright-dark exciton splitting on the magnetic-field-induced brightening. The width of the lines represent the oscillator strength of the transitions. For larger bright-dark exciton splitting, the population difference is larger and when the in-plane magnetic field is applied, a large difference in photoluminescence intensity is observed when oscillator strength is transferred. For a smaller splitting, the population difference is smaller and hence when the field is applied, the brightening is less pronounced. (B) Magnetic-field dependent photoluminescence spectra of (PEA)₂PbI₄ at 6 K. The inset shows the spectral decomposition by fitting multiple Gaussian functions. (C) Integrated intensity (amplitude) of Gaussian components versus magnetic field for the individual bright exciton (BX), dark exciton (DX), and biexciton (XX) transitions.

it is difficult to estimate the biexciton binding energy directly from the positions of emission peaks since the small Stokes shift and the overlap of different spectral contributions from the exciton fine structure cause the precise energetic position of the exciton emission to become contaminated by self-absorption effects, leading to a systematic underestimation of the binding energy (E_B). This explains why the difference in energy between the dark and biexciton emission peaks is significantly lower than the value of ~ 36.5 meV for the biexciton binding energy obtained from equation 1. Moreover, these considerations oppose the possibility of biexcitons forming from (or dissociating into) one of the bright exciton states, since the spectral energy difference between these is larger than 36.5 meV, instead ranging from ~ 40 -42 meV.

Conclusion

In conclusion, our study reveals the crucial role of organic spacer cations in determining the exciton fine structure in two-dimensional perovskites. By using modest magnetic fields, we have been able to identify and modulate the emission properties of the optically inactive dark exciton state, which is known to play a vital role in semiconductor light emission processes. The degree of magnetic-field-induced mixing and the characteristics of these states were found to be significantly influenced by the choice of spacer cation, with phenylethylammonium and 4-methoxyphenylethylammonium exhibiting the largest effect. Since PEA-based compositions have been the most successfully utilised materials for 2D perovskite optoelectronics in the field, our work highlights a potential correlation between observed dark-exciton brightening and material performance. We have found significant evidence that biexcitons are formed from dark excitons in $(\text{PEA})_2\text{PbI}_4$ and $(\text{MeO-PEA})_2\text{PbI}_4$ and mimic their magnetic-field-induced photoluminescence brightening. In $(\text{BA})_2\text{PbI}_4$, the surface and interior fine structure can be distinguished, with different bright-dark exciton splitting between the two emission sources. These findings provide valuable insights into the underlying mechanisms behind the exciton fine structure in 2D perovskites and highlight the importance of the organic spacer cation in controlling their optoelectronic properties. Our results are important for the design and development of next-generation, efficient light-emitting devices and other optoelectronic technologies based on 2D perovskites.

Experimental Section

Materials: Lead iodide (PbI_2 , 99.999%) was purchased from TCI. N,N-dimethylformamide (DMF, 99.99%) and dimethyl sulfoxide (DMSO, 99.50%) were purchased from Sigma-Aldrich. Phenethylammonium Iodide (PEAI) was purchased from Xi'an Polymer Light Technology Corporation. *n*-butylammonium iodide (*n*-BAI) and *n*-octylammonium Iodide (*n*-OAI) were purchased from Dysol (Australia).

2D Perovskite Thin-Film Fabrication: Quartz substrates were cleaned using sonication and rinsing in distilled water, acetone, and isopropanol. Following this, the substrates were treated by UV-Ozone for 15 mins. The optimised 1M (BA)₂PbI₄, (OA)₂PbI₄, and (PEA)₂PbI₄ 2D perovskite precursor solutions were prepared by dissolving the mixture of 2:1 (PEAI:PbI₂, *n*-BAI:PbI₂, and *n*-OAI:PbI₂) in DMF:DMSO=4:1 (v:v). The compact 2D perovskite layers were deposited on the substrates by spin-coating at 5000 rpm for 30 s, with an acceleration of 4000 rpm/s. Following this, the coated substrates were transferred onto a hotplate and annealed at 100 °C for 5 mins.

Photoluminescence Spectroscopy: The photoluminescence was measured using a 405 nm Thorlabs M405L2 mounted LED for the excitation beam. The excitation was reflected from a 400 nm dichroic mirror, and the collection is obtained through the same lens as the excitation. The collection is then passed through a 450 nm long-pass filter and into a Thorlabs CS200 fibre-coupled spectrometer. The temperature was controlled using a cryogen-free variable temperature cryostat (Cryogenic Ltd), with a model 350 temperature controller (Lakeshore). The magnetic field was applied in the Voigt configuration using an electromagnet as part of a E500 electron spin resonance system (Bruker).

UV-Vis Spectrophotometry: UV-visible absorbance of the thin films was measured using UV-2600 Shimadzu spectrophotometer with integrating sphere attachment ISR2600.

X-ray Diffraction: X-Ray diffraction patterns were measured by a PANalytical Xpert materials research diffractometer (MRD) with Cu K α radiation ($\lambda = 1.54056 \text{ \AA}$), using an accelerating voltage of 45 kV and a current of 40 mA.

Figure S9: **Total integrated photoluminescence versus applied magnetic field for $(\text{PEA})_2\text{PbI}_4$ at (A) 10 K and (B) 15 K.**

Fitting of photoluminescence spectra

The integrated intensity change is calculated by first fitting each measured spectra with the sum of multiple Gaussian functions, which are attributed to the bright, dark, and biexciton emission:

$$I(E) = \sum A_i e^{-\frac{(E-E_i)^2}{2\sigma_i^2}}, \quad (\text{S1})$$

where A_i is the amplitude, E_i is the peak centre energy, and σ_i is the standard deviation. i represents the individual exciton transitions such as bright exciton, dark exciton, and biexciton states. The amplitude of these individual Gaussian functions is used to calculate the percentage change in photoluminescence ($\frac{\Delta PL}{PL}$) as a function of an external magnetic field using the expression,

$$\frac{\Delta PL}{PL} = \frac{A(B) - A(0)}{A(0)} \times 100\%, \quad (\text{S2})$$

where $A(B)$ is the amplitude at a given magnetic field B , and $A(0)$ is the zero-field amplitude for a given exciton transition.

Determining the biexciton binding energy

The decay rate constant (k_{ex}) for excitons can be expressed as the sum of individual contributions, given by,

$$k_{ex} = k_r + k_{nr} + k_{dis} e^{\left(\frac{-E_B}{k_B T}\right)}, \quad (\text{S3})$$

where k_r and k_{nr} are the temperature-independent radiative and nonradiative decay rate constants, respectively, k_{dis} is the temperature-dependent dissociation constant, and k_B is the Boltzmann constant. E_B is the 'activation energy' for exciton dissociation, which is equivalent to the exciton binding energy. Given that the photoluminescence quantum yield

ϕ at a certain temperature T and 0K can be defined by k_r/k_{ex} and $k_r/k_r + k_{nr}$, respectively, the inverse of PL emission quantum yield, $1/\phi(T)$, as a function of temperature thus can be expressed as:

$$1/\phi(T) = 1/\phi(T = 0) + (k_{dis}/k_r)e^{\left(\frac{-E_B}{k_B T}\right)} \quad (S4)$$

The biexciton emission component of the PL is extracted from equation S3 and its temperature-dependent integrated intensity is determined. The biexciton binding energy E_B can be determined by fitting the following equation:

$$1/I(T) = A + Be^{\left(\frac{-E_B}{k_B T}\right)}, \quad (S5)$$

where A corresponds to the inverse PL intensity ($1/I_0$) at $T = 0K$, and B is equal to k_{dis}/k_r .

Table 1: Fitting parameters for exciton binding energy (E_B) of the biexciton emission in (PEA)₂PbI₄

Fitting parameters	Obtained values \pm standard error
E_B	40.18 ± 3.24 meV
A ($1/I_0$)	161 ± 52.86
B (k_{dis}/k_r)	27291 ± 5395
