Abstract

Strictly serializable datastores greatly simplify application development. However, existing techniques pay unnecessary costs for naturally consistent transactions, which arrive at servers in an order that is already strictly serializable. We exploit this natural arrival order by executing transactions with minimal costs while optimistically assuming they are naturally consistent, and then leverage a timestamp-based technique to efficiently verify if the execution is indeed consistent. In the process of this design, we identify a fundamental pitfall in relying on timestamps to provide strict serializability and name it the timestamp-inversion pitfall. We show that timestamp inversion has affected several existing systems.

We present Natural Concurrency Control (NCC), a new concurrency control technique that guarantees strict serializability and ensures minimal costs—i.e., one-round latency, lock-free, and non-blocking execution—in the common case by leveraging natural consistency. NCC is enabled by three components: non-blocking execution, decoupled response management, and timestamp-based consistency checking. NCC avoids the timestamp-inversion pitfall with response timing control and proposes two optimization techniques, asynchrony-aware timestamps and smart retry, to reduce false aborts. Moreover, NCC designs a specialized protocol for read-only transactions, which is the first to achieve optimal best-case performance while guaranteeing strict serializability without relying on synchronized clocks. Our evaluation shows NCC outperforms state-of-the-art strictly serializable solutions by an order of magnitude on many workloads.

1 Introduction

Strictly serializable datastores have been advocated by much recent work [12, 18, 19, 34, 54, 60, 70] because they provide the powerful abstraction of programming in a single-threaded, transactionally isolated environment, which greatly simplifies application development and prevents consistency anomalies [8]. However, only a few concurrency control techniques provide strict serializability and they are expensive.

Common techniques include distributed optimistic concurrency control (dOCC), distributed two-phase locking (d2PL), and transaction reordering (TR). They incur high overheads which manifest in extra rounds of messages, distributed lock management, blocking, and excessive aborts. The validation round in dOCC, required lock management in d2PL, blocking during the exchange of ordering information in TR, and aborts due to conflicts in dOCC and d2PL are examples of these four overheads, respectively. These costs are paid to enforce the two requirements of strict serializability: (1) ensuring there is a total order by avoiding interleaving transactions, and (2) ensuring the *real-time ordering* i.e., later-issued transactions take effect after previously-finished ones. However, we find these costs are unnecessary for many *datacenter workloads* where transactions are executed within a datacenter and then replicated within or across datacenters.

Many datacenter transactions do not interleave: e.g., many of them are dominated by reads [12], and the interleaving of reads returning the same value does not affect correctness. Many of them are short [25, 28, 41, 54, 66, 73], and short lifetimes reduce the likelihood of interleaving. Advances in datacenter networking also reduce variance in delivery times of concurrent requests [5, 14, 23], resulting in less interleaving.

In addition, many datacenter transactions arrive at servers in an order that trivially satisfies their real-time order requirement. That is, a transaction arrives at all participant servers after all previously committed transactions.

Because many transactions do not interleave and their arrival order satisfies the real-time order constraints, intuitively, simply executing their requests in the order servers receive them (i.e., treating them as if they were non-transactional simple operations) will naturally satisfy strict serializability. We call these transactions *naturally consistent*.

Ideally, naturally consistent transactions can be safely executed without any concurrency control, incurring zero costs. However, existing techniques pay unnecessary overheads. For instance, dOCC still requires extra rounds of messages for validation, d2PL still acquires locks, and TR still blocks transactions to exchange ordering information, even if validation always succeeds, locks are always available, and nothing needs to be reordered. Therefore, this paper strives to make naturally

*This technical report is an extended version of the paper under the same title that appeared in OSDI 2023 [42].

consistent transactions as cheap as possible.

In this paper, we present Natural Concurrency Control (NCC), a new concurrency control technique that guarantees strict serializability and ensures minimal costs—i.e., one-round latency, lock-free, and non-blocking execution—in the common case. NCC’s design insight is to execute naturally consistent transactions in the order they arrive, as if they were non-transactional operations, while guaranteeing correctness without interfering with transaction execution.

NCC is enabled by three components. *Non-blocking execution* ensures that servers execute transactions in a way that is similar to executing non-transactional operations. *Decoupled response management* separates the execution of requests from the sending of their responses, ensuring that only correct results are returned. *Timestamp-based consistency checking* uses timestamps to verify transactions’ results, without interfering with execution.

While designing the consistency-checking component, we identified a correctness pitfall in timestamp-based, strictly serializable techniques. Specifically, these techniques sometimes fail to guard against an execution order that is total but incorrectly inverts the real-time ordering between transactions, thus violating strict serializability. We call this the *timestamp-inversion* pitfall. Timestamp inversion is subtle because it can happen only if a transaction interleaves with a set of *non-conflicting* transactions that have real-time order relationships. The pitfall is fundamental as we find it affects multiple prior systems (TAPIR [73] and DrTM [68]), which, as a result, do not provide strict serializability as claimed.

NCC handles timestamp inversion through response timing control (RTC), an integral part of decoupled response management, without interfering with non-blocking execution or relying on synchronized clocks. NCC proposes two timestamp optimization techniques, asynchrony-aware timestamps and smart retry, to reduce false aborts. Moreover, NCC designs a specialized protocol for read-only transactions, which, to the best of our knowledge, is the first to achieve optimal performance [41] in the best case while ensuring strict serializability, without relying on synchronized clocks.

We compare NCC with common strictly serializable techniques: dOCC, d2PL, and TR, and two serializable protocols, TAPIR [73] and MVTO [57]. We use three workloads: Google-F1, Facebook-TAO, and TPC-C (§6). The Google-F1 and Facebook-TAO workloads synthesize production-like workloads for Google’s Spanner [12, 61] and Facebook’s TAO [10], respectively. Both workloads are read-dominated. TPC-C [65] consists of few-shot transactions that are write-intensive. We further explore the workload space by varying the write fractions in Google-F1. NCC significantly outperforms dOCC, d2PL, and TR with 2–10× lower latency and 2–20× higher throughput. NCC outperforms TAPIR with 2× higher throughput and 2× lower latency, and closely matches the performance of MVTO.

In summary, this work makes the following contributions:

- Identifies timestamp inversion, a fundamental correctness pitfall in timestamp-based, strictly serializable concurrency control techniques.
- Proposes NCC, a new concurrency control technique that provides strict serializability and achieves minimal overhead in the common case by exploiting natural consistency in datacenter workloads.
- A strictly serializable read-only protocol with optimal best-case performance that does not rely on synchronized clocks.
- An implementation and evaluation that shows NCC outperforms existing strictly serializable systems by an order of magnitude and closely matches the performance of systems that provide weaker consistency.

2 Background

This section provides the necessary background on transactional datastores, strict serializability, and general techniques for providing strict serializability.

2.1 Transactional Datastores

Transactional datastores are the back-end workhorse of many web applications. They typically consist of two types of machines. Front-end *client* machines receive users’ requests, e.g., managing a web page, and execute these requests on behalf of users by issuing transactions to the storage *servers* that store the data. Servers are fault-tolerant, e.g., the system state is made persistent on disks and replicated via replicated state machines (RSM), like Paxos [31].

Transactions are managed by coordinators, which can be co-located either with a server or the client. This paper adopts the latter approach to avoid the delays caused by shipping the transaction from the client to a server, while explicitly handling client failures. The coordinator issues read/write operations to relevant servers, called *participants*, following the transaction’s logic, which can be *one-shot*, i.e., it knows a priori which data to read/write and can send all requests in one step, or *multi-shot*, i.e., it takes multiple steps as the data read in one step determines which data to read/write in later steps. The system executes transactions following a concurrency control protocol, which ensures that transactions appear to take effect in an order that satisfies the system’s consistency requirements. The stronger the consistency provided by the system, the easier it is to develop correct applications.

2.2 Strict Serializability

Strict serializability [24, 55], also known as external consistency [22], is often considered the strongest consistency model. It requires that (1) there exists a *total order* of transactions, and (2) the total order must respect the *real-time order*, which means if transaction tx_1 ends before tx_2 starts, then tx_1 must appear before tx_2 in the total order. As a result, transactions appear to take effect one at a time in the order the system receives them.

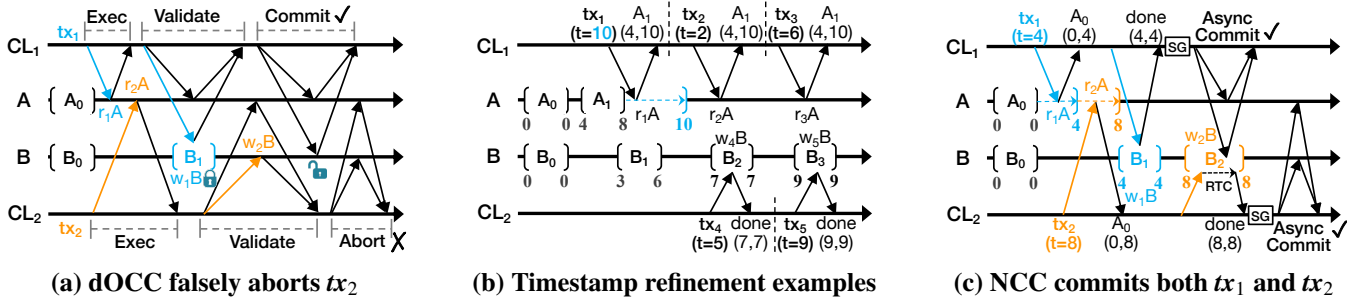

Figure 1: tx_1 and tx_2 are naturally consistent. dOCC incurs unnecessary validation costs, and tx_2 could be falsely aborted due to lock unavailability. NCC can commit both transactions with timestamp pre-assignment, refinement, and the safeguard check (denoted by SG). These techniques are detailed in Section 5.1. Each version in NCC has a (t_w, t_r) pair which is included in server responses. RTC means response timing control, detailed in Section 5.2.

Formal definition. We use Real-time Serialization Graphs (RSG) [1] to formalize the total order and real-time order requirements. An RSG is a directed graph that captures the order in which transactions take effect. Specifically, two requests from different transactions have an *execution edge* $req_1 \xrightarrow{\text{exe}} req_2$ if any of the following happens: req_1 creates some data version v_i and req_2 reads v_i ; req_1 reads some data version v_j and req_2 creates v_j 's next version that is after v_j ; or req_1 creates some data version v_k and req_2 creates v_k 's next version that is after v_k . Two transactions have an execution edge $tx_1 \xrightarrow{\text{exe}} tx_2$ if there exist req_1 and req_2 from tx_1 and tx_2 , respectively, such that $req_1 \xrightarrow{\text{exe}} req_2$. A chain of execution edges constructs a directed path between two transactions (requests), denoted by $tx_1 \xrightarrow{\text{exe}} tx_2$ ($req_1 \xrightarrow{\text{exe}} req_2$), meaning that tx_1 (req_1) affects tx_2 (req_2) through some intermediary transactions (requests). Two transactions have a *real-time edge* $tx_1 \xrightarrow{\text{rt}} tx_2$ if there is a real-time ordering between tx_1 and tx_2 , meaning that tx_1 commits before tx_2 's client issues tx_2 's first request. In an RSG, vertices are committed transactions, connected by execution and real-time edges.

There exists a total order if and only if transactions do not circularly affect each other. That is, the subgraph that comprises all vertices and only execution edges is acyclic, meaning that the following invariant holds:

Invariant 1: $\forall tx_1, tx_2 (tx_1 \xrightarrow{\text{exe}} tx_2 \implies \neg(tx_2 \xrightarrow{\text{exe}} tx_1))$

The (total) execution order respects the real-time order if and only if the execution edges (paths) do not *invert* the real-time edges, meaning that the following invariant holds:

Invariant 2: $\forall tx_1, tx_2 (tx_1 \xrightarrow{\text{rt}} tx_2 \implies \neg(tx_2 \xrightarrow{\text{exe}} tx_1))$

These invariants correspond to the total order and real-time order requirements, respectively. Therefore, a system is strictly serializable if and only if for any execution it allows, both invariants hold.

By enforcing a total order and the real-time order, strictly serializable systems provide application programmers with the powerful abstraction of programming in a single-threaded, transactionally isolated environment, and thus they greatly simplify application development and eliminate consistency

anomalies. For example, if an admin removes Alice from a shared album and then notifies Bob of the change (via a channel external to the system, e.g., a phone call), who then uploads a photo he does not want Alice to see, then Alice must not see Bob's photo, since $\text{remove_Alice} \xrightarrow{\text{rt}} \text{new_photo}$. Such guarantees cannot be enforced by weaker consistency models, e.g., serializability, because they do not enforce the real-time order that is external to the system.

2.3 dOCC, d2PL, & Transaction Reordering

Only a few techniques provide strict serializability. The common ones are dOCC, d2PL, and transaction reordering (TR). dOCC and d2PL typically require three round trips, one for each phase: execute, prepare, and commit. In the execute phase, the coordinator reads the data from the servers while writes are buffered locally. d2PL acquires read locks in this phase while dOCC does not. In the prepare phase, the coordinator sends prepare messages and the buffered writes to the participant servers. d2PL locks all participants while dOCC only locks the written data. dOCC must also validate that values read in the execute phase have not changed. If all requests are successfully prepared, i.e., locks are available and/or validation succeeds, the coordinator notifies the participants to commit the transaction and apply the writes; otherwise, the transaction is aborted and retried.

Transaction reordering typically requires two steps. In the first step, the coordinator sends the requests to the servers, which make requests wait while recording their arrival order relative to those of concurrent transactions. This ordering information usually increases linearly in size with respect to the number of concurrent transactions. In the second step, the coordinator collects the ordering information from participants, sorts the requests to eliminate interleavings, and servers execute the transactions in the sorted order.

These techniques are expensive, e.g., they require multiple rounds of messages, locking, waiting, and aborts. We find that these overheads are wasteful for most of the transactions in many datacenter workloads, and this observation has inspired our protocol design.

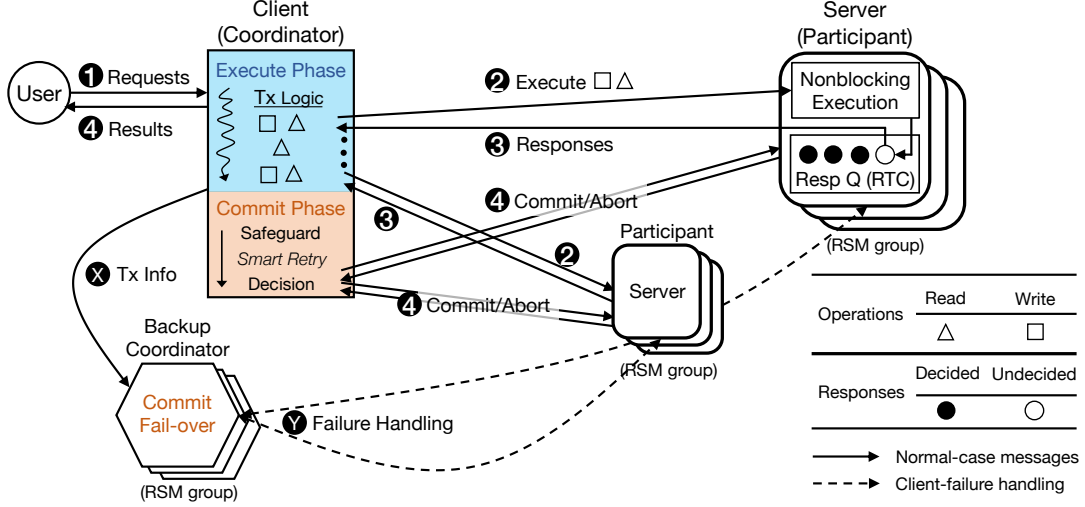

Figure 2: An overview of system architecture and transaction execution. NCC follows two-phase commit and has three design pillars: non-blocking execution, decoupled response management, and timestamp-based consistency checking.

3 Design Insight & Overview

This section explains natural consistency, which inspires our design, and overviews the key design components.

3.1 Exploiting Natural Consistency

For many datacenter transactions, simply executing their requests in the order servers receive them, as if they were non-transactional read/write operations, would naturally satisfy strict serializability. In other words, they arrive at servers in an order that is already strictly serializable. We call these transactions *naturally consistent*. Key to natural consistency is the arrival order of transaction requests.

Many requests in datacenter workloads arrive in an order that is total, i.e., transactions do not circularly affect each other, due to the following reasons. First, many requests in real-world workloads are reads [10, 12], and reads do not affect other reads. For instance, reads that return the same value can be executed in any order, and thus servers can safely execute them in their arrival order. Second, many transactions are short, e.g., they are one-shot [25, 28, 41, 54, 66, 73] or can be made one-shot using stored procedures [21, 35, 53, 62, 69], and thus their requests are less likely to interleave with others’ requests. Third, advances in datacenter networks reduce the variance of message delivery times [51, 52, 56], and thus further reduces the likelihood of request interleaving.

In most cases, the (total) arrival order satisfies the real-time order between transactions because a transaction that happens later in real-time, i.e., it starts after another transaction has been committed, must arrive at servers after the committed transaction has arrived.

Ideally, the system would treat naturally consistent transactions as non-transactional operations and execute them in the order they arrive without any concurrency control, while still guaranteeing strict serializability. This insight suggests room

for improvement in existing techniques. For instance, dOCC still requires validation messages which are unnecessary when transactions are naturally consistent. Further, during validation between prepare and commit, dOCC has a *contention window* where it can cause other concurrent transactions to abort. As shown in Figure 1a, such contention windows lead to *false aborts*, where a transaction is aborted despite being consistent. Our design aims to minimize costs for as many naturally consistent transactions as possible.

3.2 Three Pillars of Design

Our design executes naturally consistent transactions in a manner that closely resembles non-transactional operations. This is made possible through three components.

Non-blocking execution. Assuming transactions are naturally consistent, servers execute requests in the order they arrive. Requests are executed “urgently” to completion without acquiring locks, and their results are immediately made visible to prevent blocking subsequent requests. As a result, transactions are executed as cheaply as non-transactional operations, without incurring contention windows.

Decoupled response management. Because not all transactions are naturally consistent, servers must prevent returning inconsistent results to clients and ensure there are no cascading aborts. This is achieved by decoupling requests’ responses from their execution, with a response sent asynchronously only once it is verified consistent. Inconsistent results are discarded, and their requests are re-executed.

Timestamp-based consistency checking. We must check consistency as efficiently as possible, without interfering with server-side execution. We leverage timestamps to capture the arrival order (thus the execution order) of requests and design a client-side checker that verifies if requests were executed in

a total order, without incurring overheads such as messages (as in dOCC and TR) or locks (as in dOCC and d2PL).

Figure 2 shows at a high level how these three pillars support our design, and depicts the life cycle of transactions:

- ❶ The user submits application requests to a client, which translates the requests into transactions.
- ❷ The (client) coordinator sends operations to the participant servers, following the transaction’s logic. The servers execute requests in their arrival order. Their responses are inserted into a queue and sent asynchronously. The responses include timestamps that capture requests’ execution order.
- ❸ Responses are sent to the client when it is safe, determined by response timing control (RTC).
- ❹ The safeguard checks if transactions were executed in a total order by examining the timestamps in responses. The coordinator sends commit/abort messages to the servers and returns the results of committed transactions to the user in parallel, without waiting for servers’ acknowledgments. \otimes and \otimes explicitly handle client failures by leveraging a server as a backup coordinator.

Limitations. First, our design leverages natural consistency, which is observed in short (e.g., one or few shots) datacenter transactions; while our design supports arbitrary-shot transactions, many-shot long-lasting transactions that are more likely to interleave might not benefit from our design. Second, the timestamps associated with each request, including both reads and writes, must be made persistent (e.g., written to disks) and replicated for correctly handling failures, which could lead to replication overhead, which we detail in Section 5.6.

An observation. Key to the correctness of our design is leveraging timestamps to verify a total order that respects the real-time order. Yet, we identify a correctness pitfall in relying on timestamps to ensure strict serializability.

4 Timestamp-Inversion Pitfall

We discover that timestamp-based techniques sometimes fail to guard against a total order that violates the real-time order in subtle cases. As a result, executing transactions in such a total order inverts the real-time relationship between transactions, which leads to a violation of strict serializability. We call such violations the *timestamp-inversion* pitfall. Figure 3 shows a minimal construction of timestamp inversion using three transactions. tx_1 and tx_2 are single-machine transactions issued by different clients, and tx_3 starts after tx_1 finishes, so there exists a real-time order $tx_1 \xrightarrow{rto} tx_2$ that strict serializability must enforce. tx_3 is a multi-shard transaction by a third client that interleaves with tx_1 and tx_2 . tx_1 , tx_2 , and tx_3 have timestamps 10, 5, and 7, respectively.¹ By following these

¹A timestamp is generated by either a loosely synchronized physical clock [49] or a causal counter, e.g., a Lamport clock [29].

Figure 3: A minimal example of timestamp inversion, a real-time diagram shows the ordering of transactions, and how NCC tackles the timestamp-inversion pitfall.

timestamps, the transactions are executed in a total order denoted as $tx_2 \xrightarrow{exe} tx_3 \xrightarrow{exe} tx_1$, i.e., tx_3 situates itself after tx_2 and before tx_1 , which inverts the real-time order $tx_1 \xrightarrow{rto} tx_2$ and thus violates strict serializability. Specifically, the execution of these transactions violates Invariant 2, subjecting them to consistency anomalies discussed in §2.2.

The timestamp-inversion pitfall is subtle because it happens only if a transaction interleaves with a set of *non-conflicting* transactions that have real-time ordering constraints. We find timestamp inversion to be fundamental as it has affected multiple different systems; we discuss two such systems below. In addition, we find that there are several existing systems that do not explicitly define their consistency model, but give a strong indication of providing strict serializability—e.g., they claim invariants that are equivalent to strict serializability, or are built on or evaluated against strictly serializable protocols. These systems also fall into the pitfall.

Timestamp inversion affects several prior systems. The minimal example in Figure 3 can be extended to variants of timestamp inversion that affect different types of transactions in real system designs, suggesting that this pitfall is general and fundamental. For instance, we find two systems from recent SOSPs fall into different variants of the pitfall, and thus are not strictly serializable as claimed. We elaborate below to help future work avoid timestamp inversion, and provide the full counterexamples in Appendices A and B.

TAPIR [73, 74] is an integrated protocol that co-designs concurrency control and replication. Its concurrency control is a variant of dOCC which validates writes using timestamps without acquiring locks, while reads are validated in the traditional way. Because reads and writes are executed in timestamp order but validated with separate mechanisms, TAPIR’s read-write transactions may cause an inversion of concurrent writes. For instance, if tx_1 , tx_2 , and tx_3 in Figure 3 are read-write transactions, then all three transactions would pass TAPIR’s validation, which results in the inversion of

$tx_1 \xrightarrow{rto} tx_2$. The effect of this inversion is perceivable to the client via future reads. This variant of timestamp inversion requires a detailed analysis of the possible executions, showing that none of them are admissible by strict serializability (Appendix A).

DrTM [11, 68] is a specialized design for modern datastores equipped with hardware transactional memory and remote direct memory access. DrTM uses timestamps to validate read leases which are acquired before reading the data, a technique equivalent to executing read requests in the timestamp order. This makes DrTM’s read-only transactions subject to inversion, e.g., when tx_1 , tx_2 , and tx_3 in Figure 3 are read-write, read-write, and read-only transactions, respectively.

The main contributions of TAPIR and DrTM still stand, just with weaker consistency than claimed. Both teams conjecture that they can fix the systems by using synchronized clocks (e.g., TrueTime [12]) and adapting their designs to use these clocks. Thus, it is likely that their contributions still stand with strict serializability when synchronized clocks are used. However, synchronized clocks require specialized infrastructure and are not generally available (§7). Therefore, NCC is designed to avoid timestamp-inversion without relying on synchronized clocks.

5 Natural Concurrency Control

This section presents the basic components of NCC, explains how NCC avoids the timestamp-inversion pitfall, introduces two timestamp optimization techniques and a specialized algorithm for read-only transactions, and concludes with discussions of failure handling and correctness.

5.1 Protocol Basics

We build NCC on the three design pillars (§3.2) to minimize the costs for naturally consistent transactions.

Pre-timestamping transactions. NCC processes a transaction in two phases: execute and commit. Algorithm 5.1 shows the client (coordinator)’s logic. The coordinator starts a transaction tx by pre-assigning it a timestamp t that consists of two fields: clk which is the client’s physical time (Section 5.3 details how it is computed), and cid which is the client identifier. t uniquely identifies tx (line 3). When two timestamps have the same clk , NCC breaks the tie by comparing their cid . t is included in all of tx ’s requests that are sent to servers shot by shot, following tx ’s application logic (lines 4 and 5). These timestamps accompany tx throughout its life cycle and will be used to verify if the results are consistent.

Refining timestamps to match execution order. Algorithm 5.2 details the server-side logic for request execution and commitment. Each key stores a list of versions in the order of the server creating them. A version has three fields: *value*, a pair of *timestamps* (t_w, t_r), and *status*. *value* stores the data; t_w is the timestamp of the transaction that created the version; t_r is the highest timestamp of transactions that

Algorithm 5.1: Client (transaction coordinator) logic

```

1 Function EXECUTERWTRANSACTION( $tx$ ) :
2    $results \leftarrow \{\}$ ;  $t\_pairs \leftarrow \{\}$  // server responses
3    $t.clk \leftarrow ASYNCHRONYAWARETS(tx)$ ;  $t.cid \leftarrow clientID$ 
4   for  $req$  in  $tx$  do
5     // send requests shot by shot,
6     // following tx’s logic
7      $res, t\_pair \leftarrow NONBLOCKINGEXECUTE(req, t)$ 
8      $results \leftarrow results \cup res$ 
9      $t\_pairs \leftarrow t\_pairs \cup t\_pair$ 
10    // all shots done, tx’s logic complete
11     $ok, t' \leftarrow SAFEGUARDCHECK(t\_pairs)$ 
12    if not  $ok$  then
13       $ok \leftarrow SMARTRETRY(tx, t')$  // §5.4
14    if  $ok$  then
15       $ASYNC COMMITORABORT(tx, "committed")$ 
16      return  $results$ 
17    else
18       $ASYNC COMMITORABORT(tx, "aborted")$ 
19      go to 2 // abort, and retry from scratch
20
21 Function SAFEGUARDCHECK( $t\_pairs$ ) :
22    $t_w\_set \leftarrow \{\}$ ;  $t_r\_set \leftarrow \{\}$ 
23   for  $t\_pair$  in  $t\_pairs$  do
24      $t_w\_set \leftarrow t_w\_set \cup t\_pair.left$ 
25      $t_r\_set \leftarrow t_r\_set \cup t\_pair.right$ 
26    $t_w\_max \leftarrow \max\{t_w\_set\}$ ;  $t_r\_min \leftarrow \min\{t_r\_set\}$ 
27   if  $t_w\_max \leq t_r\_min$  then
28     //  $t\_pairs$  overlap,  $\exists$  a snapshot
29     return  $true, t_w\_max$ 
30   else
31     return  $false, t_w\_max$ 

```

read the version; and *status* indicates the state of the transaction that created the version: either (initially) *undecided*, or *committed*. An aborted version is removed from the datastore.

The server always executes a request against the most recent version $curr_ver$, which is either undecided or committed (line 35). Specifically, the server executes a write by creating a new undecided version new_ver , which is now the most recent version of the key, ordered after $curr_ver$ (lines 39 and 40), and executes a read by reading the *value* of $curr_ver$ (line 44). NCC’s basic protocol can work with a single-versioned data store; multi-versioning is required only for smart retry, a timestamp optimization technique (§5.4). The server refines the most recent version’s timestamp pair to match the order in which requests are executed. Specifically, a write request computes new_ver ’s t_w as follows: its physical time field is no less than that of the write’s timestamp t and that of $curr_ver$ ’s t_r , and its client identifier is the same as t ’s (line 37); new_ver ’s t_r is initialized to t_w (line 38). Similarly, a read request updates $curr_ver$ ’s t_r if needed (line 43). Figure 1b shows examples of how timestamps are refined. A version is associated with a t_w and a t_r , e.g., A_1 initially has a timestamp pair (4, 8). tx_1 – tx_3 are single-key read transactions with pre-assigned timestamps 10, 2, and 6, respectively. They return the most recent version

Algorithm 5.2: Server execution and commitment

```

28 Multi-versioned data store:
29  $DS[key][ver]$  // indexed by key, vers sorted by  $t_w$ 
// ver is either committed or undecided
30 Response queue:
31  $resp\_qs[key][resp\_q]$  // resp queues for each key
32
33 Function NONBLOCKINGEXECUTE( $req, t$ ):
34    $resp \leftarrow []$  // response message
35    $curr\_ver \leftarrow DS[req.key].most\_recent$ 
36   if  $req$  is write then
37      $t_w.clk \leftarrow \max\{t.cclk, curr\_ver.t_r.cclk + 1\}; t_w.cid \leftarrow t.cid$ 
38      $t_r \leftarrow t_w$ 
39      $new\_ver \leftarrow [req.value, (t_w, t_r), "undecided"]$ 
40      $DS[req.key] \leftarrow DS[req.key] + new\_ver$ 
41      $resp \leftarrow ["done", (t_w, t_r)]$ 
42   else
43      $curr\_ver.t_r \leftarrow \max\{t, curr\_ver.t_r\}$ 
44      $resp \leftarrow [curr\_ver.value, (curr\_ver.t_w, curr\_ver.t_r)]$ 
45    $resp\_qs[req.key].enqueue(resp, req, t, "undecided")$ 
46   RESPTIMINGCONTROL( $resp\_qs[req.key]$ ) // §5.2
47
48 Function ASYNCCOMMITORABORT( $tx, decision$ ):
49   foreach  $ver$  created by  $tx$  do
50     if  $decision = "committed"$  then
51        $ver.status \leftarrow decision$ 
52     else
53        $DS.remove(ver)$ 
54   foreach  $resp\_q$  in  $resp\_qs$  do
55     foreach  $resp$  in  $resp\_q$  do
56       if  $resp.request \in tx$  then
57          $resp.q\_status \leftarrow decision$ 
58   RESPTIMINGCONTROL( $resp\_q$ ) // §5.2

```

of A , i.e., A_1 , update its t_r if needed, and return A_1 's timestamp pair. tx_4 and tx_5 show how writes manage timestamps.

These (refined) timestamps match requests' arrival order and thus also match the execution order: on each key, a read must have a timestamp greater than that of the write it sees, i.e., a read is ordered after the most recent write, and a write must have a timestamp greater than that of the most recent read, i.e., a write is ordered after the most recent read (and thus all previous writes).

Non-blocking execution and response queues. The server executes requests in a non-blocking manner and decouples their execution from responses. Specifically, a write creates a version and immediately makes it visible to subsequent transactions; a read fetches the value of the most recent version whose *status* could be undecided, without waiting for it to commit; the server prepares the response (lines 34, 41, and 44), inserts it into a *response queue* (lines 45 and 46), which asynchronously sends the responses to clients when it is safe. (Section 5.2 details response timing control, which determines when sending a response is safe so timestamp inversion and cascading aborts are prevented.) Unlike d2PL and dOCC, which lock data for at least one round-trip time in

the execute and prepare phases (i.e., the contention window), non-blocking execution ensures that a transaction never exclusively owns the data without performing useful work. As a result, the server never stalls, and CPUs are fully utilized to execute requests. Moreover, non-blocking execution eliminates the contention window and thus reduces false aborts.

Client-side safeguard. A server response includes the timestamp pair (t_w, t_r) of the most recent version, e.g., new_ver for a write and $curr_ver$ for a read. The returned (t_w, t_r) represents the time range in which the request is valid. That is, a read must take effect after t_w , which is the time when the most recent write on the same key took effect, and no later writes can take effect between t_w and t_r on the same key. A write must have $t_w = t_r$, meaning that it takes effect exactly at t_w . When a transaction has completed its logic (i.e., all shots are executed) and the client has received responses to all its requests, the safeguard looks for a consistent snapshot that intersects all (t_w, t_r) pairs in server responses by checking if the (t_w, t_r) pairs overlap (lines 8, 18–27). This intersecting snapshot identifies the transaction's synchronization point, i.e., all requests are valid at the intersecting timestamp.

Figure 1c shows an example where NCC executes the same transactions in Figure 1a. The default versions A_0 and B_0 both have a timestamp pair $(0, 0)$. tx_1 and tx_2 are pre-assigned 4 and 8, respectively, and their requests arrive in the same order as they were in Figure 1a. The safeguard enables NCC to commit both transactions, i.e., tx_1 's responses intersect at 4 while tx_2 's responses intersect at 8, without unnecessary overhead such as dOCC's validation cost and false aborts.

When the client has decided to commit or abort the transaction, the protocol enters the commit phase by sending the commit/abort messages to the servers. If the transaction is committed, the server updates the *status* of the created versions from undecided to committed; otherwise, the versions are deleted (lines 48–53). The client retries the aborted transaction. The client sends the results of the committed transaction to the user in parallel with the commit messages, i.e., asynchronous commit, without waiting for servers' acknowledgments (lines 11–16).

Supporting complex transaction logic. NCC supports transactions accessing a key multiple times, e.g., read-modify-writes and repeated reads/writes, by treating its requests to the same key as a single logical request. For instance, if a read-modify-write has its read and write requests executed consecutively (i.e., they are not intersected by other writes), then only the write response is checked by the safeguard, treating read-modify-write as one logical request; otherwise, it is aborted if there are intersecting writes, e.g., when the most recent version has a t_w greater than that returned by the read of this read-modify-write. The responses of these requests are grouped together in the response queue, e.g., the write response of a read-modify-write is inserted right after the read response of the same read-modify-write. We explain

the details of handling complex logic in Appendix C.

NCC achieves minimal costs by urgently executing transactions in a non-blocking manner and by ensuring a total order with the light-weight timestamp-based safeguard. Yet, in order to provide strict serializability, NCC must enforce the real-time order between transactions by handling the timestamp-inversion pitfall, as we discuss next.

5.2 Response Timing Control

NCC avoids the timestamp-inversion pitfall by disentangling the subtle interleaving between a set of non-conflicting transactions that have real-time order dependencies (e.g., Figure 3), without relying on synchronized clocks. Specifically, NCC introduces *response timing control* (RTC), which controls the sending time of responses. It is safe to send the response of a request req_1 when the following dependencies are satisfied:

- D₁ If req_1 reads a version created by req_0 of another transaction, then req_1 's response is not returned until req_0 is committed or it is discarded if req_0 is aborted (then req_1 will be re-executed).
- D₂ If req_1 is a write and there are reads that read the version which immediately precedes the one created by req_1 , then req_1 's response is not returned until the reads are committed/aborted.
- D₃ If req_1 creates a version immediately after the version created by req_0 of another transaction, then req_1 's response is not returned until req_0 is committed/aborted.

By enforcing these dependencies, NCC controls the sending of responses so that the transactions which form the subtle interleaving are forced to take effect in their real-time order. For instance, in Figure 3, server A cannot send the response of tx_1 until tx_3 has been committed (assuming at least one of them writes to A). As a result, any transaction tx_2 that begins after tx_1 receives its response, i.e., $tx_1 \xrightarrow{rto} tx_2$, must be executed after tx_1 , and thus after tx_3 as well. In detail, tx_2 's execution on each server is after it begins, which is after tx_1 ends, which is after tx_1 's response is sent, which is after tx_3 commits, which is after tx_3 executes on each server. This results in a total order $tx_3 \xrightarrow{exe} tx_1 \xrightarrow{exe} tx_2$, which respects the real-time order of Invariant 2, as shown in Part III of Figure 3.

NCC implements RTC by managing response queues independently from request execution. NCC maintains one queue per key. A queue item consists of four fields: *response* that stores the response message of a request, the *request* itself, *ts* which is the pre-assigned timestamp of the request, and *q_status* that indicates the state of the request, which is initially *undecided*, and updated to either *committed* or *aborted* when the server receives the commit/abort message for this request (lines 54–57, Algorithm 5.2).

Managing response queues. Algorithm 5.3 details how NCC manages the response queue of each key. This logic is invoked every time the server finishes executing a request

Algorithm 5.3: Response timing control

```

59 Function RESP_TIMING_CONTROL(resp_q) :
60   head ← resp_q.head() // the oldest response
61   while head.q_status ≠ "undecided" do
62     // find the first response we can send
63     resp_q.dequeue()
64     new_head ← resp_q.head()
65     new_req ← new_head.request; t ← new_head.ts
66     while head.q_status = "aborted"
67       and head.request is write and new_req is read do
68         // handle reads seeing aborted writes
69         resp_q.dequeue() // discard read response
70         // re-execute the read locally
71         NONBLOCKING_EXECUTE(new_req, t)
72         new_head ← resp_q.head()
73         new_req ← new_head.request; t ← new_head.ts
74   head ← resp_q.head()
75   curr_item ← head
76   repeated loop
77     // send dependency-satisfied responses
78     resp ← curr_item.response
79     if resp.is_sent ≠ true then
80       sys_call.send(resp) // send to client
81       resp.is_sent ← true
82     // send consecutive read responses
83     next_item ← curr_item.next()
84     if curr_item.request is not read
85       or next_item.request is not read then
86       break repeated loop
87     curr_item ← next_item

```

(line 46) and receives a commit/response message (line 58). NCC iterates over the queue items from the head (i.e., the oldest response) until it finds the first response whose *q_status* is undecided, which means all earlier requests on the same key have been committed or aborted, i.e., this response has satisfied the three dependencies (lines 60–62 and 71). The server sends this response message to the client if it has not done so (lines 72, 74–77). If this is a read response, then the server sends all consecutive read responses that follow it (lines 73 and 78–81), because all these read responses satisfy the three dependencies. In other words, reads returning the same value do not have dependencies between them. RTC is *effectively* similar to locking the response queues, e.g., the queue is “locked” when a response is sent and other responses must wait, and is “unlocked” when the commit/abort message for the request to which the sent response belongs is received. However, RTC differs from lock-based mechanisms in that it is decoupled from execution and does not introduce contention windows, i.e., data objects are not locked.

Fixing reads locally. When the server receives an abort message for a write request, it must invalidate the responses of any reads that have fetched the value of the aborted write. This is necessary to avoid returning invalid results to the client and to prevent cascading aborts. Specifically, the server removes the response of such a read from the response queue and re-executes the read request, e.g., it fetches the current

most recent version, prepares a new response, and inserts the new response to the tail of the queue (lines 65–68).

Avoiding indefinite waits. To avoid responses from circularly waiting on dependencies across different keys, NCC early aborts a request (thereby aborting the transaction to which it belongs) if its pre-assigned timestamp is not the highest the server has seen *and* if its response cannot be sent immediately, i.e., it is not the head of the queue. Specifically, a write (read) is aborted if there is an undecided request (write request) with a higher timestamp. Then, the server sends a special response to the client without executing the request. The special response includes a field *early_abort* which allows the client to bypass the safeguard and abort the transaction. We omit the details from the pseudocode for clarity.

RTC is a general solution to timestamp inversion, without the need for synchronized clocks. It does not incur more aborts even when responses are not sent immediately, because response management is decoupled from request execution. That is, whether a transaction is committed or aborted is solely based on timestamps, and RTC does not affect either pre-assignment or refinement of timestamps. Yet, NCC’s performance also depends on how well timestamps capture the arrival order of (naturally consistent) transactions. That is, timestamps that do not match transactions’ arrival order could cause transactions to falsely abort even if they are naturally consistent. Next, we will discuss optimization techniques that enable timestamps to better match the arrival order.

5.3 Asynchrony-Aware Timestamps

NCC proposes two optimizations: a proactive approach that controls how timestamps are generated before transactions start, and a reactive approach that updates timestamps to match the naturally consistent arrival order after requests are executed. This subsection discusses the proactive approach.

The client pre-assigns the same timestamp to all requests of a transaction; however, these requests may arrive at their participant servers at different physical times, which could result in a mismatch between timestamp and arrival order, as shown in Figure 4a. Transactions tx_1 and tx_2 start around the same time and thus are assigned close timestamps, e.g., $t_1 = 1004$ and $t_2 = 1005$, respectively (client IDs are omitted). Because the latency between B and CL_1 is greater than that between B and CL_2 , tx_1 may arrive at B later than tx_2 , but tx_1 has a smaller timestamp. As a result, the safeguard may falsely reject tx_1 , e.g., server B responds with a refined timestamp pair (1006, 1006) which does not overlap with (1004, 1004), the timestamp pair returned by server A . However, aborting tx_1 is unnecessary because tx_1 and tx_2 are naturally consistent.

To tackle this challenge, NCC generates timestamps while accounting for the time difference, t_Δ , between when a request is sent by the client and when the server starts executing the request. Specifically, the client records the physical time t_c before sending the request to the server; the server records the physical time t_s before executing the request and piggy-

Algorithm 5.4: Smart retry

```

83 Function SMARTRETRY( $tx, t'$ ) :
84   foreach  $ver$  accessed by  $tx$  do
85     // next version of the same key
86      $next\_ver \leftarrow ver.next()$ 
87     if  $next\_ver.t_w \leq t'$  then
88       return false
89     if  $ver$  created by  $tx$  and  $ver.t_w \neq ver.t_r$  then
90       return false
91     if  $ver$  created by  $tx$  then
92        $ver.t_w \leftarrow t'; ver.t_r \leftarrow t'$ 
93     else
94        $ver.t_r \leftarrow \max\{ver.t_r, t'\}$ 
95   return true

```

backs t_s onto the response sent back to the client; and the client calculates t_Δ by finding the difference between t_c and t_s , i.e., $t_\Delta = t_s - t_c$. By measuring the end-to-end time difference, t_Δ effectively masks the impact of queuing delays and clock skew. The client maintains a t_Δ for each server it has contacted. An asynchrony-aware timestamp is generated by adding the client’s current physical time and the greatest t_Δ among the servers this transaction will access. For instance, given the values of t_Δ shown in Figure 4a, CL_1 assigns tx_1 timestamp 1014 (i.e., $1004 + 10$) and CL_2 assigns tx_2 1010 (i.e., $1005 + 5$), and both transactions may successfully pass their safeguard check, availing their natural consistency.

5.4 Smart Retry

NCC proposes a reactive approach to minimizing the performance impact of the safeguard’s false rejects, which happen when timestamps fail to identify the naturally consistent arrival order, as shown in Figure 4b. Initially, version A_0 has a timestamp pair (0, 0), and B_0 has (0, 5). The same transactions tx_1 and tx_2 as those in Figure 1c access both keys. Following NCC’s protocol, tx_1 ’s responses contain the timestamp pairs (0, 4) and (6, 6) from A and B , respectively, which will be rejected by the safeguard because they do not overlap. However, aborting tx_1 is unnecessary because tx_1 and tx_2 are naturally consistent.

Instead, NCC tries to “reposition” a rejected transaction with respect to the transactions before and after it to construct a total order, instead of aborting and re-executing the rejected transaction from scratch, which would waste all the work the server has done for executing it. Specifically, NCC chooses a timestamp that is nearest “in the future” and hopes the rejected transaction can be re-committed at that time. This is possible if the chosen time has not been taken by other transactions.

Algorithm 5.4 shows the pseudocode for smart retry. When the transaction fails the safeguard check, NCC suggests a new timestamp t' , which is the maximum t_w in the server responses. The client then sends smart retry messages that include t' to the participant servers, which then attempt to reposition the transaction’s requests at t' . The server can reposition a re-

Figure 4: Optimizations that match the timestamps with transactions' arrival order. Asynchrony-aware timestamps proactively controls the pre-assigned timestamps before execution. Smart retry reactively fixes the safeguard's false rejects after execution thus avoids aborting and re-executing transactions.

quest if there has not been a newer version that was created before t' (lines 85–87) and, if the request is a write, the version it created has not been read by any transactions (lines 88 and 89). The server updates the timestamps of relevant versions if smart retry succeeds, e.g., the created version has a new timestamp pair (t', t') , and t_r of the read version is updated to t' if t' is greater (lines 90–93). (Our implementation does not smart-retry the request that returned the maximum t_w , i.e., $t_w = t'$, because its smart retry always succeeds.) The client commits the safeguard-rejected transaction if all its smart retry requests succeed, and aborts and retries it from scratch otherwise (lines 9 and 10, Algorithm 5.1).

Not only does smart retry avoid false aborts, it also unleashes a higher degree of concurrency, as shown in Figure 4c. The servers have executed a newer transaction tx_2 when tx_1 's smart retry (SR) messages arrive, and both transactions can be committed even if the messages interleave, e.g., tx_1 's smart retry succeeds and tx_2 passes its safeguard check, because tx_2 's pre-assigned timestamps have left enough room for repositioning tx_1 's requests. In contrast, validation-based techniques would unnecessarily abort tx_1 (considering SR as dOCC's validation messages) due to the presence of the conflicting transaction tx_2 .

Garbage collection. Old versions are temporarily stored and garbage collected as soon as they are no longer needed by undecided transactions for smart retry. Only the most recent versions are used to serve new transactions.

5.5 Read-Only Transactions

NCC designs a specialized read-only transaction protocol for read-dominated workloads [10, 12, 27, 41, 45]. Similar to existing works, NCC optimizes read-only transactions by eliminating their commit phase because they do not modify the system state and have nothing to commit. By eliminating commit messages, read-only transactions achieve *optimal performance* in the best case, i.e., one round of non-blocking messages with constant metadata [41, 43, 44].

Eliminating commit messages brings a new challenge to response timing control: write responses can no longer

track their dependencies on preceding read-only transactions, as they do not know if and when those reads are committed/aborted. To tackle this challenge, NCC aborts a read-only transaction if it could possibly cause the subtle interleaving that leads to timestamp inversion. In other words, NCC commits a read-only transaction if its requests arrive in a naturally consistent order and no intervening writes have been executed since the last time the client accessed these servers.

Specifically, each client tracks t_{ro} which is the t_w of the version created by the most recent write on a server, and the client maintains a map of t_{ro} for each server this client has contacted. A read-only transaction is identified by a Boolean field *IS_READ_ONLY*. The client sends each of its requests to the participant server together with the pre-assigned timestamp (as in the basic protocol) and the t_{ro} of the server. To execute a read request, the server checks the version at t_{ro} . If the version is still the most recent, the server continues to execute the read following the basic protocol, i.e., it fetches the most recent version, refines its t_r if needed, and returns its timestamp pair; otherwise, the server sends a special response that contains a field *ro_abort* immediately without executing the request. If any of the responses contain *ro_abort*, the client aborts this read-only transaction; otherwise, the client continues with the safeguard check and, if needed, smart retry, after which the client does not send any commit/abort messages.

This protocol pays more aborts in the worst case in exchange for reduced message overhead in the normal case, a trade-off that is worthwhile for read-dominated workloads where writes are few (so aborts are rare), and read-only transactions are many, making the savings in message cost significant. This protocol also expedites the sending of responses for read-write transactions because read-only transactions do not insert responses into the response queue, i.e., a write response depends only on the reads of preceding read-write transactions in Dependency D_2 , not those of read-only transactions.

5.6 Failure Handling

Tolerating server failures. NCC assumes servers never fail as their state is typically made persistent on disks and replicated via state machine replication such as Paxos [30]. All

state changes incurred by a transaction in the execute phase (e.g., t_w and t_r of each request) must be written to the disk and replicated for correctness. For instance, after a request is executed, the server inserts its response into the response queue and, in parallel, writes the state changes to the disk and replicates the request to other replicas. Its response is sent back to the client when it is allowed by response timing control and when its replication is finished. Commit/abort and smart retry messages are also made persistent and replicated. This simple scheme ensures correctness but incurs high overhead. We plan to investigate possible optimizations in future work, e.g., NCC could defer disk writes and replication to the last shot of a transaction where all state changes are made persistent and replicated once and for all, without having to replicate each request separately. Server replication inevitably increases latency but does not introduce more aborts, because whether a transaction is committed or aborted is solely based on its timestamps, which are decided during request execution and before replication starts.

Tolerating client failures. NCC must handle client failures explicitly because clients are not replicated in most systems and NCC co-locates coordinators with clients. NCC adopts an approach similar to that in Sinfonia [4] and RIFL [32]. We briefly explain it as follows and present its details in Appendix D. For a transaction tx , one of the storage servers tx accesses is selected as the backup coordinator, and the other servers are cohorts. In the last shot of the transaction logic, which is identified by a field *IS_LAST_SHOT* in the requests, the client notifies the backup coordinator of the identities of the complete set of cohorts. Cohorts always know which server is the backup coordinator. When the client crashes, e.g., is unresponsive for a certain amount of time, the backup coordinator reconstructs the final state of tx by querying the cohorts for how they executed tx , and commits/aborts tx following the same safeguard and smart retry logic. Because this computation is deterministic, the backup coordinator always makes the same commit/abort decision as the client would if the client did not fail. To tolerate one client failure, NCC needs one backup coordinator which is selected among storage servers replicated in a usual way.

5.7 Correctness

This section provides proof intuition for why NCC is safe and live. At a high level, NCC guarantees a total order, the real-time order, and liveness, with the mechanisms (M_1) the safeguard, (M_2) non-blocking execution with response timing control, and (M_3) early aborts, respectively. We provide a formal proof of correctness in Appendix E.

NCC is safe. We prove that NCC guarantees strict serializability by demonstrating that both Invariants 1 and 2 are upheld. These two invariants correspond to the total order and real-time order requirements, respectively.

Intuitively, NCC commits all requests of a transaction at the

same synchronization point, which is the intersection of all (t_w, t_r) pairs in responses, and the synchronization points of all committed transactions construct a total order. Specifically, we prove that the safeguard enforces Invariant 1, by contradiction. Assume both tx_1 and tx_n are committed, and $tx_1 \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$. Without loss of generality, there must exist a chain of transactions such that $tx_1 \xrightarrow{\text{exe}} tx_2 \xrightarrow{\text{exe}} \dots \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$. Then, consider requests req and req' in each pair of adjacent transactions, we must have $req'_1 \xrightarrow{\text{exe}} req_2, req'_2 \xrightarrow{\text{exe}} req_3, \dots, req'_{n-1} \xrightarrow{\text{exe}} req_n, req'_n \xrightarrow{\text{exe}} req_1$. Considering their returned timestamps, we can derive the following:

- ① $t'_{r1} \leq t_{w2}, t'_{r2} \leq t_{w3}, \dots, t'_{rn} \leq t_{w1}$, by NCC's protocol.
- ② $t_{w1} \leq t'_{r1}, t_{w2} \leq t'_{r2}, \dots, t_{wn} \leq t'_{rn}$, because all transactions are committed and by the safeguard logic.
- ③ $t_{w1} \leq t'_{r1} \leq t_{w2} \leq t'_{r2} \leq \dots \leq t_{wn} \leq t'_{rn} \leq t_{w1}$, by ① and ②.
- ④ $t'_{r1} = t_{w2} = t'_{r2} = t_{w3} = \dots = t_{wn} = t'_{rn} = t_{w1}$, by ③.
- ⑤ req'_i is a write and req_i is a read, $i \in [1, n]$, by ④, NCC's protocol, and $tx_1 \xrightarrow{\text{exe}} tx_2 \xrightarrow{\text{exe}} \dots \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$.
- ⑥ $t_{w1} = t'_{r1}$ and $t_{w1} = t'_{rn}$, by ⑤ and NCC's protocol.
- ⑦ $t'_{w1} = t'_{wn}$, by ④ and ⑥, which contradicts that writes from different transactions must have distinct t_w because timestamps are unique. Therefore, Invariant 1 holds.

We prove that NCC enforces Invariant 2 by assuming $tx_1 \xrightarrow{\text{rto}} tx_2$ and showing that it must be that $tx_1 \xrightarrow{\text{exe}} tx_2$. There are two cases to consider. In case 1, tx_1 and tx_2 access some common data items. Then, we must have $tx_1 \xrightarrow{\text{exe}} tx_2$, because NCC executes requests in their arrival order. Then, it must be true that $\neg(tx_2 \xrightarrow{\text{exe}} tx_1)$, by Invariant 1. In case 2, tx_1 and tx_2 access disjoint data sets, and we prove the claim by contradiction. Assume that $tx_2 \xrightarrow{\text{exe}} tx_1$; then, there must exist req_2 and req_1 in tx_2 and tx_1 , respectively, such that $req_2 \xrightarrow{\text{exe}} req_1$. req_1 's response is not returned until req_2 is committed or aborted, by applying response timing control (§5.2). Then, req_2 is issued before req_1 's client receives req_1 's response because a request, e.g., req_2 , can be committed or aborted only after it is issued. Thus, we can derive $\neg(tx_1 \xrightarrow{\text{rto}} tx_2)$ because tx_2 has at least one request, e.g., req_2 , which starts before tx_1 receives all its responses. This means tx_2 starts before tx_1 is committed, which contradicts our assumption $tx_1 \xrightarrow{\text{rto}} tx_2$. Therefore, Invariant 2 must hold.

NCC is live. NCC's non-blocking execution guarantees that requests always run to completion, i.e., execution never stalls (§5.1). Blocking can happen only to the sending of responses due to response timing control, and NCC avoids circular waiting with early aborts (§5.2). Thus, NCC guarantees that transactions finish eventually.

NCC's specialized read-only transaction protocol and optimization techniques such as asynchrony-aware timestamps and smart retry do not affect correctness, because transactions are protected by the three mechanisms (i.e., M_1 , M_2 , and M_3 summarized at the beginning of this subsection) regardless of

Workload	Write fraction	Assoc-to-obj	# keys/RO	# keys/RW	Value size	# cols/key	Zipfian
Google-F1	0.3% [0.3%–30%]	—	1–10	1–10	1.6 KB \pm 119 B	10	0.8

whether optimizations or the specialized protocol are used.

6 Evaluation

This section answers the following questions:

1. How well does NCC perform, compared to common strictly serializable techniques dOCC, d2PL, and TR?
2. How well does NCC perform, compared to state-of-the-art serializable (weaker consistency) techniques?
3. How well does NCC recover from client failures?

Implementation. We developed NCC on Janus’s framework [54]. We improved the framework by making it support multi-shot transactions, optimizing its baselines, and adding more benchmarks. NCC’s core protocols have ~ 3 K lines of C++ code. We also show the results of NCC-RW, a version without the read-only transaction protocol, i.e., all transactions are executed as read-write transactions.

Baselines. The evaluation includes three strict serializable baselines (dOCC, d2PL, and Janus) and two serializable baselines (MVTO and TAPIR). We chose d2PL and dOCC because they are the most common strictly serializable techniques. We chose Janus because it is the only open-source TR-based strictly serializable system we could find. We chose MVTO because it has the highest best-case performance among all (weaker) serializable techniques, presenting a performance upper bound. We chose TAPIR because it utilizes timestamp-based concurrency control.

Our evaluation focuses on concurrency control and assumes servers never fail. Janus and TAPIR are unified designs of the concurrency control and replication layers, so we disabled their replication and only compare with their concurrency control protocols, shown as Janus-CC and TAPIR-CC, to make the comparisons fair. We compare with two variants of d2PL. d2PL-no-wait aborts a transaction if the lock is not available. d2PL-wound-wait makes the transaction wait if it has a larger timestamp and aborts the lock-holding transaction otherwise. All baselines are fully optimized: we co-locate coordinators with clients (even if baselines cannot handle client failures), combine the execute and prepare phases for d2PL-no-wait and TAPIR-CC, and enable asynchronous commitment, i.e., the client replies to the user without waiting for the acknowledgments of commit messages.

6.1 Workloads and Experimental Setup

We evaluate NCC under three workloads that cover both read-dominated “simpler” transactions and many-write more “complex” transactions. Google-F1 and Facebook-TAO synthesize real-world applications and capture the former: they are one-shot and read-heavy. TPC-C has multi-shot transactions and is write-intensive, capturing the latter. We also vary write fractions in Google-F1 to further explore the latter. Table 5 shows the workload parameters.

Google-F1 parameters were published in F1 [61] and Spanner [12]. Facebook-TAO parameters were published in TAO [10]. TPC-C’s New-Order, Payment, and Delivery are read-write transactions. Its Order-Status and Stock-Level are read-only. Janus’s original implementation of TPC-C is one-shot, so we modified it to make Payment and Order-Status multi-shot, to demonstrate NCC is compatible with multi-shot transactions and evaluate its performance beyond one-shot transactions (though they are still relatively short).

Experimental setting. We use Microsoft Azure [48]. Each machine has 4 CPUs (8 cores), 16GB memory, and a 1 Gbps network interface. We use 8 machines as servers and 16–32 machines as clients that generate open-loop requests to saturate the servers. (The open-loop clients back off when the system is overloaded to mitigate queuing delays.) Google-F1 and Facebook-TAO have 1 M keys, with the popular keys randomly distributed to balance load. We run 3 trials for each test and 60 seconds for each trial. Experiments are CPU-bound (i.e., handling network interrupts).

6.2 Result Overview

NCC outperforms strictly serializable protocols dOCC, d2PL, and TR (Janus-CC) by 80%–20 \times higher throughput and 2–10 \times lower latency under various workloads (Figure 7) and write fractions (Figure 8a). NCC outperforms and closely matches serializable systems, TAPIR-CC and MVTO, respectively (Figure 8b). NCC recovers from client failures with minimal performance impact (Figure 8c). Please note that Figure 7 and Figure 8b have log-scale axes. Figure 6 summarizes the takeaway of performance improvements.

6.3 Latency vs. Throughput Experiments

Figure 7 shows NCC’s overall performance is strictly better than the baselines, i.e., higher throughput with the same

Workload	Contention	# shots	Characteristics	NCC takeaway
Facebook-TAO	Low	1	Read-dominated	Performance-optimal reads by the RO protocol
Google-F1	Low	1	Read-dominated	Performance-optimal reads by the RO protocol
TPC-C	Medium→High	Multi-shot	Write-intensive	Leverages the natural arrival order, minimizes false aborts
Google-WF	Low→High	1	Write-intensive	Leverages the natural arrival order, minimizes false aborts

Figure 6: Facebook-TAO and Google-F1 have low contention. TPC-C and Google-WF (varying write fractions) are write-intensive. TPC-C Payment and Order-Status are multi-shot.

Figure 7: NCC achieves much lower latency under read-dominated workloads with its specialized read-only transaction algorithm, 50% lower latency under write-intensive workload, and at least 80% higher throughput across workloads.

latency and lower latency with the same throughput.

Google-F1 and Facebook-TAO. Figure 7a shows the results under Google-F1. X-axis is the system throughput, and y-axis shows the median read latency in log scale. A horizontal line (O.P.) marks the operating point with reasonably low latency (< 10 ms). At the operating point, NCC has a 2–4 \times higher throughput than dOCC and d2PL. We omit the results for Janus-CC to make the graph clearer as we found that Janus-CC’s performance is incomparable (consistently worse) with other baselines, because Janus-CC is designed for highly contended workloads by relying on heavy dependency tracking, which is more costly under low contention.

NCC has better performance because Google-F1 and Facebook-TAO have many naturally consistent transactions due to the prevalence of reads. NCC enables low overhead by leveraging natural consistency. In particular, its read-only transaction protocol executes the dominating reads with the minimum costs (Figure 6). For instance, at the operating point, NCC has about 99% of the transactions that passed their safeguard check and finished in one round trip. 99.1% of the transactions did not delay their responses, i.e., the real-time order dependencies were already satisfied when they arrived. That is, 99% of the transactions were finished by NCC within a single RTT without any delays. For the 1% of the transactions that did not pass the safeguard check initially, 70% of them passed the smart retry. Only 0.2% of the transactions were aborted and retried from scratch. All of them were committed eventually.

As a result, NCC can finish most transactions with one round of messages (for the read-only ones) and a latency of one RTT (for both read-only and read-write) while dOCC

and d2PL-wound-wait require three rounds of messages and a latency of two RTTs (asynchronous commitment saves one RTT). NCC has much higher throughput than d2PL-no-wait due to its novel read-only protocol which requires one round of messages, while d2PL-no-wait requires two. The fewer messages of NCC translate to lower latency under medium and high load due to lower queuing delay. d2PL-no-wait performs similar to NCC-RW because NCC-RW executes read-only transactions by following its read-write protocol. However, NCC-RW outperforms d2PL-no-wait under higher load because conflicts cause d2PL-no-wait to abort more frequently, while NCC-RW has fewer false aborts by leveraging the natural arrival order. This is more obvious in the Facebook-TAO results shown in Figure 7b, because Facebook-TAO has larger read transactions that are more likely to conflict with writes. The results of Facebook-TAO show similar takeaways.

TPC-C. Each experiment ran all five types of TPC-C transactions, and Figure 7c shows the latency and throughput (both in log scale) of New-Order while the throughput of the other four types is proportional. NCC and NCC-RW have $\sim 20\times$ higher peak throughput with $\sim 10\times$ lower latency compared to dOCC. dOCC and d2PL-no-wait have many false aborts when load increases due to conflicting writes. NCC and NCC-RW can execute most naturally consistent transactions with low costs, even if they conflict. For instance, NCC-RW has more than 80% of the transactions passing the safeguard check and fewer than 10% of the transactions being aborted and retried from scratch. NCC-RW has a 50% higher peak throughput than d2PL-wound-wait because NCC-RW requires only two rounds of messages, while d2PL-wound-wait requires three. NCC-RW has higher peak throughput than NCC because

Figure 8: NCC’s performance with different write fractions (Google-WF), compared to serializable protocols (TAPIR-CC and MVTO), and under failures for the Google-F1 workload.

TPC-C has very few read-only transactions, which are also more likely to abort in NCC due to conflicting writes. Janus-CC’s performance benefits mostly come from unifying the transaction and replication layers and are less significant in a single-datacenter setting, especially after we made some TPC-C transactions multi-shot.

6.4 Additional Experiments

We show more experiments with Google-F1. We chose Google-F1 because it has both read-write and read-only transactions, while Facebook-TAO only has read-only transactions and non-transactional writes.

Varying write fractions. Figure 8a shows the throughput while increasing the write fraction. Each system is run at $\sim 75\%$ load according to Figure 7a. The y-axis is the throughput normalized to the maximum throughput of each system during the experiment. The higher the write fraction, the more conflicts in the system. The results show that NCC-RW is most resilient to conflicts because NCC-RW can exploit more concurrency in those conflicting but naturally consistent transactions, i.e., NCC has fewer aborts. In contrast, other protocols may falsely abort transactions due to failed validation (dOCC) or lock unavailability (d2PL variants). NCC’s read-only transactions are more likely to abort when writes increase because frequent writes cause the client to have stale knowledge of the most recently executed writes on each server; as a result, NCC must abort the reads to avoid timestamp inversion.

Comparing with serializable systems. Figure 8b compares NCC with MVTO and TAPIR-CC, which provide serializability, under Google-F1. NCC outperforms TAPIR-CC because NCC has fewer messages with its read-only transaction protocol. MVTO and NCC have similar performance under low and medium load because they have the same number of messages and RTTs. Under high load, MVTO outperforms NCC when many read-only transactions in NCC are aborted: MVTO never aborts reads because it is allowed to read stale versions, whereas NCC must read the most recent version and handle timestamp inversion. In this sense, MVTO presents a performance upper bound for strictly serializable systems, and NCC closely matches the upper bound.

Failure recovery. Figure 8c shows how well NCC-RW handles client failures under Google-F1. We inject failures 10 seconds into the experiment by forcing *all* clients to stop sending the commit messages of ongoing transactions while they continue issuing new transactions. Undelivered commit messages cause servers to delay the responses of later transactions due to response timing control, until the recovery mechanism is triggered after a timeout. We show two timeout values, 1 and 3 seconds. NCC-RW recovers quickly after failures are detected, thus client failures have a limited impact on throughput. In realistic settings, failures on one or a few clients would have a negligible impact because uncommitted reads do not block other reads. Similarly, NCC is minimally impacted by client failures because its read-only transactions do not send commit messages and thus never delay later writes.

7 Related Work

NCC proposes a new strictly serializable distributed protocol. This section places it in the context of existing strictly serializable techniques, single-machine concurrency control, and techniques that provide weaker consistency. At a high-level, NCC provides better performance, addresses a different problem setting, and provides stronger guarantees, compared to these categories of work, respectively.

General strictly serializable protocols. As discussed in Section 2.3, existing general strictly serializable protocols are d2PL, dOCC, TR, or their variants, suffering extra costs when transactions are naturally consistent. For instance, Spanner’s read-write transactions [12], Sinfonia [4], and Carousel [70] are variants of d2PL that must acquire locks. FaRM [15], FaRMv2 [60], RIFL [32] are variants of dOCC that suffer extra validation costs, even if they use timestamp-based techniques to reduce validation aborts. AOCC [2] is a variant of dOCC and operates in a data-shipping environment, e.g., data can move from servers to client caches, which is different from NCC which works in a function-shipping environment, i.e., data resides only on servers. Rococo [53] and its descendant Janus [54] reorder transactions to minimize aborts. Granola [13] requires an all-to-all exchange of timestamps between servers, incurring extra messages and RTTs. Our evaluation shows that NCC outperforms these techniques

System	Consistency	Technique	Latency (RTT)	Lock-free	Non-blocking	False aborts
NCC	Strict Ser.	NC+TS	1	Yes	Yes	Low
Spanner [12]	Strict Ser.	d2PL+TrueTime	RO: 1, RW: 2	RO: Yes, RW: No	No	RO: None, RW: Med
d2PL-NoWait	Strict Ser.	d2PL	1	No	No	High
AOCC [2]	Strict Ser.	dOCC	2	Yes	No	High
Janus [54]	Strict Ser.	TR	2	Yes	No	None
dOCC	Strict Ser.	dOCC	2	No	No	High
d2PL-WoundWait	Strict Ser.	d2PL	2	No	No	Med
FaRMv2 [60]	Strict Ser.	dOCC	2	No	No	Med
TAPIR [74]	Ser.	dOCC+TS	1	Yes	No	Med
DrTM [68]	Ser.	RO: TS, RW: d2PL	RO: 2, RW: 3	RO: Yes, RW: No	No	Med
TO [7]	Ser.	TS	1	Yes	No	Med
MVTO [57]	Ser.	TS	1	Yes	No	Low

Figure 9: The consistency and best-case performance of representative distributed protocols for naturally consistent workloads, processing one-shot transactions with possible optimizations considered. NC means natural consistency, and TS means timestamp-based technique. NCC has the lowest performance costs while providing strict serializability.

for real-world workloads where natural consistency is prevalent. When transactions are not naturally consistent, however, these techniques could outperform NCC. Figure 9 summarizes performance and consistency properties of NCC and some representative distributed systems.

Special strictly serializable techniques. In addition to the general techniques discussed above, there are several interesting research directions that use specialized techniques to provide strict serializability. Some work utilizes a centralized sequencer to enforce strict serializability [6, 19, 34, 37, 46, 58, 64, 75]. Because all transactions must contact the sequencer before execution (e.g., Eris [34]), in addition to the extra latency, the sequencer can be a single point of failure and scalability bottleneck. Scaling out sequencers incurs extra costs, e.g., Calvin [64] requires all-to-all messages among sequencers for each transaction (epoch). Some ensure strict serializability by moving all data a transaction accesses to the same machine, e.g., LEAP [36]. Some rely on program analysis and are application-dependent, e.g., the homeostasis protocol [59]. Some rely on extensive gossip messages for liveness, which lower throughput and increase latency, e.g., Ocean Vista [18] whose latency of a transaction cannot be lower than the gossiping delay of the slowest server even if this server is not accessed by the transaction. General techniques such as NCC do not have the above limitations.

Strictly serializable read-only transaction protocols. To the best of our knowledge, the only existing strictly serializable read-only transaction protocol that has optimal *best-case* performance is Spanner [12]. Spanner ensures strict serializability by using d2PL for read-write transactions and by using synchronized clocks (TrueTime) for read-only transactions. TrueTime must be accurately bounded for correctness and those bounds need to be small to achieve good performance, which are achieved by Google’s infrastructure using special hardware, e.g., GPS and atomic clocks [9] that are not generally available. For instance, CockroachDB [63], which

began as an external Spanner clone, chose not to support strict serializability because it does not have access to such infrastructure [26]. In contrast, NCC’s read-only transactions achieve optimal best-case performance and provide strict serializability, without requiring synchronized clocks.

Single-machine concurrency control. Concurrency control for single-machine databases is different from the distributed setting on which this paper focuses. First, some techniques are not feasible in a distributed setting. For instance, Silo [66] relies on atomic instructions, and MVTL [3] relies on shared lock state, which are challenging across machines. Second, most techniques, e.g., Silo [66] and TicToc [71], follow a multi-phase design and would be expensive if made distributed, e.g., they need distributed lock management and one round of inter-machine messages for each phase, which would be unnecessary costs for naturally consistent transactions. Their designs, however, are feasible and highly performant for the single-machine setting they target.

Protocols for weaker consistency. Many systems trade strong consistency for better performance. For instance, some settle for restricted transaction APIs, e.g., read-only and/or write-only transactions [16, 38, 39]. Some choose to support weaker consistency models, e.g., causal consistency and serializability [17, 33, 39, 40, 47, 63, 67, 72]. In contrast, NCC provides stronger consistency and supports general transactions, greatly simplifying application development.

8 Conclusion

Strictly serializable datastores are advocated by recent work because they greatly simplify application development. This paper presents NCC, a new design that provides strict serializability with minimal overhead by leveraging natural consistency in datacenter workloads. NCC identifies and overcomes timestamp inversion, a fundamental correctness pitfall in timestamp-based concurrency control techniques. NCC significantly outperforms existing strictly serializable techniques

and closely matches the performance of serializable systems.

A A Discussion on TAPIR

TAPIR’s novelty was a unified design of transaction and replication layers, and was not in the transaction layer in particular. Whether providing strict serializability or weaker serializability does not affect their contributions in the unified design. Our work identifies the cases where it is not strictly serializable and helps TAPIR users and the works inspired by TAPIR avoid the correctness violations caused by misassuming the consistency model. TAPIR’s authors confirmed our findings, i.e., TAPIR is not strictly serializable and is subject to timestamp-inversion.

A.1 TAPIR’s Read-Write Transactions

Here we summarize how TAPIR works, which is based on the TOCS version [74]. TAPIR is built on a multi-versioned data store. A transaction in TAPIR goes through three phases: execution, validation, and commit. In the execution phase, the transaction reads the data items in the read set from the servers, which return the most recently committed versions of each data item and their timestamps. Writes are buffered locally on the client. In the validation phase, TAPIR chooses a proposed timestamp for this transaction, which is the combination of the machine’s current physical time and the client identifier. The proposed timestamp is sent together with the validation messages to servers. When a server receives a validation message, it validates the transaction with the proposed timestamp. If all servers successfully validate the transaction, TAPIR will commit it; otherwise, it will abort the transaction.

Figure 10 shows the pseudocode of TAPIR’s validation mechanism, which is a screenshot of Figure 9 in the paper. TAPIR fails a read validation if the data item has newer versions than the one returned in the execution phase (lines 2, 3).

TAPIR's validation is lock-free. TAPIR accepts a write validation if both conditions are satisfied: 1. the write's proposed timestamp is greater than the maximum proposed timestamp of prepared-but-uncommitted reads on this data item (skipping lines 7, 8); and 2. the write's proposed timestamp is greater than the timestamp of the most recent version (skipping lines 9, 10).

In addition, TAPIR implements a third check: a write is aborted if there are any pending (prepared) conflicting writes. This third check was informed by the authors during our conversations and was not included in the paper.

A.2 A Counterexample

As shown in Figure 11, There are four transactions tx_1 , tx_2 , tx_3 , and tx_4 by three different users. tx_1 and tx_4 are from user U_1 ; tx_2 is from user U_2 ; and tx_3 is from user U_3 . (U_2 and U_3 are not shown in the figure.) W and R denote a write and a read request, respectively. U_1 issues transaction tx_1 which reads A and then reads B , and (if B returns 0, then) resets C to 0. Initially A , B , and C each store value 0 at timestamp 0. Meanwhile, U_2 issues tx_2 that updates B to 1, with W_2 . After U_2 is notified that tx_2 is committed, U_3 issues tx_3 which updates C to 2, with W_3 . Because tx_3 is issued after tx_2 was finished, tx_3 is in real-time after tx_2 , i.e., $tx_2 \xrightarrow{rt} tx_3$. tx_2 and tx_3 are blind writes only for simplicity, and the counterexample still holds if they are read-modify-writes. After tx_1 is committed, U_1 issues a read-only transaction tx_4 that reads B and C . The events of TAPIR processing these transactions happen in the following order:

1. U_1 starts tx_1 .
2. tx_1 reads A , reads B , and buffers W_{1C} locally.
3. tx_1 chooses a proposed timestamp, $t_1 = 8$.
4. tx_1 validates R_{1A} at A .
5. tx_1 validates R_{1B} at B .
6. U_2 starts tx_2 .
7. tx_2 sends W_{2B} to B and validates W_{2B} with a proposed timestamp, $t_2 = 10$.
8. tx_2 is committed and U_2 finishes tx_2 .
9. U_3 starts tx_3 .
10. tx_3 sends W_{3C} to C and validates W_{3C} with a proposed timestamp, $t_3 = 5$.
11. tx_3 is committed and U_3 finishes tx_3 .
12. tx_1 sends W_{1C} to C and validates W_{1C} .
13. tx_1 is committed and U_1 finishes tx_1 .
14. U_1 starts tx_4 .
15. tx_4 reads B and C and returns $B = 1$ and $C = 0$.
16. tx_4 validates $B = 1$ and $C = 0$ at B and C with a proposed timestamp, $t_4 = 20$.
17. tx_4 is committed and returns $B = 1$ and $C = 0$ to U_1 .

Figure 11: An execution of four transactions that may be accepted by TAPIR but violate strict serializability.

All tx_1 , tx_2 , tx_3 , and tx_4 are able to pass TAPIR's validation and commit. tx_1 's read validation on A succeeds because there are no other transactions accessing A . tx_1 's read validation on B succeeds because tx_2 has not started yet when tx_1 's validation message arrives at B . tx_2 is successfully validated and committed because both validation conditions (lines 7–12 in Figure 10) and the new assumption are met. Specifically, lines 7 and 8 are skipped because tx_2 has a greater timestamp ($t_2 = 10$) than the greatest prepared read timestamp ($t_1 = 8$); lines 9 and 10 are skipped because tx_2 's timestamp is larger than that of the latest version which is 0; the third check is met because there are no prepared writes at B . tx_3 is successfully validated and committed because when W_{3C} arrives at C , there are no other transactions. tx_1 's write on C succeeds because both validation conditions are met ($t_1 > t_3$, so lines 9 and 10 are skipped; no reads happened at C , so lines 7 and 8 are skipped), and the third check is met because W_3 has been committed when W_1 arrives and thus there are no conflicting prepared writes. Finally, tx_4 's reads are successfully validated and returned to the user because there are no transactions ongoing on B and C when tx_4 is executed and validated.

Strict serializability requires that there exists a total order among transactions, and the total order must respect the real-time ordering. Because tx_4 begins in real-time after tx_1 , tx_2 , and tx_3 end, it must be ordered last. This leaves 6 possible total orders, which are listed below along with an explanation of why they are not a legal strictly serializable order:

Total order	
tx_1, tx_2, tx_3 tx_1, tx_3, tx_2	Not legal because tx_4 observes tx_1 's write to C , not tx_3 's
tx_2, tx_1, tx_3	Not legal because tx_4 observes tx_1 's write to C , not tx_3 's, and because tx_1 observes the initial value of B , not tx_2 's
tx_2, tx_3, tx_1 tx_3, tx_2, tx_1	Not legal because tx_1 observes the initial value of B , not tx_2 's
tx_3, tx_1, tx_2	Not strictly serializable because tx_2 finishes in real-time before tx_3 starts

This counter-example shows that TAPIR admits executions that cannot form a total order that respects the real-time order. Therefore, TAPIR's read-write transaction protocol is not strictly serializable.

B A Discussion on DrTM

DrTM’s novelty was the first system that combined HTM and RDMA for distributed transaction processing. Our work identifies the cases where it is not strictly serializable and helps DrTM users and the works inspired by DrTM avoid the correctness violations caused by misassuming the consistency model. DrTM’s authors confirmed that our findings are correct, i.e., DrTM’s read-only transactions are subject to the timestamp-inversion pitfall.

B.1 DrTM’s Transaction Protocol

The discussion is based on DrTM’s original paper published in SOSP [68] and its extended version published in TOCS [11].

Read-write transactions. DrTM’s read-write transaction protocol is a variant of two-phase locking (2PL), which keeps write (exclusive) locks and replaces read (shared) locks with leases. A transaction first attempts to acquire write lock and/or read leases on remote machines using RDMA compare-and-set requests. We omit how write locks are managed because it is the same as that in standard 2PL. We focus on how read leases are managed.

Figure 12 shows the pseudocode for the high-level structure of a distributed read-write transaction in DrTM, which is a screenshot of Figure 3 in the SOSP version. Before a transaction starts, the issuing server generates a timestamp, *end_time*, which is the server’s current physical time plus a duration (1 ms for read-only and 0.4 ms for other transactions). Servers’ physical clocks are periodically synchronized using the precision time protocol. *end_time* is included in remote read requests of this transaction and specifies the time when the read leases will expire (if the reads are granted access to the records). A lease is considered expired if the server’s current clock value is greater than the lease’s *end_time* (with some *DELTA* for clock skew). On the remote server, a read request is granted access if the data record is not write-locked. If there is an existing lease, its *end_time* is extended to the request’s *end_time* if the latter is greater. The read request is then granted access. The *end_time* of the lease is also returned. To commit a transaction, the issuing server checks if write locks are successfully acquired and all read leases are still valid. The issuing server *assumes* read leases are still valid if its current local time is smaller than the minimum *end_time* in all read responses (with some *DELTA* for clock skew).

That is, a write is rejected only if the data record either is write-locked or has an active (unexpired) read lease; a read is rejected only if the record is write-locked. A read-write transaction is aborted only if either any read/write request was rejected or the issuing server’s clock value is greater than *end_time* upon commit.

Read-only transactions. A read-only transaction only involves leases since there are no writes in it. Figure 13 is a screenshot of the read-only transaction protocol (Figure 8 in the SOSP paper). The read-only transaction protocol is

```
START(remote_writeset, remote_readset)
//lock remote key and fetch value
foreach key in remote_writeset
    REMOTE_WRITE(key)

end_time = now + duration
foreach key in remote_readset
    end_time = MIN(end_time,
        REMOTE_READ(key, end_time))

XBEGIN() //HTM TX begin
READ(key)
if key.is_remote() == true
    return read_cache[key]
else return LOCAL_READ(key)

WRITE(key, value)
if key.is_remote() == true
    write_cache[key] = value
else LOCAL_WRITE(key, value)

COMMIT(remote_writeset, remote_readset)
//confirm all leases are still valid
if !VALID(end_time)
    ABORT() //ABORT: invalid lease

XEND() //HTM TX end

//write back value and unlock remote key
foreach key in remote_writeset
    REMOTE_WRITE_BACK(key, write_cache[key])
```

Figure 12: DrTM’s read-write transaction protocol, a screenshot of Figure 3 in the SOSP paper [68].

equivalent to the read-write transaction protocol with its write part taken out. Then, leases (timestamps) are used to order read-only transactions, i.e., they are ordered by *end_time*. A read-only transaction is aborted only if either any of its read was rejected or the issuing server’s clock value is greater than *end_time* upon commit.

B.2 A Counterexample

Figure 14 shows a counterexample where the read-only transaction may return system state that is not strictly serializable. There are three transactions tx_1 , tx_2 , and tx_3 , from users U_1 , U_2 , and U_3 , respectively. All transactions are distributed, and we omit local HTM transactions. U_1 is the DrTM server that starts tx_1 , and we omit showing U_2 and U_3 in the figure. Assume each server stores one data item for simplicity. Both A and B have an initial value of 0. tx_1 is a read-only transaction reading both servers A and B . (We combine RDMA-CAS and RDMA-READ as one message for simplicity.) tx_2 and tx_3 are single-key write transactions, having write requests, W_2 and W_3 , respectively. We make tx_2 and tx_3 blind writes only for simplicity, and the counterexample still holds if they are read-modify-writes. After tx_2 updates A to 1 and responds to U_2 , tx_3 is started by U_3 and updates B to 2, so tx_3 is after tx_2 in real time, i.e., $tx_2 \xrightarrow{rto} tx_3$. tx_1 is concurrent with both tx_2 and tx_3 , e.g., $R_1(A)$ arrives before tx_2 , and $R_1(B)$ arrives after tx_3 . Clk is the server’s physical clock time. ET is the *end_time* of a read lease. In this example, we use small integers for a simpler representation of clock values. The events of DrTM processing these transactions happen in the following order:

```

START_RO(readset)
  //lock key and fetch value (even local)
  L: end_time = now + duration
  foreach key in readset
    end_time = MIN(end_time,
      REMOTE_READ(key, end_time))

  //confirm all leases are still valid
  if !VALID(end_time)
    goto L //RETRY: invalid lease

READ_RO(key)
  return read_cache[key]

```

Figure 13: DrTM’s ro transaction protocol, screenshot of Fig 8 in the SOSp paper [68].

1. U_1 starts tx_1 , at its clock time 1, and sets end_time 8.
2. $R_1(A)$ arrives at A , at A ’s local time 7, and starts a read lease on A with an end_time of 8.
3. tx_2 arrives at A , at A ’s local time 9, and is granted the write lock.
4. tx_2 commits and releases the write lock on A .
5. tx_3 is started and arrives at B , and is granted the write lock.
6. tx_3 commits and releases the write lock on B .
7. $R_1(B)$ arrives at B , at B ’s local time 5, and starts a read lease on B with an end_time of 8.
8. U_1 commits tx_1 at its local time 7, and returns $A = 0$ and $B = 2$.

All transactions in the execution are able to commit in DrTM. $R_1(A)$ is able to hold a lease on A because there is no active lease or lock on A when it arrives and because A ’s local time is 7, smaller than the lease’s end_time 8. tx_2 is able to acquire the write lock because there is no write lock on A and the read lease of $R_1(A)$ has expired at time 9. tx_3 is able to acquire the write lock on B because there is no active lease or lock on B when it arrives. $R_1(B)$ can hold a lease on B because there is no write lock, e.g., tx_3 has released it, and B ’s local time is 5, smaller than the end_time 8. tx_1 is committed by U_1 because both reads hold the leases and because U_1 “believes” the read leases are still valid at the commit time 7, which is smaller than the end_time 8.

Strict serializability requires there is a total order of transactions and the total order respects the real-time order. For instance, because tx_2 is before tx_3 in real time, a total order is legal only if tx_2 is before tx_3 in the total order. DrTM’s execution constructs a total order of $tx_3 \xrightarrow{exe} tx_1 \xrightarrow{exe} tx_2$, because tx_1 observes tx_3 ’s state but not tx_2 ’s. However, this total order violates the real-time order: $tx_2 \not\xrightarrow{rt} tx_3$. Therefore, DrTM’s read-only transactions are not strictly serializable. DrTM’s authors believe that synchronized clocks such as TrueTime must be used (and the protocol needs update accordingly to work with TrueTime) to make the clock skew *DELTA relative to the ground truth of time* to be accurately captured in order to possibly avoid the above counterexample from happening.

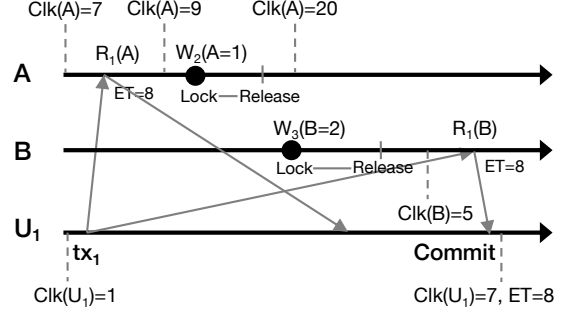

Figure 14: An execution of three transactions that would be accepted by DrTM but violate strict serializability.

C Supporting Complex Transaction Logic

NCC supports complex logic, e.g., a transaction accesses the same key multiple times via read-modify-writes and repeated reads/writes, by treating its requests to the same key as a single logical operation.

Read-modify-write. If a read-modify-write has its read and write requests executed consecutively (i.e., they are not intersected by other writes), then only the write response is checked by the safeguard, treating read-modify-write as one logical request; otherwise, it is aborted if there are intersecting writes, e.g., when the most recent version has a t_w greater than that returned by the read of this read-modify-write. The response of the read is not sent (thus the modify-write part will not start) until it is allowed by response timing control. After the modify-write part is executed, its write response is inserted right after the read response of the same read-modify-write, and sent back to the client immediately. This is safe because its read response has satisfied all real-time dependencies and was safely sent by response timing control, so its own write response is also safe to send together with the read response. In the commit phase, the client sends commit/abort messages for both read and write requests in the read-modify-write to the servers.

Read-after-write. When the transaction writes to a key and then later reads the same key, NCC does not send a request to the server for the read. Instead, the client feeds the read with the value of its own earlier write to the key, and buffers the read locally. For read-after-write, the safeguard only checks the write response (together with the responses of the other requests of this transaction) for consistency, and the result of the read (which is the value of its own write) will be returned at the end to the user when the transaction is committed.

Repeated reads and repeated writes. When the transaction reads/writes the same key multiple times, these requests are executed, checked (by the safeguard and smart retry), and committed/aborted normally, following NCC’s protocol.

D Details on Failure Handling

This section presents the details of how NCC handles client failures. In particular, we must handle the scenario where the

```

1 record # record kept by each tx
2 txs[tid] # ongoing transactions indexed by tx id
3
4 function handle_failure(tx):
5     if tx.record.status == uncleared; then
6         tx.record.status = aborted # avoid deadlocks
7         AsyncCommitOrAbort(tx, 'aborted') # Algorithm 5.2
8         return
9     if tx.record.coord == this_svr; then # coordinator
10         status = resolve_status(tx)
11     else # cohort
12         status = resolve_status_coord(tx.tid)
13     if status == uncleared; then
14         return # do nothing
15     else # finalize this tx
16         AsyncCommitOrAbort(tx, status) # Algorithm 5.2
17
18 function resolve_status(tx):
19     if tx.record.status != cleared; then
20         return tx.record.status
21     records = {}
22     for svr in tx.record.cohorts; do # RPC to cohorts
23         record = svr.get_record(tx.tid)
24         records.add(record)
25     for record in records; do
26         if record.status == committed; return committed
27         if record.status == aborted; return aborted
28         if record.status == uncleared; return uncleared
29     # all parts in tx are cleared
30     # reconstruct client decision
31     # with record's {(tw, tr)} field
32     invoke lines 8--16 in Algorithm 5.1
33
34 function get_record(tid):
35     if txs.find(tid) == nil; then
36         record = {}; record.status = aborted
37         return record
38     tx = txs[tid]
39     return tx.record
40
41 function resolve_status_coord(tid):
42     if txs.find(tid) == nil; then return aborted
43     tx = txs[tid]
44     return resolve_status(tx)

```

Figure 15: NCC client failure handling.

client has made a commit (or abort) decision for a transaction and sent its results to the user, but failed before (during) sending the commit/abort messages to the servers. NCC must make servers arrive at the same commit/abort decision as the client would if the client did not fail, i.e., making the final state consistent with what was returned to the user. Figure 15 shows the pseudocode.

Each transaction keeps a *record* that consists of four fields: *status*, $\{(t_w, t_r)\}$, *coord*, and *cohorts* (line 1). *status* stores the current status of the transaction: *uncleared*, *cleared*, *committed*, or *aborted*. When a transaction arrives at the server for the first time, its *record* is created with *status* initially being *uncleared*. *status* is changed to *cleared* when the server has received the last-shot requests of the transaction (a flag, *IS_LAST_SHOT*, in the requests indicates the last shot) and the responses of this transaction are ready to be sent by re-

sponse timing control. That is, *status* is cleared when a transaction has finished its logic and is ready to commit or abort. *status* is changed from cleared to either committed or aborted when the server has received the commit messages. *status* is changed from uncleared to aborted when this transaction early aborts to avoid indefinite waits. When *status* is aborted, future requests of this transaction are ignored.

$\{(t_w, t_r)\}$ stores the set of (t_w, t_r) pairs in request responses. *coord* stores the identity of the backup coordinator, which is chosen by the client and is typically one of the servers the transaction accesses. *cohorts* stores the identities of the other participant servers this transaction accesses. The identity of the backup coordinator is piggybacked on each request. The identities of cohorts are sent to the backup coordinator in the last shot. The client will not start the commit phase, e.g., the safeguard check, until it has received the responses of the last-shot requests/messages.

After a *record* is created for a transaction, a function, *handle_failure*, is registered and a timer starts. *handle_failure* is invoked every time a timeout t fires. The system suspects the client failed if the server has not received the commit messages within time t . The timer is canceled and *handle_failure* is deleted when the transaction is committed or aborted. Our evaluation shows two values for t , 1 and 3 seconds.

If *status* is still uncleared when *handle_failure* is invoked, *status* is set to aborted and we abort this transaction. (*handle_failure* will not be invoked if this transaction has been committed or aborted.) It is safe to unilaterally abort an uncleared transaction because the client must have not received all responses and thus must have not made a commit/abort decision. (For details, see the proof in Appendix E.4.) If the server is the backup coordinator, then it resolves the final decision of this transaction by contacting the cohorts with *get_record* RPCs (lines 9–10, 22–24). When a cohort receives a *get_record* request, it returns what it knows about this transaction. For instance, if the cohort does not have a *record* for this transaction, which means it has not received the requests, it returns *status = aborted* (lines 35–37). Otherwise, the cohort returns the *record* of this transaction.

After receiving all the responses of *get_record*, the coordinator resolves the final decision. If any cohort replies committed, it commits this transaction (line 26). If any cohort replies aborted, it aborts this transaction (line 27). If any cohort replies uncleared, it does nothing in this round of *handle_failure* and restarts the timer (lines 28, 13, 14). If all cohorts reply cleared, which means all participant servers are waiting for the commit messages from the possibly-failed client, the coordinator reconstructs the client decision deterministically based on the same inputs used in transaction execution. That is, the coordinator invokes the same safeguard check with the same (t_w, t_r) pairs and smart retry if necessary (lines 29–32). Note that, if the client did a smart retry and it succeeded, then a re-issued smart retry by the coordinator must succeed; if the earlier smart retry failed, then the

re-issued one must also fail. This is because the timestamps are in the past and have already been properly updated by the original smart retrieved. Due to deterministic computation, the coordinator must arrive at the same commit/abort decision for this transaction as the client would have if it did not fail.

When a cohort receives a message that invokes *handle_failure* to a transaction, the transaction is aborted if it is still uncleared. Otherwise, the cohort sends a *resolve_status_coord* request to the backup coordinator (line 12). When the coordinator receives the request, it goes through the *resolve_status* logic, which could then send *get_record* requests to all cohorts for resolving the decision (lines 41–44). When the cohort receives the response of *resolve_status_coord*, it commits or aborts the transaction accordingly (lines 15, 16). If the response is uncleared, then it does nothing in this round of *handle_failure* (lines 13, 14).

NCC’s failure handling guarantees that the backup coordinator always makes the same decision for a transaction as the client would have if the client did not fail. We present a formal proof of correctness in Appendix E.4.

E Proof of Correctness

This section provides a correctness proof of NCC. We prove that NCC is safe, i.e., it guarantees strict serializability, and is live, i.e., transactions eventually terminate. We also prove that the failure handling mechanism is safe and live. We first state some preliminaries (§E.1) and then provide a proof summary (§E.2) followed by the main proof (§E.3 and §E.4).

E.1 Preliminaries

System model. We adopt a system model similar to that used in FLP [20]. A distributed datastore is modeled as a set of N processes, P_1, P_2, \dots, P_n . We denote the set of front-end client machines by c and the server machines that store the data by S . Processes communicate by sending and receiving messages.

Transaction processing is modeled as I/O automata: each process (either a server or a client) is an automaton that implements a deterministic state machine. Upon receiving a message, a process does local computation based on its current state and the message input, then moves to the next state and sends out one or more output messages. For instance, upon receiving a transaction request (input message), the server executes this request against its current state by either reading or modifying the data and associated metadata according to the transaction protocol (local computation and state transition), and then sends the response to the client (output message).

For simplicity and clarity, we consider local computation, e.g., executing a transaction request, as one atomic step even though they could consist of a sequence of sub-state transitions in general, e.g., memory updates, disk updates, etc.

Assumptions. Our system model assumes the following:

- A₁. The system network is reliable: messages are eventually delivered, guaranteed by most distributed datastores.

- A₂. Each process (e.g., a server or a client) has a physical clock that is not perfectly synchronized. Clocks can be loosely synchronized, e.g., via NTP [50].

- A₃. Both clients and servers can fail. Failure handling was discussed in Section 5.6 and Appendix D.

E.2 Proof Summary

The proof consists of two parts. The first part (§E.3) proves that NCC ensures strict serializability and is live. Specifically, Lemma 1 proves that committing all parts of each transaction at the same timestamp, i.e., the one intersecting all returned (t_w, t_r) pairs, guarantees a total order. In particular, this total order is aligned with the numerical order of timestamps. Lemma 2 proves that NCC satisfies the real-time order by proving that if a transaction is included in a consistent snapshot, then all transactions that in real-time precede it are included in the snapshot. Lemma 3 proves liveness by demonstrating that early aborts ensure it is impossible for responses to circularly wait on each other during RTC. The second part (§E.4) proves that client failure handling is safe and live by proving three invariants enforced by the protocol.

E.3 Correctness of NCC

Definition E.3.1 (execution order). We define the execution order between transactions (requests) as follows. Two requests from different transactions $req_1 \xrightarrow{\text{exe}} req_2$ if any of the following happens: req_1 creates some data version v_i and req_2 reads v_i ; req_1 reads some data version v_j and req_2 creates v_j ’s next version that is after v_j ; or req_1 creates some data version v_k and req_2 creates v_k ’s next version that is after v_k . Two transactions $tx_1 \xrightarrow{\text{exe}} tx_2$ if there exist req_1 and req_2 from tx_1 and tx_2 , respectively, such that $req_1 \xrightarrow{\text{exe}} req_2$. Execution order is transitive in that if $tx_1 \xrightarrow{\text{exe}} tx_2$ and $tx_2 \xrightarrow{\text{exe}} tx_3$, then $tx_1 \xrightarrow{\text{exe}} tx_3$. Execution order represents the order in which transactions take effect.

Definition E.3.2 (total order). We construct a Directed Serialization Graph (DSG) [1], which presents the execution order between transactions. Vertices in a DSG are all committed transactions in the system. A directed execution edge is drawn from transaction tx_1 to tx_2 if $tx_1 \xrightarrow{\text{exe}} tx_2$. Thus, we use the same symbol, $\xrightarrow{\text{exe}}$, to denote both the execution order between transactions and the execution edge in a DSG. Then, $tx_1 \xrightarrow{\text{exe}} tx_2$ denotes a directed path in the DSG from tx_1 to tx_2 . All committed transactions construct a total order if and only if their DSG is acyclic, i.e., the following invariant holds:

$$\text{Inv_total: } \forall tx_1, tx_2 (tx_1 \xrightarrow{\text{exe}} tx_2 \implies \neg(tx_2 \xrightarrow{\text{exe}} tx_1))$$

Definition E.3.3 (real-time order). The lifetime of a transaction tx starts with its invocation, $\text{INV}(tx)$, i.e., when the client sends out the transaction requests to servers, and ends with its response, $\text{RESP}(tx)$, i.e., when the user has received the results of the transaction from the client. Two transactions, tx_1 and tx_2 , have a real-time ordering relationship if

tx_2 's invocation happens in real-time after tx_1 's response, i.e., $tx_1 \xrightarrow{rto} tx_2$. We construct Real-time Serialization Graphs (RSGs) [1], which augment DSGs by introducing a real-time edge from transaction tx_1 to tx_2 if $tx_1 \xrightarrow{rto} tx_2$. We use \xrightarrow{rto} to denote both the real-time ordering between transactions and the real-time edge in an RSG. The real-time ordering requirement of strict serializability requires that if $tx_1 \xrightarrow{rto} tx_2$, then tx_1 must be ordered before tx_2 in the total order. That is, the following invariant holds:

Inv_realtime: $\forall tx_1, tx_2 (tx_1 \xrightarrow{rto} tx_2 \implies \neg(tx_2 \xrightarrow{exe} tx_1))$

Definition E.3.4 (strict serializability). A concurrency control protocol guarantees strict serializability if and only if there exists a total order among all transactions (Definition E.3.2), and the total order respects the real-time order (Definition E.3.3). That is, for any execution allowed by the protocol, both **Inv_total** and **Inv_realtime** hold.

Lemma 1. *Natural Concurrency Control (NCC) guarantees a total order among transactions (**Inv_total**).*

Proof. We prove by contradiction. Assume that there exist committed transactions tx_1 and tx_n such that $tx_1 \xrightarrow{exe} tx_n$ and $tx_n \xrightarrow{exe} tx_1$. Then, there exist a chain of committed transactions such that $tx_1 \xrightarrow{exe} tx_2 \xrightarrow{exe} \dots \xrightarrow{exe} tx_{n-1} \xrightarrow{exe} tx_n$, by $tx_1 \xrightarrow{exe} tx_n$ and Definition E.3.1. Let $\{(t_{wi}, t_{ri})\}$ be the set of returned timestamp pairs for each transaction i , where $i \in [1, n]$. Because all transactions in the chain are committed, $\{(t_{wi}, t_{ri})\}$ must overlap for each transaction tx_i , by NCC's commit protocol, i.e., the safeguard and smart retry logic. Let t_{ci} be the greatest t_w that intersects $\{(t_{wi}, t_{ri})\}$. t_{ci} is the commit timestamp (or synchronization point) of tx_i .

Consider $tx_1 \xrightarrow{exe} tx_2$. Then, there exist req_1 and req_2 in tx_1 and tx_2 , respectively, such that $req_1 \xrightarrow{exe} req_2$, by Definition E.3.1. Let (t_{w1}, t_{r1}) and (t_{w2}, t_{r2}) be the returned timestamp pairs of req_1 and req_2 , respectively. There are three cases, by Definition E.3.1 and NCC's protocol.

Case 1: req_1 is a write and req_2 is a write, then $t_{w1} = t_{r1} < t_{w2} = t_{r2}$. Case 2: req_1 is a read and req_2 is a write, then $t_{w1} \leq t_{r1} < t_{w2} = t_{r2}$. Case 3: req_1 is a write and req_2 is a read, then $t_{w1} = t_{r1} = t_{w2} \leq t_{r2}$. Thus, we can derive $t_{w1} \leq t_{r1} \leq t_{w2} \leq t_{r2}$. Because $t_{w1} \leq t_{c1} \leq t_{r1}$ and $t_{w2} \leq t_{c2} \leq t_{r2}$ where t_{c1} and t_{c2} are the commit timestamps of tx_1 and tx_2 , respectively, we have $t_{c1} \leq t_{c2}$. By applying the same argument to the rest of the chain: $tx_2 \xrightarrow{exe} \dots \xrightarrow{exe} tx_{n-1} \xrightarrow{exe} tx_n$, we can derive $t_{c1} \leq t_{c2} \leq \dots \leq t_{cn}$, which implies $t_{c1} \leq t_{cn}$.

Similarly, by applying the same argument to the assumption $tx_n \xrightarrow{exe} tx_1$, we can derive $t_{cn} \leq t_{c1}$. This implies that $t_{c1} = t_{cn}$. Given $t_{c1} = t_{cn}$ and $tx_1 \xrightarrow{exe} tx_n$, there must exist req_1 and req_n in tx_1 and tx_n , respectively, such that $req_1 \xrightarrow{exe} req_n$, by NCC's protocol, and $t_{w1} = t_{wn} = t_{c1} = t_{cn}$, by the definition of t_c and E.3.1. Then, req_1 and req_n must be a write and a read, respectively, by NCC's protocol (because only reading a write can result in the latter request, i.e., the read, returning the same timestamp pairs as the former request, i.e., the write).

Similarly, because $t_{cn} = t_{c1}$ and $tx_n \xrightarrow{exe} tx_1$, we can derive that there must exist req'_n and req'_1 in tx_n and tx_1 , respectively, such that $t'_{wn} = t'_{w1} = t_{c1} = t_{cn}$, where req'_n and req'_1 are a write and a read, respectively. Then, $t_{w1} = t'_{wn}$, which is impossible because t_{w1} and t'_{wn} are the returned t_w of write requests req_1 and req'_n , respectively, and writes from different transactions must have distinct timestamps, i.e., NCC's timestamps are unique. Because all four cases lead to contradictions, we have proved the lemma is true. ■

Lemma 2. *NCC guarantees the real-time ordering between transactions (**Inv_realtime**).*

Proof. We prove by contradiction. Let tx_1 and tx_2 be two arbitrary transactions. Let t_1 be the time when $RESP(tx_1)$ happens and t_2 be the time when $INV(tx_2)$ happens. Without loss of generality, we assume tx_1 is in real-time before tx_2 , i.e., $t_1 < t_2$ (Definition E.3.3). Assume for the sake of contradiction that $tx_2 \xrightarrow{exe} tx_1$. Then, there exists a set of k transactions $tx_{i1}, tx_{i2}, \dots, tx_{ik}$, such that $tx_2 \xrightarrow{exe} tx_{i1} \xrightarrow{exe} tx_{i2} \xrightarrow{exe} \dots \xrightarrow{exe} tx_{ik} \xrightarrow{exe} tx_1$, for $k \geq 0$ (Definition E.3.1). Then, for each transaction tx , there exist two requests req and req' (not necessarily distinct), such that $req'_2 \xrightarrow{exe} req_{i1}, req'_{i1} \xrightarrow{exe} req_{i2}, \dots, req'_{ik} \xrightarrow{exe} req_1$, by Definition E.3.1. For each request, let t_u and t_v be the physical (real) time when the server sends its response and receives a commit message, respectively. Then, $t'_{v2} < t_{u(i1)}, t'_{v(i1)} < t_{u(i2)}, \dots, t'_{v(ik)} < t_{u1}$, by response timing control. Specifically, tx_2 and tx_{i1} must access at least one common data item by the definition of " \xrightarrow{exe} ", and thus RTC ensures that tx_{i1} will not be responded until tx_2 is committed/aborted. Because the server can receive the commit messages only after responses of all requests have been received by the client, $t_u < t_v$ for any pair of requests, req and req' , in the same transaction. Thus, $t_{u2} < t'_{v2} < t_{u(i1)} < t'_{v(i1)} < t_{u(i2)} < \dots < t'_{v(ik)} < t_{u1}$. Thus, $t_{u2} < t_{u1}$. Because $t_2 < t_{u2}$ and $t_{u1} < t_1$, we can derive $t_2 < t_{u2} < t_{u1} < t_1$, which implies $t_2 < t_1$, contradicting the assumption, $t_1 < t_2$. Therefore, the lemma is true. ■

Lemma 3. *NCC transactions do not prevent each other from making progress, i.e., they eventually commit or abort.*

Proof. Waiting happens only to server responses due to response timing control, i.e., the sending of a response waits until its real-time dependencies are met (§5.2). Because response queues are kept one per key, circular waiting is only possible when a transaction tx_1 is executed before tx_2 on one key but after tx_2 on another key and they have write conflicts on both servers, i.e., interleaved read-write or write-write conflicts. However, we prove that at least one transaction must abort and thus break the cycle of waiting.

Let tx_1 and tx_2 be interleaved read-write transactions that both access keys A and B . Without loss of generality, let tx_1 arrive before tx_2 on key A and after tx_2 on key B . Suppose there is at least one write on each server by these two transactions, so circular waiting is possible. Because tx_1 and tx_2

are interleaved and have write conflicts, they must be both waiting for each other to be committed/aborted. Let t_1 and t_2 be the pre-assigned timestamps of tx_1 and tx_2 , respectively. Without loss of generality, assume $t_1 < t_2$ (timestamps are all unique). Then, tx_1 must abort early on B because tx_1 arrives later and has a smaller timestamp, while tx_2 has not been committed/aborted, by NCC's protocol (specifically, the logic of early aborts). Therefore, circular waiting is not possible in NCC. Because read-only transactions never block later writes, i.e., they do not insert responses into the response queues or send commit messages, they do not cause other writes to wait. Moreover, read-only transactions eventually commit/abort because their responses only wait for the preceding writes, which will eventually commit/abort, as argued above. ■

Proof of NCC. We have proved that Natural Concurrency Control (NCC) guarantees strict serializability by proving that it ensures a total order (Lemma 1) and the total order respects the real-time order (Lemma 2). We also have proved that NCC is live by proving that it is impossible for transactions to depend on each other while no transaction can proceed to commit/abort (Lemma 3). ■

E.4 Correctness of Client Failure Handling

This section proves the correctness of failure handling by proving that the following invariants always hold for any transaction tx when *handle_failure* is triggered, i.e., tx 's client either fails or is very slow. (Unspecified line numbers referenced in the proof are those in Figure 15.)

- I_1 . If the client has not made a commit/abort decision for tx , i.e., tx has not entered its commit phase, then tx will eventually abort, i.e., there are no dangling transactions on servers.
- I_2 . If the client has decided to commit/abort tx , then tx will always be committed or aborted by the servers following the client's decision.
- I_3 . Failure handling is live, i.e., tx does not prevent concurrent transactions issued by either healthy or failed clients from making progress. That is, transactions will eventually commit or abort when failures are present.

Lemma 4. *Invariant I_1 always holds.*

Proof. Let C be the client that fails and tx be an arbitrary transaction by C when C fails. Assume tx has not entered the commit phase. Then, either tx has not finished executing its logic or C has not received all of the server responses. That is, at least one of the following cases must occur, corresponding to each of the three dependencies.

Case 1: There exists at least one server S , such that tx accesses S but S has not received tx 's last-shot request. Then, tx 's *record* does not exist on S if tx is a one-shot transaction, or tx 's *record* must have uncleared *status* if tx is a multi-shot transaction because *status* is cleared only after a transaction

has received requests for all shots. Then, in either case, tx will abort (lines 5, 35, 42).

Case 2: There exists at least one read r in tx , such that r waits for version v , which was created by write w of another transaction, to be committed (Dependency D_1). Then, tx 's *status* must be uncleared because r 's response is not ready to be sent. Then, S will abort tx (lines 5–8). By a similar argument to Case 1, the decision of aborting tx will be passed to tx 's cohorts.

Case 3: There exists at least one write w in tx , such that w is waiting for preceding transactions to commit/abort (Dependency D_2 and D_3). Similar to the argument in Case 2, tx will abort, and the decision will be passed to the cohorts.

According to the above three cases, covering the three dependencies, tx will eventually abort on all its participant servers. Therefore, the lemma is true. ■

Lemma 5. *Invariant I_2 always holds.*

Proof. Let C be the client that fails and tx be an arbitrary transaction by C when C fails. Assume that tx has entered the commit phase, and C has made a commit/abort decision for tx . Then, there are two cases.

Case 1: C made a commit decision for tx . Because tx is committed, tx must pass the safeguard check. Then, all servers involved in tx must have sent the responses, which include (t_w, t_r) pairs. Let S be an arbitrary server that is involved in tx . If S had received tx 's commit/abort message before C failed, then *handle_failure* is not triggered on S since failure timeout is cancelled upon receiving the commit/abort message. tx 's *status*, which is committed, will be passed to the other participant servers when S is queried via *get_record* and *resolve_status_coord*. If S did not receive tx 's commit/abort message before C failed, then tx 's *status* on S must be cleared. If S is the coordinator, then *get_record* will be triggered to query the cohorts. If any of the cohorts return committed, then S will commit tx . Otherwise, if all cohorts reply cleared, then S will invoke the same safeguard check logic to reconstruct the decision for tx (lines 29–32). Because the set of input and the safeguard logic are the same as those used by C , S will derive the same decision for tx as C , which is committed, by the fact that the computation is deterministic.

Case 2: C made an aborted decision for tx . By the same arguments in Case 1, we can derive that S will make the same decision for tx as the client C , which is to abort.

Because S makes the same commit or abort decision for tx as the client would make, the lemma is true. ■

Lemma 6. *Invariant I_3 always holds.*

Proof. We have proved that NCC is live without failures (Lemma 3). When client failures are present, an affected transaction tx could block future transactions during *handle_failure*. That is, tx cannot be committed/aborted until *handle_failure* is done, and future transactions cannot be committed/aborted before tx commits/aborts due to response timing

control. We will prove that such situation is impossible. There are four cases while resolving *tx*'s *status* via *handle_failure*.

Case 1: *tx*'s *status* is committed on at least one participant server (coordinator or cohort). Then, this *status* will be passed to the other servers via *resolve_status_coord* and *get_record* (lines 34, 41). Then, *tx* will be committed on all servers, thus unblocking future transactions.

Case 2: *tx*'s *status* is aborted on at least one participant server (coordinator or cohort). Then, *tx* will abort on all servers by the same argument in Case 1, thus unblocking future transactions.

Case 3: *tx*'s *status* is cleared on all servers. Then, the coordinator will reconstruct the client decision for *tx* by invoking the safeguard check, which will make *tx*'s final *status* be either committed or aborted (lines 29–32). This reconstructed decision will be passed to the cohorts, which will commit/abort *tx* accordingly and unblock future transactions.

Case 4: *tx*'s *status* is unclear on at least one server. Then, *tx*'s *status* will eventually become aborted on this server when *handle_failure* is invoked (lines 5–8). This final *status* will be passed to the other servers via either *resolve_status_coord* or *get_record*. Therefore, *tx* will be eventually aborted on all participant servers, thus unblocking future transactions.

Because *tx*'s *status* is eventually resolved in all cases, *tx* will not prevent other transactions from making progress. ■

Proof of failure handling. Because all three invariants always hold, NCC's client failure handling is safe and live. ■
