ABSTRACT

Cyanides, ranging from three carbon atoms to PAHs, and alkenyl compounds are abundant in the interstellar medium (ISM). Aminoacrylonitrile (3-Amino-2-propenenitrile, $\text{H}_2\text{N}-\text{CH}=\text{CH}-\text{C}\equiv\text{N}$), an alkenyl cyanide, thus represents a promising candidate for new interstellar detection. A comprehensive spectroscopic laboratory investigation of aminoacrylonitrile in its rotational ground vibrational state has been herein performed. The measurements carried out up to the THz regime made it possible to generate a precise set of reliable rest frequencies for its search in space up to sub-millimetre wavelengths. The Z-aminoacrylonitrile (Z-apn) isomer spectrum has been recorded employing a source-modulated sub-millimetre spectrometer, from 80 GHz to 1 THz. A combination of Doppler and sub-Doppler measurement regimes allowed to record 600 new lines. The collected data have enabled the characterisation of a set of spectroscopic parameters up to decic centrifugal distortion constants. The catalogue generated from the improved spectral data has been used for the search of Z-apn in the spectral survey of the G+0.693-0.027 molecular cloud located in the central molecular zone, in the proximity of the Galactic centre.

1. INTRODUCTION

Scientists have proposed many theories in order to explain the origin of life. According to one of the most widely accepted, it may have originated from the self-catalytic function of an RNA chain, an idea originally proposed by Gilbert 1986 and currently known as the RNA-world. However, how the RNA and subsequently life were formed still remains unknown. Among the various hypotheses, it is possible to outline two main lines of thought. Life could have emerged starting from precursors of biomolecular building blocks synthesised *in situ*, during our planet’s cooling. Successive RNA polymerization could have then emerged in warm little ponds as a result of condensation of lightning synthesised abiotic precursors (Pearce et al. 2022), produced in a Urey-Miller experiment fashion (Miller 1953). Another hypothesis is that prebiotic compounds might have had an extraterrestrial origin. The prebiotic material could have been formed in the interstellar medium (ISM), and subsequently delivered to Earth to give rise to more complex molecules (Oparin 1957, Chyba & Sagan 1992). Pristine building blocks synthesized in the ISM would have been inherited by interplanetary dust particles, comets, and meteorites that in later stages might have acted as carriers of those seeds essential for life ignition (Chyba et al. 1990, Altwegg et al. 2016, Rivilla et al. 2020a).

Only in the last stages, molecules might have started to self-organize and replicate on Earth, giving rise to life as we know it.

Clues about prebiotic precursors’ origin come from the composition of celestial bodies. Carbonaceous chondrites, considered among the youngest objects formed along with the formation of planetary systems, have been found rich in sugar-like compounds, long-chain monocarboxylic acids, amino acids, and nucleobases precursors, such as purines and pyrimidines (Stoks & Schwartz 1979, Pizzarello et al. 2006, Burton et al. 2012, Oba et al. 2022). Following the work by Bockelée-Morvan et al. (2000), further evidence of the partial inheritance of volatile composition from prestellar and protostellar evolution phases to cometsimals and planetesimals, came from the PILS¹ project. With the data therein obtained, Drozdovskaya et al. (2019) were able to outline the correlation existing among CHO-, N-, and S-bearing molecules between the low-mass protostar IRAS 16293-2422, a homologue of our protosolar system, and the bulk composition of the comet 67P/Churyumov-Gerasimenko. Analogously, Öberg et al. (2015) observed a correlation between abun-

dances of interstellar Complex Organic Molecules (iCOMs) in comets and protoplanetary disks and many detections of several key precursors of the RNA world sustain such an idea (e.g. Zeng et al. 2019, Jiménez-Serra et al. 2020, Rivilla et al. 2022a).

Although the chemical processes of such systems are being studied extensively, our knowledge is still limited by what has been therein identified. Predictions of current abundances rely on observations, and since physical conditions are time-dependent we might still miss a large portion of information (Herbst & van Dishoeck 2009). The identification of new molecules can expand our chemical and physical insight of star-forming regions, and iCOMs have been proved to be excellent probes. Precise identification of ISM chemical species thus remains a crucial point to understand these environments.

In this study, we focused on 3-Amino-2-propenenitrile ($\text{H}_2\text{N}-\text{CH}=\text{CH}-\text{C}\equiv\text{N}$, Aminoacrylonitrile or apn, from here on), a promising candidate that could take part in the chemical network leading to amino-acids formation. Previous works (Miller & Orgel 1974; Sanchez et al. 1966; Kitadai & Maruyama 2018) suggested that in the liquid phase, this molecule might be one of the key steps leading to two α -amino acids Asparagine and Aspartic acid. Apn is the adduct of ammonia to cyanoacetylene ($\text{H}-\text{C}\equiv\text{C}-\text{CN}$, firstly detected in space by Turner 1971), and is a member of the ISM well represented cyanide group. Cyanides represent one of the most abundant families in the ISM, and are a key molecular precursors of prebiotic chemistry (Rivilla et al. 2022b). In recent years several prebiotic species have been detected (e.g. cyanomethanimines by Zaleski et al. 2013, Rivilla et al. 2019 and glyconitrile by Zeng et al. 2019). In 2021 alone, among closed shell molecules, 1-cyano-1,3-cyclopentadiene ($\text{c}-\text{C}_5\text{H}_5\text{CN}$, McCarthy et al. 2021), HC_{11}N

(Loomis et al. 2021), trans-cyanovinylacetylene and vinylcyanoacetylene ($\text{HC}\equiv\text{CCH}=\text{CHC}\equiv\text{N}$ and $\text{H}_2\text{C}=\text{CHC}\equiv\text{N}$, respectively, Lee et al. 2021a), 2-cyanocyclopentadiene ($\text{C}_5\text{H}_5\text{CN}$, Lee et al. 2021b), cyano thioformaldehyde ($\text{HC}-\text{SCN}$, Cernicharo et al. 2021) and cyanoacetyleneallene ($\text{H}_2\text{CCCHC}_3\text{N}$, Shingledecker et al. 2021) were detected; among open shell molecules, cyanomidyl radical (HNCN , Rivilla et al. 2021a), 3-cyano propargyl radical (CH_2CCCN , Cabezas et al. 2021) and Magnesium radicals (MgC_5N , Pardo et al. 2021) were detected.

The importance of apn comes also from its prochiral trait, i.e. it can be converted into new and different chiral molecules in a single chemical step. To date, only one chiral molecule has been detected in the ISM: propylene oxide ($\text{CH}_3\text{CHCH}_2\text{O}$, McGuire et al. 2016). Understanding the abundance of chiral molecules in space would make it possible also to explain the origin of enantiomeric abundance in meteorites (Pizzarello & Groy 2011; de Marcellus et al. 2011) and hopefully shed light on the predominance of left-handed amino acids in living organisms.

The quiescent G+0.693-0.027 molecular clouds (hereafter G+0.693), located at the central molecular zone (CMZ) in the inner $\sim 500\text{pc}$ of our Galaxy, has recently shown to be abundant in complex organic molecules of prebiotic interest. Since 2019, it has been the subject of 13 new interstellar detections, including many cyanides (Rivilla et al. 2022b) and amines like NH_2OH (Rivilla et al. 2020b), ethanolamine (Rivilla et al. 2021b), vinyl and ethyl amine (Zeng et al. 2021). In a previous work carried out by Askeland et al. (2006), a low-frequency experiment characterised Z-apn isomer in the 4-80 GHz band. However, the excitation temperature (T_{ex}) found for most of the molecules in G+0.693 molecular cloud, is typically in the range 5-20 K (see e.g. Zeng et al. 2018). At a temperature of 15 K, the Z-apn Planck function picks at almost 75 GHz, where one of the most intense transitions, the $34_{6-28} - 33_{6-27}$, has an uncertainty of almost 19 km s^{-1} , insufficient to guide an accurate search for this molecule in space. In the present work, we extended the spectroscopic characterisation of apn up to 1 THz. This frequency coverage and the accuracy of high resolution (43 kHz) spectroscopy measurements, allowed us to improve the precision of rotational and distortion constants producing a reliable catalogue for the search of this molecule not only in cold molecular clouds but in hotter ISM regions as well. It will therefore be possible to understand in which stages Z-apn might have formed and how chemical complexity can differ among the different phases of the star formation.

2. EXPERIMENT

The spectroscopic characterization of Z-apn, was conducted using the CASAC (Center for Astrochemical Studies Absorption Cell) spectrometer of the Center for Astrochemi-

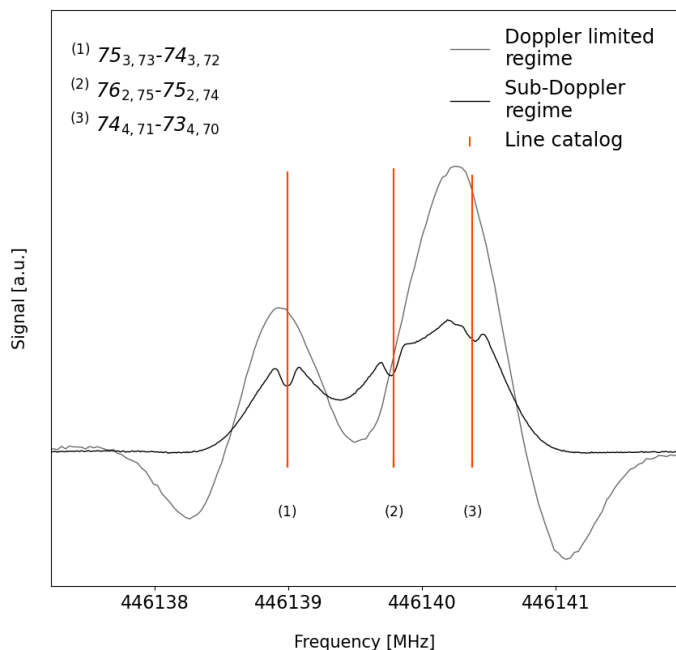

Figure 2. Doppler and Sub-Doppler measurements comparison for *a*-type Z-apn isomer transitions $J'_{K'_a, K'_c} - J_{K_a, K_c} = 75_{3-73} - 74_{3-72}$, $76_{2-75} - 75_{2-74}$ and $74_{4-71} - 73_{4-70}$. For the Sub-Doppler regime, modulation width: 100 kHz; modulation frequency: 15 kHz; total integration time: 555 s. For Doppler-limited conditions, modulation width: 600 kHz; modulation frequency: 40kHz total; total integration time: 88s.

cal Studies at the Max Planck Institute for Extraterrestrial Physics. The instrument has been described comprehensively elsewhere (Bizzocchi et al. 2017), and only the distinctive features of the instrument are listed below.

The main radiation source of the CASAC spectrometer is a frequency synthesizer (Keysight E8257D) locked to a Rb atomic clock (Stanford Research Systems) operating at 10 MHz for accurate frequency and phase stabilisation. The radiation from the synthesizer is then coupled to a Virginia Diodes (VDI) solid-state active multiplier chain, providing continuous coverage across the 80–1600 GHz frequency range. The radiation is directed through a Pyrex tube of 3 m in length and 5 cm in diameter and is detected by a cryogenic-free magnetically enhanced InSb hot-electron bolometer (QMC Instruments Ltd.).

The frequency modulated signal is obtained by encoding the synthesizer radiation with a modulated sine-wave having a modulation width ranging from 100 to 600 kHz. A lock-in amplifier (SR830, Stanford Research Systems) is used for demodulating the detector output at twice the modulation frequency ($2f$) resulting in a second derivative profile of the absorption signal recorded by the computer-controlled acquisition system. Z-apn was measured letting its vapours directly flow through the absorption cell which was continu-

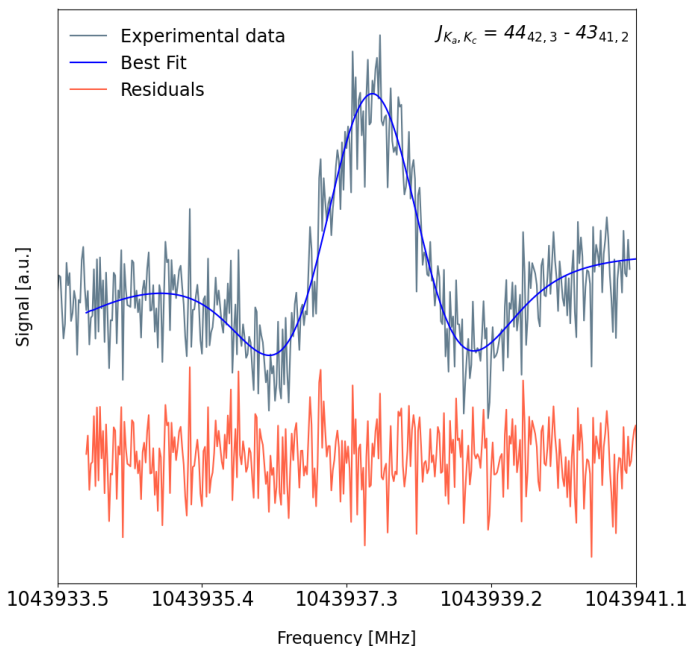

Figure 3. A detail of a *b*-type Z-apn transition recorded at 1.04 THz. The line profile is a Voigt profile. In grey is the experimental data, in blue is the best fit, and in red are the residuals. Integration time: 4 minutes; modulation width: 800 kHz; frequency step: 30 kHz.

ously pumped and kept at about 3–4 mTorr (0.5 Pa) and 300K.

3. MOLECULAR PROPERTIES

3-Amino-2-propenenitrile ($\text{H}_2\text{N}-\text{CH}=\text{CH}-\text{C}\equiv\text{N}$) is produced by the addition of two ISM abundant molecules, ammonia (NH_3) and cyanoacetylene ($\text{HC}\equiv\text{C}-\text{C}\equiv\text{N}$). The reaction occurs both in solution (Xiang et al. 1994) or in gas phase (Guillemin et al. 1998), and yields in a yellow-brown mixture of *E* and *Z* isomers in a 1:1 ratio. After vacuum distillation at 63°C and 0.1 mbar, a colorless mixture of *E* and *Z* isomers was obtained in a 5:95 ratio (Benidar et al. 2005). Apn is a disubstituted ethene ($\text{H}_2\text{C}=\text{CH}_2$), whose substituents are an amino ($-\text{NH}_2$) and a cyano group ($-\text{CN}$). Depending on the orientation of these two groups with respect to the sp^2 hybridized carbons, apn leads to two isomers. The most stable is denominated as *Z*-, and has the two subunits oriented on the same side; *E*-apn, has the $-\text{NH}_2$ and $-\text{CN}$ moieties opposed to each other and is the less energetically favoured (Askeland et al. 2006). Figure 1 shows the energy diagram of the two isomers.

In order to estimate this energy difference, we herein conducted an all-electron ab-initio calculations at couple-cluster (CC) level of theory comprising a single, double, and a perturbed triple excitation treatment, i.e. CCSD(T). Employing a cc-pVTZ basis set, the estimated energy difference ΔE between *E* and *Z*-apn is $\Delta E = 6.63 \text{ kJ mol}^{-1}$ (798K). These

Figure 4. Simulated spectra of Z-apn. In red and gray, a-type and b-type transition spectra, respectively. The upper and lower panels are showing the spectra computed at 300 K and 10 K, respectively. The x- and y-axis values were chosen to take into account the shift in the Planck function. To note, the spectrum at 300 K has a frequency span of three times and an intensity of one-thirtieth compared to the spectrum at 10 K. [a.u.] stays for arbitrary units.

same ab-initio calculations allowed us to predict dipole moment components of E-apn, extending the contribution of Askeland et al. (2006) to Z-apn alone. The values of both isomers are reported in Table 1, and are expected to be $\mu_a = 5.92$ D, $\mu_b = 0.52$ D and $\mu_c = 0.82$ D and $\mu_a = 4.93(4)$ D and $\mu_b = 0.86(6)$ D, for E- and Z-apn, respectively. For all calculations we used CFOUR quantum chemistry package (Matthews et al. 2020). For the most energetically favoured isomer the inertial defect $\Delta = 0.0117$ is also presented, and indicates an almost molecular planarity, with Δ given by:

$$\Delta = I_c - I_b - I_a \quad (1)$$

Z- and E- isomers are both prolate symmetric top rotors and exhibit a Ray’s asymmetry parameter $\kappa \approx -0.82$ and $\kappa \approx -0.99$, respectively (Ray 1932). In the current work, we will focus only on the Z- isomer, since this is the only species detected in our laboratory measurements.

4. ANALYSIS

The high-resolution rotational spectrum of Z-apn was herein recorded from 80 GHz to 1.04 THz. 541 new lines were acquired, for a total of 687 components. 492 and 195 transitions belong to the a-type and b-type spectrum transitions, respectively. For the former, $^aR_{0,+1}$ branches were recorded, while for the latter both R and Q branches were observed. A summary of the different branches recorded is

reported in Table 2. The principal quantum number J ranged from 12 to 117, and the first pseudo quantum number K_a from 0 up to 42.

Whether nitrogen is present in a molecule, quadrupole nuclear hyperfine splitting emerges due to the coupling between the ^{14}N nuclear quadrupole moment $I = 1$ and the end-over-end molecular rotation. The hyperfine splitting of a given transition goes with $\Delta_Q \sim -6K^2/J^3$ (Townes & Schawlow 1975). The transition with the lower principle quantum number recorded in the present work has $J = 12$, around 80 GHz, and no hyperfine features were present. Hyperfine param-

Table 1. Relative energies and dipole moment components of the most stable apn isomers.

Parameter	unit	Z	E
E	kJ/mol	0.0	6.63

μ_b	D	0.86	0.52
μ_c	D	0.0	0.82
κ^a		0.82	0.99

^a κ is the asymmetric rotor parameter, given by $(2B - A - C)/(A - C)$ (Gordy & Cook 1984). μ_x is the dipole moment with respect to the x inertia axis.

eters were hence not improved or affected by our measurements, therefore those determined by [Askeland et al. \(2006\)](#) were maintained.

Most of the transitions were recorded at a pressure of ~ 4 mTorr at 300 K, but in a few cases, some lines were blended. Among the various contributions that affect line shape and line width², a substantial role is played by the Doppler broadening effect, a consequence of the Maxwellian distribution of molecular velocities. For electromagnetic radiation tuned at the molecular resonance ν_1 , only those molecules having no velocity component along the line of incident radiation will resonate with such frequency. Instead, molecules having a non-zero velocity component along this same axis (in the case in which $v_z \ll c$, where c = speed of light), will resonate with frequencies given by

$$\nu = \nu_1 \left(1 + \frac{v_z}{c} \right) \quad (2)$$

The radiation having frequency ν will then resonate with all those molecules having a velocity along the radiation pathway of

$$v_z = \left(\frac{\nu - \nu_1}{\nu_1} \right) c \quad (3)$$

As theoretically pointed out by [Lamb \(1964\)](#), a power saturation of a Doppler-broadened line can produce a sharp

Table 2. Transitions and components recorded for Z-apn in this work.

Type	Branches ¹	No. of components	No. of lines
<i>a</i> -type	^a <i>R</i> _{0,+1}	492	390
<i>b</i> -type	^b <i>R</i> _{+1,+1}	46	35
	^b <i>R</i> _{+1,-1}	32	15
	^b <i>R</i> _{-1,+1}	7	7
	^b <i>Q</i> _{+1,-1}	110	94

¹ The branch symbol ^x*M* _{$\delta K_a, \delta K_c$} refers to the transition type of an asymmetric rotor. *x* stays for the component of the dipole moment, *M* = *P*, *Q*, *R* for transitions with $\Delta J = -1, 0, +1$, respectively, and δK_a and δK_c for the (signed) change of the *K_a* and *K_c* pseudo-angular quantum numbers ([Gordy & Cook 1984](#)).

² An important contribution arises due to pressure broadening, other minor ones for power effects, collisions between molecules and cell walls, and distortion introduced by modulators, detectors, and amplifiers.

dip whenever other broadening factors are small in comparison with Doppler broadening and there is a radiation linearly passing in opposite direction of the gas flow ([Winton & Gordy 1970](#)). In the present work, the difference of one order of magnitude in pressure obtained passing from the routinely Doppler-limited conditions of few mTorr to 0.2–0.3 mTorr (sub-Doppler regime), allowed to reduce pressure-broadening effects, enabling the saturation of the transition that occurs at frequency ν_1 . The subsequent interaction with the radiation reflected by the bottom lens of the absorption cell results in a stimulated emission identifiable by the appearance of a dip in the absorption $2f$ profile, in correspondence of ν_1 . Such low pressures are also important to induce an appreciable separation of the dips from the Doppler profile as well as to minimise possible pressure line shifts ([Cazzoli et al. 2003](#)).

In Fig. 2, the experimental data recorded under the sub-Doppler regime, are shown in black. In the course of the analysis, the shape of the rightmost line led us to suspect that it was the result of multiple unresolved components, a fact also supported by the predictions obtained from the fit up to that point. By switching to a Lamb-dip regime (black line), it was possible to resolve and assign both lines $J_{K_a, K_c} = 75_{3,73}-74_{3,72}$ and $76_{2,75}-75_{2,74}$, which were then included into the fit. The measured line widths at half maximum (FWHM) of the transition $75_{3-73}-74_{3-72}$ passed from 640 kHz to 97 kHz. This same procedure was performed to deal with comparable situations, and in combination with sub-Doppler regime analysis allows us to record transitions up to 1 THz. Fig. 3 shows the transition obtained at the highest frequency, 1.04 THz. Residuals of this line fitting are in good agreement with the Voigt profile fitted using the line profile with our in-house analysis software, that implements the $2f$ Voigt profiles presented by [Dore \(2003\)](#).

The new lines were fitted including the ones recorded by [Askeland et al. \(2006\)](#), using the SPFIT/SPCAT software. Figures 4 shows the simulated spectra computed at 300 K and 10 K, obtained with the new rotational and distortion constants, presented in Table 3. The files employed to compute the Z-apn catalogue are provided as Supplementary materials³. The Z-apn catalogue will be available at CDMS ([Müller et al. 2005](#); [Endres et al. 2016](#)) with the name Z-apn.cat. The file format matches the one of CDMS⁴ and JPL⁵ ([Pickett et al. 1998](#)). In contrast to the latter work, we used the S Watson’s reduction asymmetric Hamiltonian, maintaining the *I'* representation. This was done to keep the free pa-

³ The Supplementary materials comprise of the *.lin, *.int, *.fit, *.par, *.var, and *.cat files. These are all available in *Zenodo* DOI: 10.5281/zenodo.7904967.

⁵ <https://spec.jpl.nasa.gov/ftp/pub/catalog/catform.html>

Figure 5. Transitions of Z-apn used to compute the column density upper limit towards G+0.693 (see text). The black line and gray histogram show the observed spectrum, the red curve is the LTE synthetic model of Z-apn using the column density upper limit derived toward G+0.693, and the blue curve indicates the emission of all the molecules previously identified towards the source.

parameter s_{111} , which takes part in the unitary transformation of the Hamiltonian, the lowest as possible, as suggested by [Watson \(1978\)](#). This way, the convergence of the fit is sped up and additional terms in the Hamiltonian can be avoided ([Margulès et al. 2010](#)). In the sub-table of Table 3 the values used to determine the constants $s_{111}(A)$ and $s_{111}(S)$ are listed, showing a difference of 50 between the former and the latter, respectively. The fit was performed by assigning transitions with gradually increasing quantum numbers J and K_a . Distortion constants were added in the process in order to account for the divergence due to their increasing values and the corresponding frequencies.

All 687 rotational transitions, including the ones observed in the previous microwave experiment, were reproduced by our model with a final rms uncertainty of 44 kHz. The uncertainty of the new rotational constants has been decreased by a factor of 1000 for A , and more than 40 for both B and C . A full set of quartic, sextic and octic distortion constants⁶ with an average uncertainty of 0.003%, 0.1% and 1%, respectively, were determined. For the old lines, the same experimental uncertainties attributed by the authors $\sigma = 3$ kHz and $\sigma = 50$ kHz were used, for the hyperfine transitions recorded with the Fourier transform spectrometer and Stark spectrometer, respectively. Depending on experimental conditions, line-width and S/N ratio, σ ranging from 25 to 50 kHz, were assigned for the transitions recorded in this work.

Rotational (Q_{rot}) partition functions for Z-apn are provided in Table 4. The values have been computed for $T = 2.725 - 1000$ K and are obtained by direct summation over the rotational or hyperfine levels, whose energies have been accurately determined from the spectral analysis. The vibrational partition functions Q_{vib} have been computed using harmonic frequencies at the CCSD(T)/cc-pVTZ level of theory, calculated in this work using CFOUR software ([Matthews](#)

[et al. 2020](#)). Ab-initio calculation to assist the measurements to determine also the rotational constants of E -apn are planned.

5. INTERSTELLAR SEARCH TOWARDS THE G+0.693-0.027 MOLECULAR CLOUD

We searched for Z-apn towards the G+0.693-0.027 molecular cloud, located in the Sgr B2 region of the Galactic Center. Several molecular species, including cyanides and amines, have been recently detected for the first time toward this cloud (see e.g. [Rivilla et al. 2019](#); [Rivilla et al. 2020b](#); [Bizzocchi et al. 2020](#); [Rivilla et al. 2021b,c, 2022a,c](#); [Rodríguez-Almeida et al. 2021a,b](#); [Zeng et al. 2021](#); [Jiménez-Serra et al. 2022](#)). We used a sensitive unbiased spectral survey performed with the Yebes 40m (Guadalajara, Spain), and the IRAM 30m (Granada, Spain) telescopes. The position switching observations were centered at $\alpha(J2000.0) = 17^h47^m22^s$, $\delta(J2000.0) = -28^\circ21'27''$. The line intensity of the spectra was measured in units of T_A^* as the molecular emission toward G+0.693 is extended over the beam ([Requena-Torres et al. 2006, 2008](#); [Zeng et al. 2018, 2020](#)). For more detailed information of the observational survey we refer to [Rodríguez-Almeida et al. \(2021a\)](#) and [Rivilla et al. \(2022d\)](#).

We implemented the spectroscopic entry of Z-apn (without considering HFS) from this work into the MADCUBA package⁷ (version 28/10/2022; [Martín et al. 2019](#)). Using the SLIM (Spectral Line Identification and Modeling) tool of MADCUBA, we generated a synthetic spectra of Z-apn under the assumption of Local Thermodynamic Equilibrium (LTE), and compare with the observed spectra. We used typical values of the physical parameters found in G+0.693: $T_{ex} = 8$ K, $v_{LSR} = 69$ km s⁻¹ and FWHM = 18 km s⁻¹. We show

⁶ Due to fit, the only excluded octic constants was l_2 .

No. of lines	935		86	

^a Numbers in parenthesis represent the 1 σ standard deviation of the constant in unit of the last digit. Unitless weighted deviation σ_{rms} of the fit higher than 1 assigns an uncertainty greater than the 67% confidence level.

^b The parameters employed pertain to the *I*^r representation. For a direct comparison between S- and A- Watson's reduction, refer to [Gordy & Cook \(1984\)](#).

^c List of parameters used to chose the Hamiltonian reduction type to employ in the fitting procedure. To have a straightforward comparison, nomenclature has been taken verbatim from ([Margulès et al. 2010](#)). For our purpose, *B_z*, *B_x* and *B_y* correspond to the rotational constants *A*, *B* and *C*, respectively; *R₅* and *R₆* are obtained with CFOUR software and are given by combinations of distortion constants and are used to compute the free *s*₁₁₁ parameter. The latter take part in the Hamiltonian unitary transformation.

Table 4. Rotational, hyperfine, and vibrational partition functions for Z-apn.

in Figure 5 the brightest transitions according to the LTE model that fall in the spectral range covered by the survey⁸: $7_{0,7}-6_{0,6}$ at 43.896761 GHz, $6_{0,6}-5_{0,5}$ at 38.09996 GHz, and $7_{1,7}-6_{1,6}$ at 42.94129 GHz. Although the LTE model is compatible with the observed spectra, we did not detect clear unblended transitions that would allow a secure detection of the molecule. For this reason, we report here an upper limit for its molecular abundance. To derive it we have used the higher value of the column density (N) whose LTE model is compatible with the observed spectrum, shown by red curve in Figure 5). We obtained $N < 6.6 \times 10^{12} \text{ cm}^{-2}$, which means an abundance compared to H_2 of $< 4.9 \times 10^{-11}$, using $N(\text{H}_2)=1.35 \times 10^{23} \text{ cm}^{-2}$ (Martín et al. 2008).

6. DISCUSSION

In this work we focused on the ground vibrational state of the lowest energetic isomer Z-apn. As it was already seen in the cyanides detected in G+0.693, the isomers ratio is unfavourable for the highest energy isomer (see i.e. Rivilla et al. 2019). Therefore, the probabilities to detect the highest energy isomer *E*-apn, instead of the most stable Z- isomer, are lower. Nevertheless, as explained by García de la Concepción et al. 2021, while this is true for cyanomethanimine and propynimine ($Z/E > 1$) it does not apply to ethanimine ($Z/E < 1$). The additional spectroscopic characterisation of the most energetic isomer might help to shed light on the isomer ratio of this molecule in the ISM and on whether higher sensitivity measurements might be available.

As far as rotational spectroscopy is concerned, any molecular system can be described by its angular momentum. The latter is inversely proportional to the rotational constants A , B and C , determined for Z-apn, and to be determined for *E*-apn. For spectroscopic complex molecules such as iCOMs, the associated high moment of inertia results in low rotational constants. In the case of Z-apn, the fundamental 1-0 transition, given as for all prolate asymmetric rotors by the sum of the rotational constants B and C , is at approximately 6 GHz. Due to the similarity in geometry and atom compositions, one can expect a similar value for *E* isomer. Being the fundamental rotational level, it has no associated centrifugal distortion, and it is the ideal target when beginning to assign a spectrum for which no prior experimental information is available. For Z-apn, it was possible to work nimbly with the CASAC at 300 K because we started from Askeland et al. (2006)’s work, but for *E*-apn, the same does not apply. The analysis would start from rotational constants obtained from ab-initio calculations, which always have an associated intrinsic uncertainty. On top of this, the effects of centrifugal distortions taking place in higher quantum number transitions make the identification very complex. Therefore, the Free-Unit Jet experiment is the ideal candidate to begin the assignment of complex molecules starting from ab-initio calculations, for molecules such as *E*-apn.

The upper limit of $N < 6.6 \times 10^{12} \text{ cm}^{-2}$ herein obtained (abundance compared to H_2 of 4.9×10^{-11} , with $N(\text{H}_2)=1.35 \times 10^{23} \text{ cm}^{-2}$) enables the comparison between this upper limit of Z-apn with the molecular column densities of simpler cyanides and amines already detected towards G+0.693. Cyanides with two carbon atoms, such as vinylcyanide ($\text{C}_2\text{H}_3\text{CN}$) and ethylcyanide ($\text{C}_2\text{H}_5\text{CN}$), are more abundant than Z-apn by factors of ≥ 14 and ≥ 6 , respectively (Zeng et al. 2018), while the two-carbon amines vinylamine ($\text{C}_2\text{H}_3\text{NH}_2$) and ethylamine ($\text{C}_2\text{H}_5\text{NH}_2$) are more abundant by factors of ≥ 7 and ≥ 4 , respectively (Zeng et al. 2021). This indicates that the increase of molecular complexity that involves an additional carbon and nitrogen atom implies a drop in molecular abundance of at least one order of magnitude, as it has been found for other molecular families such as alcohols (Jiménez-Serra et al. 2022) and thiols (Rodríguez-Almeida et al. 2021a).

7. CONCLUSION

We herein characterized the high-resolution rotational spectrum of Z-apn from 80 GHz to 1.04 THz. In the experiment we employed both Doppler and sub-Doppler regime measurements, allowing us to record 541 new lines. With the new Z-apn catalogue produced making use of the new rotational constants we searched for this molecule in the G+0.693 molecular cloud. Under LTE condition, we report an upper limit for its column density of $N < 6.6 \times 10^{12} \text{ cm}^{-2}$,

⁸ We have excluded the transition $8_{0,8}-7_{0,7}$ at 49.621278 GHz, because it is completely blended with a brighter transition of Z-cyanomethanimine (Z-HNCHCN; Rivilla et al. 2019).

which means an upper limit abundance compared to H_2 of 4.9×10^{-11} . Further analysis might include the characterisation of the *E*-apn and the search for both isomers in colder sources as well, i.e. L1544 or L183, to help us to better understand the underlying astrochemical link existing between different phases of the star formation regions.
