Abstract

Fiber photometry is a significantly less invasive method compared to other deep brain imaging microendoscopy approaches due to the use of thin multimode fibers (MMF diameter < 500 μm). Nevertheless, the transmitted signals get scrambled upon propagation within the MMF, thus limiting the technique's potential in resolving temporal readouts with cellular resolution. Here, we demonstrate how to separate the time trace signals of several fluorescent sources probed by a thin ($\approx 200 \mu\text{m}$) MMF with typical implantable length in a mouse brain. We disentangled several spatio-temporal fluorescence signals by using a general unconstrained non-negative matrix factorization (NMF) algorithm directly on the raw video data. Furthermore, we show that commercial and low-cost open-source miniscopes display enough sensitivity to image the same fluorescence patterns seen in our proof-of-principle experiment, suggesting that a new avenue for novel minimally invasive deep brain studies with multimode fibers in freely-behaving mice could be possible.

Keywords: Spatio-temporal demixing, time traces, scattering fingerprints, transient patterns, short multimode fiber, neuronal activity, microendoscopy, non-negative matrix factorization, NMF.

1. Introduction

Fluorescence-based techniques are providing researchers with different ways to collect functional readouts from neuronal activity in the brain^{1–10}. However, measuring neuronal activity at depths greater than 1 mm is still challenging mainly due to issues resulting from light scattering, especially in prominent paradigms such as freely behaving animals^{11–14}. To address this problem, neuronal microendoscopy methods have emerged as complementary alternatives to linear and nonlinear fluorescence microscopy techniques for studying neuronal activity in deep brain regions using genetically encoded calcium indicators (GECI)^{13–16}. Among these methods, conventional microendoscopic methods that use a single gradient index (GRIN) lens optics^{16–19}, as well as fiber photometry recordings using multimode fiber (MMF)^{15,20–23}, have been successfully used to obtain functional neuronal activity signals in deep brain regions in freely behaving mice^{15,22–24}. Nonetheless, direct imaging techniques and fiber photometry approaches bring peculiar tradeoffs in terms of spatial and temporal discerning capabilities^{13,25,26}. On one hand, albeit GRIN lens microendoscopy retrieves calcium transients with cellular resolution, it demands a somewhat invasive surgical procedure to implant the GRIN lens into the mouse brain. Commercial GRIN lenses are relatively thick ($\geq 500 \mu\text{m}$), and oftentimes they necessitate the removal of a significant amount of brain tissue to effectively conduct the experiment^{12,26}. On the other hand, the use of thin multimode fibers (< 500 μm diameter) in photometric recordings, as well as in optogenetics experiments, has a significantly less invasive surgical procedure, which does not require any brain tissue removal, but only a careful penetration of the thin fiber through the mouse brain^{6,15,25}. It is known that the implantation of multiple multimode fibers (up to a maximum of 48 fibers²⁷) to optogenetically control and/or photometrically probe different regions in freely-behaving mouse brains is already a reality in neuroscience labs^{26–28}. However, the light wavefront propagating inside multimode fiber gets spatio-temporally scrambled due to multimodal mixing (internal scattering)^{29–31}. Generally, that is not a limitation for delivering light (optogenetics) to an ensemble of neurons in a given depth (unless one wants to probe specific neurons within the fiber field of view, FoV), but it poses a challenge for fiber photometry methods which limits the technique's potential to resolve (demix) time traces from individual neurons. Consequently, fiber photometry time traces coming from a whole population of neurons transmitted through MMF are ensemble integrated during detection, and therefore, fast single-pixel detectors are frequently chosen to optimize the detection speed and sensitivity^{15,26}. While the use of fast scientific Complementary Metal–Oxide–Semiconductor (sCMOS) cameras to simultaneously probe multiple fiber photometric signals has been demonstrated^{26,28,32–35}, the mixing between all the spatial patterns transmitted by each MMF prevented the individual retrieval of each neuron time trace²⁶. Recently, researchers have developed novel techniques that utilize the deterministic nature of the multimode fiber transmission matrix (TM) to perform bioimaging^{30,31,36–47}. These approaches have enabled the acquisition of diffraction-limited images of fluorescently labeled brain structures and neuronal activity, even in deep brain regions of head-fixed mice, using a multimode fiber microendoscope^{31,46,47}. To achieve this, however, an extensive characterization of MMFs

transmission properties is necessary, ideally taking into account TM changes whenever the MMF fiber is bending or changing its transmission properties during an experiment, as well discussed in previous research^{36,47,48}. Consequently, while these techniques provide a minimally invasive method to obtain diffraction-limited resolution in deep brain regions, they are complex to implement and require a wavefront shaping device (e.g., spatial light modulator, SLM) to compensate for the fluorescence randomized wavefronts through a lengthy calibration procedure. Moreover, the calibration can be even more complex if the experiment is not performed in head-fixed mice, but in freely behaving mice, such as those in long-term social behavior studies^{31,36,46,47}. Finally, the use of spatial light modulators and complex distal optical devices poses an extra challenge in future use in miniaturized wireless systems.

In this article, we propose a novel approach to perform minimally invasive fiber photometry experiments disentangling single-source time traces transmitted by short and thin multimode fibers ($\approx 200\ \mu\text{m}$ diameter and $< 10\ \text{mm}$ length). Our method involves the demixing of fluorescence spatiotemporal signals by applying a single post-processing step on the recorded video data of 2D scattered fluorescence patterns transmitted by the fiber. By substituting the bucket detector with a camera (i.e., a pixelated detector such as CMOS sensor), we can profit from using the spatial information of the fluorescence patterns transmitted by the multimode fiber, enabling single-source temporal activity resolution. Analysis of the recorded video is performed employing a simple unconstrained Non-negative Matrix Factorization (NMF) algorithm that separates each spatial scattering pattern component with its corresponding temporal trace (singular trace)^{48–51}. With this approach, we show that it is possible to extract single-source time traces in fiber photometry without the need to perform any complicated calibration procedure.

Previous work from some of the authors showed that it is possible to spatiotemporally demix fluorescence scattering patterns (*speckles*) transmitted through a highly scattering media (e.g., mouse skull) by using a NMF^{50,51}. This algorithm relies on the premise that the input data matrix only contains non-negative values, and it has been used to decompose datasets into their representative parts or components^{49–56}. In addition, if *a priori* knowledge of the input dataset is known (e.g., sparsity, calcium transient profile, etc.), it is possible to improve the performance of NMF by adding some constraints^{57–60}. Therefore, the video data of fluorescence speckles fluctuating over time are a highly appropriate input matrix for NMF, because the superposition of these incoherent signals is naturally positive, linear, and sparse, due to the wide intensity distribution of speckle patterns. Based on that, one could in principle apply the same algorithm to the video data from scattering patterns that are characteristic of the light transmitted through short multimode fibers of the same length as the ones implanted in fiber photometry^{26,61–63}. It is well known that multimode fibers randomize the fluorescence wavefront propagating within it, acting as a scattering media over the fiber length due to multimodal mixing. Nevertheless, the multimode fibers ($< 10\ \text{mm}$) typically implanted in living mice for chronic behavioral experiments are too short to generate a fully evolved speckle wavefront^{61,63}. In fact, the light wavefront that emerges from such short fibers displays a very peculiar spatial distribution of light, which is structurally mixed, but not fully spatially randomized/sparse^{61,62}. Hence, these scattering patterns cannot be considered yet a fully developed *speckle* (such as the ones in our previous work^{50,51}), because they still display some continuous structures whose shape depends mostly on the multimode fiber core geometry⁶⁴. Here, we call these short MMF patterns as scattering fingerprints.

In the present work, we designed a proof-of-principle experiment (Figure 01) and we confirmed that a simple unconstrained NMF could also disentangle the short MMFs scattering fingerprints signals and retrieve their corresponding time traces. As a consequence, one may now temporally resolve and count the number of sources with singular time traces transmitted by a minimally invasive multimode fiber. Thus, the results of this paper consist of a proof of concept on how to obtain individual time trace resolution in fiber photometry methods. Additionally, we progressively validated our approach towards more realistic conditions, such as demixing fluorescence signal from tens of bead sources buried behind a scattering media (plastic paraffin: Parafilm M®) including a component for neuropil activity, and by selectively probing a few structurally Gad-eGFP labeled neurons in a $50\ \mu\text{m}$ fixed brain slice with literature-available time traces to mimic neuronal activity. Finally, we propose a novel method for probing neuronal microendoscopic signals by simply combining a miniscope and an implantable short multimode fiber, which we called MiniDART (for Miniaturized Deep Activity Recording with high Throughput). For that, we demonstrate that the inexpensive and commercially available open-source miniscope (Open Ephys Miniscope-v4.4) has already enough sensitivity and illumination power to detect the typical intricate patterns of short MMFs. This new way of measuring individual fluorescence time traces from an ensemble of fluctuating sources profits from the short length of multimode fibers that are naturally more rigid (bending resistant) and therefore very suitable to be used in long-term freely-moving mice neuroscience experiments.

2 Results

2.1 proof-of-principle using phantom samples made of $10\ \mu\text{m}$ diameter fluorescent beads

To demonstrate the validity of the method, we implemented an optical setup using a digital micromirror device (DMD), which was used to generate different excitation ground truth (GT)^{50,51,65,66} activity traces for each fluorescent source ($10\ \mu\text{m}$ diameter fluorescent beads \approx neuron soma size). Each source emits fluorescence that is collected and transmitted by the multimode fiber (see Figure 01 and methods for details). Upon propagating through the MMF, the fluorescence wavefront undergoes scrambling, resulting in

the emergence of fluorescence patterns upon exiting the fiber. The controlled excitation guarantees that each fluorescent source generates a fingerprint pattern whose intensity transiently fluctuates accordingly with the chosen GT time trace profile (see transient patterns in Figure 01). Thereafter, we record a video of the transient patterns that emerge from a short multimode fiber and apply the NMF to the recorded data. In Figure 02.1 we show the results retrieved by NMF and compared with the ground truth. The results consist of individual spatial fingerprint patterns (Figure 02.1f) and, most importantly, their corresponding single-activity time traces (Figure 02.1g-i) that without NMF would be mixed.

Figure 01 – Concept of single-source resolved fiber photometry (demixed fiber photometry). From left to right: ground-truth excitation mimicking neuronal activity is performed by using a DMD, which can selectively excite a set of fluorescent emitters on the sample with a given time trace, likewise in^{50,51}. A short (8 mm long) multimode fiber typically implanted in optogenetics or fiber photometry experiments (NA = 0.39, 200 μm core diameter, step-index fiber) is placed almost touching the sample (distance of $\approx 50 \mu\text{m}$) to collect the fluorescence dynamics of each source. Due to its proximity to the sample, the fiber's effective FoV is expected to be slightly larger than the core size. Fluorescence light inside the multimode fiber is subject to multimodal mixing during propagation, which scrambles/mixes the emitters' wavefront similarly to any scattering media. The transmitted superimposed signal (#1, #2, and #3) consists of fluorescence transient patterns, i.e., 2D patterns (w_1, w_2, w_3) that fluctuate in intensity over time with typical calcium transient profiles (h_1, h_2, h_3)^{65,66}. A video is recorded with a camera and a post-processing step using a spatio-temporal demixing algorithm (unconstrained NMF) is applied to disentangle the overlapped transient patterns into individual 2D spatial fingerprints and their corresponding singular time trace profiles that should match the GT excitations. For optical setup and raw data videos details, see supp info.

As can be seen in Figure 02.1b, the scattering patterns transmitted by the short MMF of 6 fluorescent bead sources (Figure 02.1d) have a significant overlap in space when all of the sources are simultaneously excited with the DMD (Figure 02.1b). On the other hand, whenever a fluorescent bead is excited individually, each detected spatial pattern has a very different spatial structure/morphology (see the GT scattering fingerprints in Figure 02.1e). After applying a simple unconstrained NMF on the recorded video data, the demixed spatio-temporal result by NMF had an overall good agreement with the GT. The ensemble superimposed signal (photometry) was decomposed on its individual fingerprint-trace components (Figure 02.1g). Not only the NMF retrieved well each singular temporal activity trace (Figure 02.1g-i), but also the individual spatial fingerprint patterns (Figure 02.1e-f). Since we know the GT activity, we sorted and assigned the source indexes in descending order of the correlation between their time trace obtained by the NMF and the GT. As we can see in Figure 02.1h, the GT-NMF temporal correlation coefficient values were high for all the first 5 beads, which were localized closer to the central region of the fiber (Figure 02.1d). More specifically, we obtained an average value of $\langle \delta_{g,n} \rangle = \delta_{\text{avg}} = 85.4\%$ with a standard deviation of $\text{std} = 3.6\%$ (Figure 02.1h). However, the NMF algorithm could not reliably recover the time trace and fluorescence patterns corresponding to bead #6 due to low SNR, probably because it was localized too far from the center, i.e. at the edge of the field of view (fiber core border, see Figure 02.1d), as suggested by the low intensity of GT scattering pattern (Figure 02.1e, index 6). In the analysis process, the input rank of NMF determines the number of components the algorithm demixes the spatio-temporal signal. When we

choose an NMF's rank value higher than the real number of fluorescence sources, we obtain replicas of the scattering fingerprints and the background (see supp info), similar to what happened in a previous work⁵⁵. Thus, counting the maximum number of unique patterns demixed by NMF could be a way to count the real number of sources probed by the fiber. A more technical analysis of it can be found in the supp info.

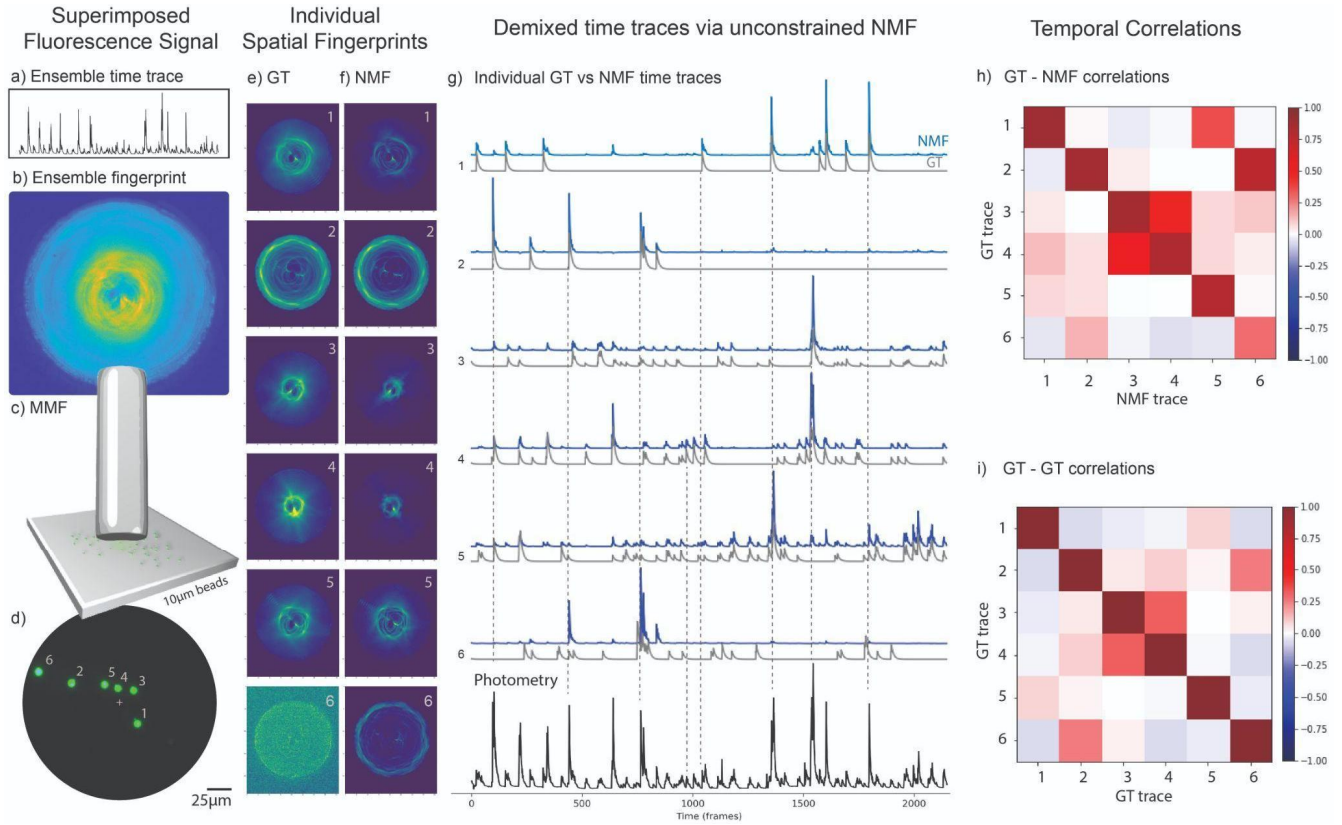

Figure 02.1 – Results of a proof-of-principle experiment performed with 6 fluorescent beads. From (a) to (d) we have: (a) the ensemble temporal activity (fiber photometry), (b) the superimposed pattern image of 6 fluorescent bead fingerprints when simultaneously excited (imaged detected via sCMOS camera (see methods and supp info)); (c) the short MMF located at a distance of $60 \pm 10 \mu\text{m}$ from the fluorescent beads; (d) a CMOS Basler camera with the ground truth image of the sample (see supp info for setup scheme details). (e) The ground truth (GT) fingerprint patterns obtained from each bead when they were individually excited. (f) The fingerprint patterns obtained via NMF demixing are to be compared with the GT patterns in (e). (g) The individual temporal activity traces of the sources obtained with NMF (blue) and their corresponding GT traces (gray). The NMF trace (#6) was not recovered well by NMF since bead #6 was localized very close to the fiber core edge, therefore yielding low signal/contrast of its pattern (see GT scattering fingerprint of bead #6 in (e)). (h) The GT-NMF time trace correlations. The average diagonal value of the first 5 beads was $\langle \delta_{g,n} \rangle = \delta_{avg} = 85.4\%$ with $\sigma_\delta = 3.6\%$. To better evaluate the off-diagonal elements (time trace cross-talk), we subtract them from their corresponding GT-GT coefficients. Then, we averaged the absolute values of these differences and we obtained the mean absolute error of $\zeta_{avg} = 7.06\%$ with a standard deviation of $\sigma_\zeta = 7.29\%$ for the first 5 beads (see supp info). (i) The GT-GT temporal trace correlation table. Importantly, the GT-GT correlation coefficients show that although each GT trace was unique over time (singular profile), GTs from different sources were not fully uncorrelated. For example, GT traces of beads #3 and #4 were fairly correlated ($\gamma_{3,4} = \gamma_{4,3} = 31.2\%$, in (i)) and had a very clear spatial overlap (see GT and NMF scattering fingerprints #3 and #4 in (e) and (f)).

2.2 NMF demixing of densely superimposed spatiotemporal signals including neuropil dynamic background

Due to the fiber geometry, it is expected that symmetrically probed sources should generate similar spatial fingerprint signals that could in principle limit the capacity of NMF to disentangle fluorescence time traces. Hence, we designed and performed an experiment to address a more realistic video recording than before, such as on a new bead sample with a higher spatial density of beads (see methods); with a fiber field of view where multiple fluorescence sources would have similar radial distance (equidistant) from the center of fiber; with more complex time traces with several overlapping peaks; and by setting one of the sources as a “noisy and dynamic background source” that would yield a rapidly fluctuating non-sparse signal throughout the experiment (e.g., mimicking a neuropil fluctuations). Interestingly, as we can see on Figure 02.2, the NMF algorithm was able to successfully demix around 22 fluorescence time traces out of 26 probed sources (see Figure 02.2g,h). Note that, all of the 4 poorly retrieved time traces were from sources that were

actually close to the fiber edge (c.f. beads 23, 24, and 25 in Figure 02.2d) or even outside of the fiber FoV (c.f. bead 26 in Figure 02.2d) as expected.

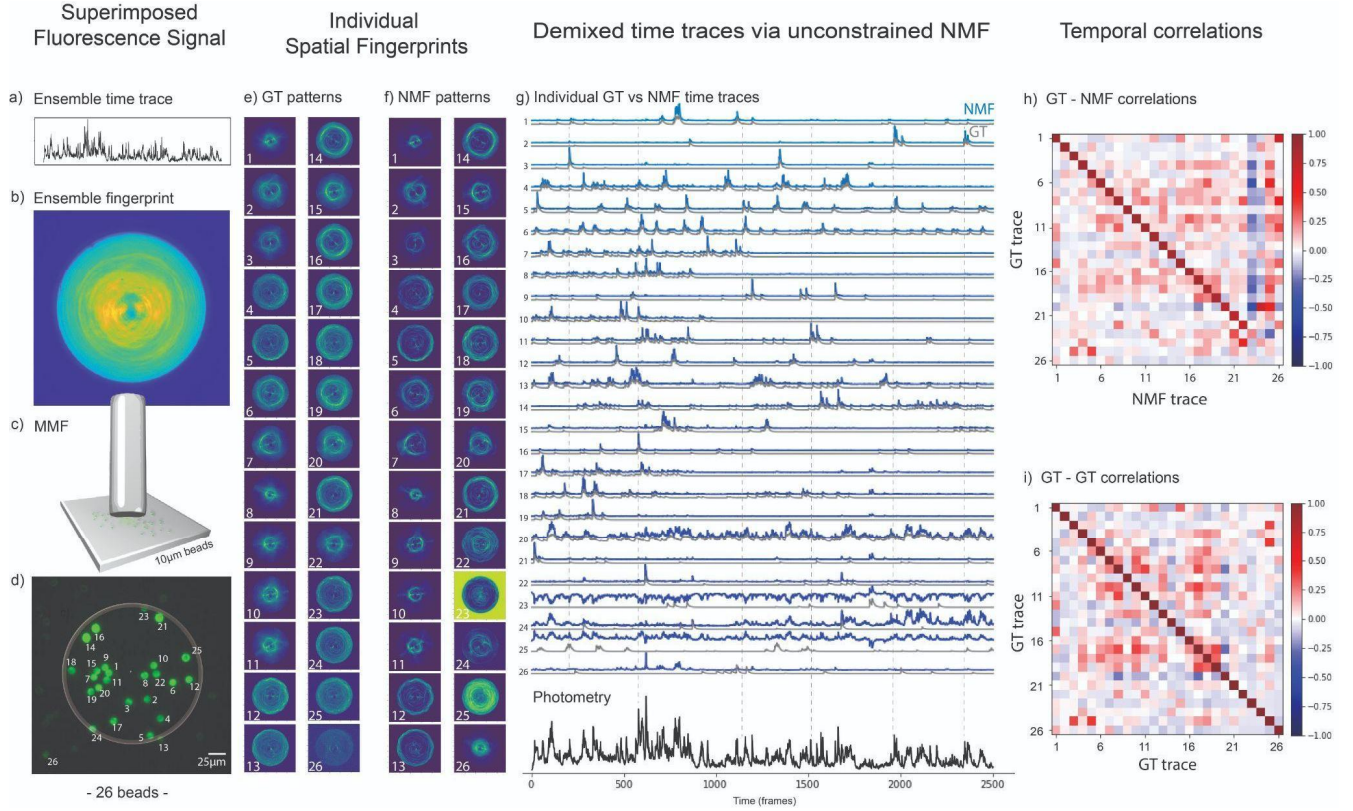

Figure 02.2 — Results of a proof-of-principle experiment performed with 26 fluorescent beads including a neuropil background source. The bead #20 is modeling the neuropil. From (a) to (d) we have: (a) the photometric (ensemble) time trace, which is the sum of 26 time traces; (b) the sCMOS detected image of the spatially overlapped fingerprint patterns from 26 fluorescent beads probed by the short MMF (see methods); (c) the short MMF located at a distance of $60 \pm 10 \mu\text{m}$ from the sample; (d) the ground truth image of the sample (backpropagated fluorescence image detected from a CMOS Basler camera, see details of the setup in the supp info). (e) The ground truth (GT) fingerprint patterns obtained from each bead when they were individually excited. (f) The fingerprint patterns obtained via NMF are to be compared with the GT patterns in e. (g) Top: the individual temporal activity traces obtained with NMF (blue) and their corresponding GT traces (gray). Bottom: the photometric ensemble signal from the recorded video (black line), which is the sum of all individual traces. The fluorescence intensity in all traces in the figure are normalized to 1. (h) The GT-NMF time trace correlations. The average diagonal value of the first 22 beads was $\langle \delta_{g,n} \rangle = \delta_{avg} = 86.0\%$ with $\sigma_\delta = 5.4\%$. To better evaluate the off-diagonal elements (time trace cross-talk), we subtract them from their corresponding GT-GT coefficients. Then, we averaged the absolute values of these differences and we obtained the mean cross-talk of $\zeta_{avg} = 4.4\%$ with a standard deviation of $\sigma_\zeta = 3.7\%$ for the first 22 beads (see supp info). (i) The GT-GT temporal trace correlation table showing that the ground truth traces were not orthogonal.

Because of experimental constraints (the DMD being conjugated to only one plane at the sample), all the experiments were performed with sources located at the same axial plane. Nevertheless, the spatial fingerprints measured for single sources in free space only slowly depend on the distance along the propagation axis z over large ($> 500 \mu\text{m}$) distances away from the fiber (data not shown). Thus, we should obtain similar outcomes to those shown here if the sources were arranged in 3D in a transparent medium rather than in 2D, such that the projection on a particular z -plane is similar to the 2D distribution of sources used in this experiment (shown for example in Figure 02-2d). Therefore, we anticipate that our method should work with sources placed in 3D (free space), with a labeling density such that the number of sources in the vicinity of the fiber is similar to what we have shown here.

2.3 NMF demixing of multiple source photometric signals buried below a scattering layer

The previous experiments mimicked a condition where there is no scattering media (e.g., brain tissue layer) in between the fluorescence sources and the fiber tip. Now, in this section, we designed a similar experiment as before, but including a layer of plastic paraffin (Parafilm M®) in between the fluorescence beads and the fiber. Parafilm M® is a well-known scattering media and it has similar scattering properties to biological tissue, as the brain^{55,67}. We assume that one layer ($\sim 120 \mu\text{m}$) of Parafilm M® mimics well $\sim 120 \mu\text{m}$ of brain tissue slice (a brief discussion about why Parafilm M® is a good material to model for biological tissue scattering can be found in the

supporting information). With this experiment, we expect to show (1) that our method could demix fluorescence spatiotemporal signals transmitted by short MMF coming from sources concealed beneath a scattering layer and (2) that the scattering layer scrambles more the fluorescence wavefront and, consequently, breaks the residual symmetry of the fingerprint patterns we currently obtained, thus affording depth sensitivity to the method. In an extreme case, where a strong scattering medium is present in between the sources and the fiber, multimode fibers are expected to transmit a fully developed speckle as fluorescence patterns, which our team has already demonstrated that NMF can successfully be employed⁵⁰.

To challenge NMF in this experiment with Parafilm M[®], we chose a distal FoV where tens of fluorescent beads were actually touching each other and had similar localization around the fiber center (equidistant). As shown in Figure 02.3-g, we chose one of the sources (bead #13) to mimic the dynamic neuropil background during the video acquisition. Despite these multiple challenges, NMF was capable of demixing most of those signals (20 time traces out of 26 sources) as we can see in Figure 02.3. As expected, the scattering patterns from this experiment (Figure 02.3) are different from the previous cases (Figure 02.1 and Figure 02.2). They became less symmetric, confirming that the scattering layer is breaking the cylindrical symmetry of the system (which should facilitate NMF demixing), but spatially noisier (i.e., with decreased intensity contrast). The latter might explain why some sources could not be demixed well even though they were close to the fiber center (see beads #23 and #24). Indeed, those beads they had a strong spatial overlap with the neuropil (bead #13), which made the signals more difficult to demix. Nevertheless, based on previous works, it is reasonable to expect that a longer acquisition would help on this issue because there would be more frames to be used in the matrix decomposition⁵⁰.

Interestingly, however, NMF is widely employed to denoise image datasets^{56,59,60,68,69}, and the new results from the Figure 02.3 strongly suggests that NMF is inherently denoising our data. Such denoising effects were already observed in the previous figures (see the comparison of GT and NMF patterns in Figures 02.1 and 02.2). A few examples have been further highlighted in Figure S07 in the supporting information). Consequently, our findings suggest a multifaceted role for NMF, wherein it not only demixes signals and performs image segmentation (fingerprints), but also naturally denoises the data, thereby exemplifying its potential in simultaneously addressing multiple aspects of fluorescence imaging data extraction^{59,60}.

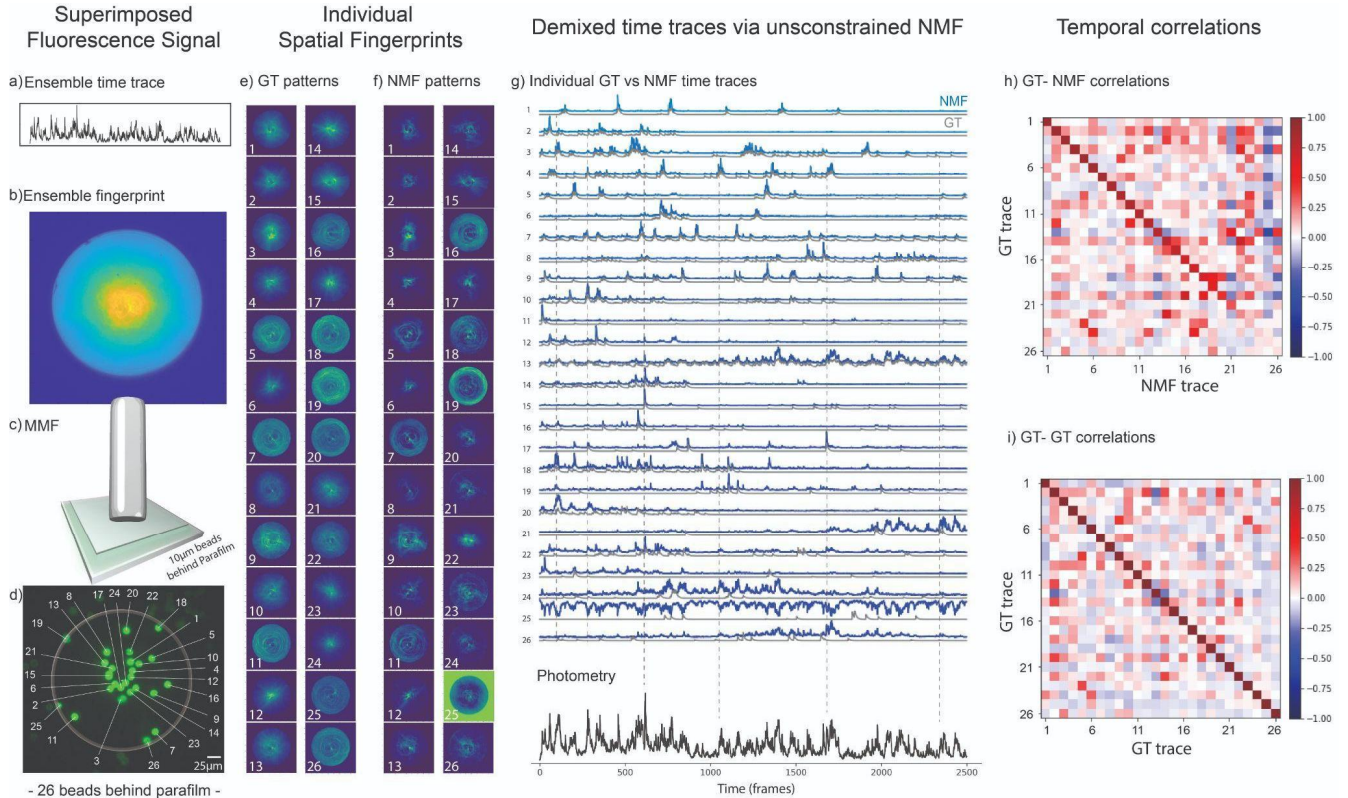

Figure 02.3 – Results of a proof-of-principle experiment performed with 26 fluorescent beads behind a Parafilm M[®] layer. The bead #13 is the source mimicking neuropil background signal. From (a) to (d) we have: (a) the photometric (ensemble) time trace, which is the sum of 26 time traces; (b) the sCMOS detected image of the spatially overlapped fingerprint patterns from 26 fluorescent beads simultaneously probed by the short MMF (see methods); (c) the short MMF located at a distance of $60 \pm 10 \mu\text{m}$ from the sample; (d) the ground truth image of the sample (backpropagated fluorescence image detected from a CMOS Basler camera, see setup in the supp info). (e) The ground truth (GT) fingerprint patterns obtained from each bead when they were individually excited. (f) The fingerprint patterns obtained via NMF are to be compared with the GT patterns in (e). (g) Top: the individual temporal activity traces obtained with NMF (blue) and their corresponding GT traces (gray). Bottom: the photometric signal from the recorded video (black line), which is the sum of all individual traces. The fluorescence intensity in all traces in the figure are normalized to 1. (h) The GT-NMF time trace correlations. The

average diagonal value of the first 20 beads was $\langle \delta_{g,n} \rangle = \delta_{avg} = 77.0\%$ with $\sigma_\delta = 11.9\%$. To better evaluate the off-diagonal elements (time trace cross-talk), we subtract them from their corresponding GT-GT coefficients. Then, we averaged the absolute values of these differences and we obtained the mean cross-talk of $\zeta_{avg} = 5.9\%$ with a standard deviation of $\sigma_\zeta = 5.6\%$ for the first 20 beads (see supp info). (i) The GT-GT temporal trace correlation table showing that the ground truth traces were not orthogonal - some of them were correlated.

2.4 Validation of the method while probing structurally GFP-labeled neurons in a 50 μm thick fixed brain slice

Next, we investigated if NMF could demix the fluorescence activity of structurally labeled GFP neurons in a fixed brain slice, whose signal has a higher background and lower fluorescence brightness compared to fluorescent bead samples⁴³. Therefore, in a another set of experiments, we changed our fluorescent sample to a 50 μm fixed brain slice (Gad-eGFP labeled neurons, see methods for more details), and we carried out the same type of GT excitation on a few selected neurons in the fiber FoV (mimicking the neuronal activity in a real brain environment). After recording a video of the scattering transient patterns and applying the unconstrained NMF, we confirmed again (see Figure O3) a good retrieval of the number of neurons, their scattering fingerprints (Figure O3d-e), and their individual activity traces (see Figure O3f-g and supp info). As in the previous experiment, the GT-NMF temporal trace correlation values obtained were high, with an average value of $\langle \delta_{g,n} \rangle = \delta_{avg} = 86.7\%$, and a standard deviation of $\text{std} = 2.8\%$.

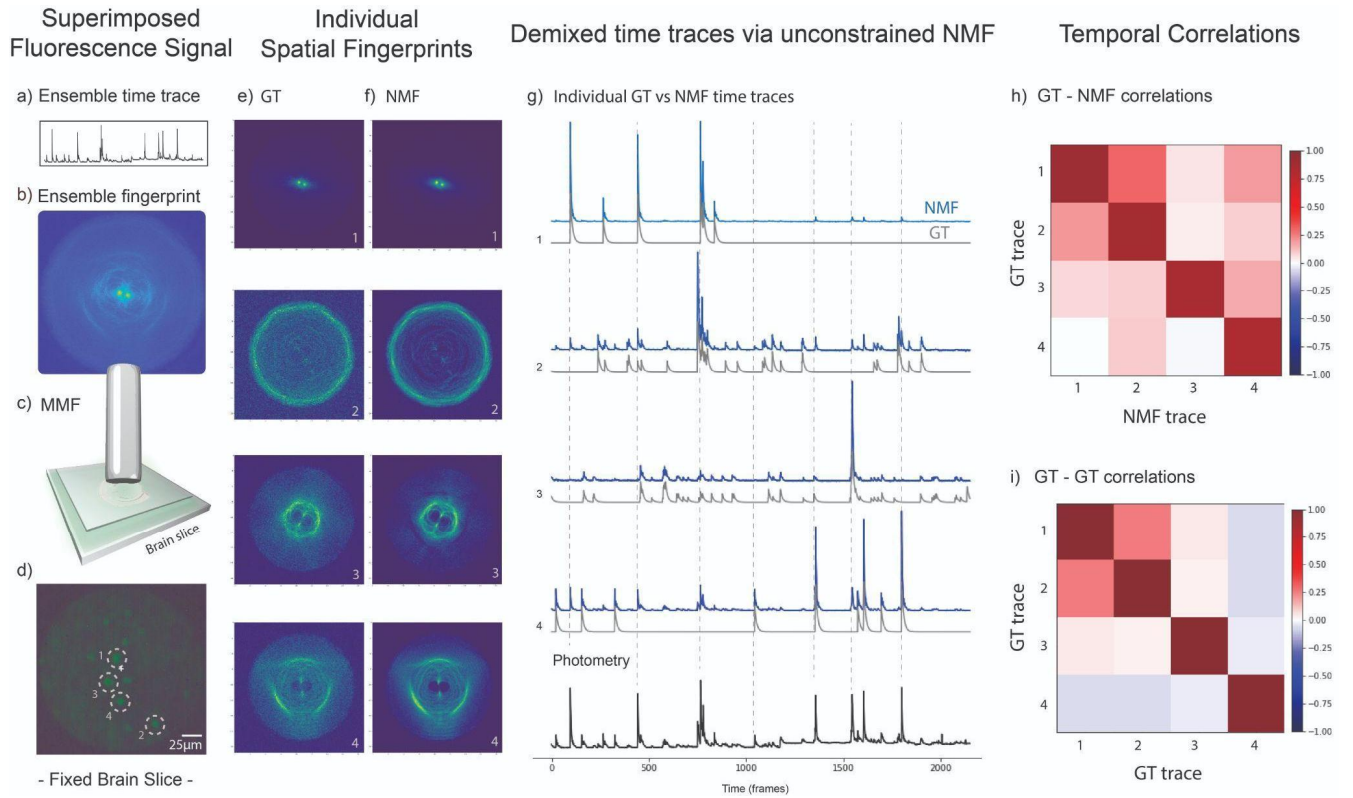

Figure O3 – Validation of the concept of single-activity resolved fiber photometry with short multimode fibers (short MMF) in a brain tissue environment (*in vitro*). Sample: Gad-EGFP neurons fixed in a 50 μm brain slice, sealed in between 2 coverslips to keep the humidity of the tissue (see methods). From (a) to (c) we have: (a) the fiber proximal end image of 4 neurons' fingerprint patterns spatially overlapped on the sCMOS camera chip; (b) an illustration of the short MMF placed above the top coverslip of the sample, at a distance of $\approx 60 \pm 10 \mu\text{m}$ from it; and (c) the GT image of the sample highlighting the 4 selected neurons to be excited (structurally labeled). (d) The GT fingerprint patterns are obtained from each neuron when individually excited. (e) The fingerprint patterns retrieved via NMF are in good agreement with the GT patterns in (d). (f) The demixed temporal activity traces are sorted in descending GT-NMF correlation order. Traces in blue are retrieved by NMF and temporal traces in gray are their GT. (g) The GT-NMF temporal trace correlation coefficients. The average diagonal value of the 4 neurons was $\langle \delta_{g,n} \rangle = \delta_{avg} = 86.7\%$, with standard deviation of $\sigma_\delta = 2.8\%$. Regarding the non-diagonal elements (cross-talk), the mean absolute error taking into account the GT-GT coefficients was $\zeta_{avg} = 8.95\%$ with a standard deviation of $\sigma_\zeta = 8.02\%$ (see supp info). Again, although each GT trace was unique in time (singular), they were not fully uncorrelated as we can see in the GT-GT correlation traces (h). Interestingly, neurons #1 and #2 (i.e., the two best NMF retrieved results) were also the most temporally correlated ones in the GT excitation ($\gamma_{1,2} = \gamma_{2,1} = 25.0\%$).

2.5 Pattern sensitivity evaluation of low-cost miniscopes while probing a single fluorescence source

Finally, we investigated if an inexpensive miniscope (Open Ephys Miniscope-v.4.4) coupled with a MMF would have enough sensitivity to excite and image an individual fluorescence fingerprint pattern emitted from a single fluorescent source (Figure 04-a). In such conditions, both the LED excitation from the miniscope and the fluorescence signal from the sample would be transmitted within the short MMF before imaging. This is an important question because the miniscope has simple, inexpensive, and compact components, such as the commercial-grade CMOS detector, rather than a high-end sCMOS camera as in our proof-of-principle tabletop experiment (see methods and supp info Figure S01). To tackle this question, we combined a miniscope with a short MMF (the MiniDART) and tested the miniscope sensitivity with a very sparse bead sample: a single fluorescent bead that we can displace laterally in the fiber FoV (see methods and Figure 04b-c). When we set the miniscope for low LED power and with no camera gain (LED = 20% corresponds to a transmitted power through the short MMF of $P_{MMF} < 10 \mu W$), it was already possible to detect short MMF scattering fingerprint patterns with very good contrast at the fastest frame rate available in the miniscope control software (FPS = 30 Hz, corresponding to 33ms exposure time, see supp info). Interestingly, whenever raising the LED power, decreasing the framerate speed, or raising the camera gain value, the detected patterns by the miniscope got saturated, suggesting that the miniscope CMOS has already enough sensitivity to probe scattering fingerprints through short MMFs even from less bright fluorescent sources than the ones used here, especially when the fluorescent source is close to the center of the fiber core (see Figure 04a,d). At distances $d < 20 \mu m$ from the core center, the CMOS got saturated while the miniscope GUI settings were: LED power = 20% (where LED_{max} = 100%, corresponding to a transmitted power through the short MMF of $P_{MMF}^{max} = 125 \mu W$), FPS = 10 Hz (where FPS_{max} = 30 Hz), and Gain = 1 (where Gain_{max} = 3.5).

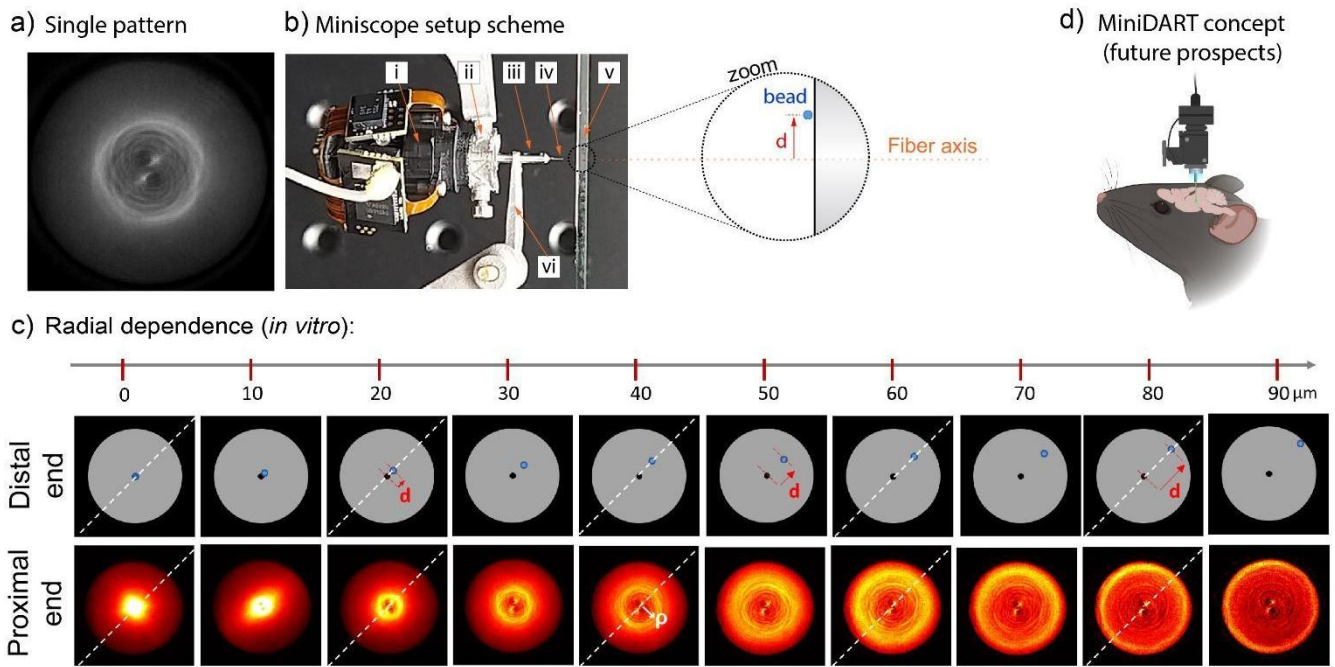

Figure 04 – Novel microendoscopy concept using a short MMF and a miniscope: the MiniDART. (a) A typical fingerprint pattern from a single-fluorescent bead (10 μm diameter) probed by using only the miniscope excitation and miniscope detection through the multimode fiber. (b) The experimental setup to probe scattering patterns from the short MMF includes (i) the miniscope, (ii) a customized titanium base plate (YMETRY®) to hold the miniscope, (iii) a ferrule (Thorlabs SFLC230-10) that rigidly holds the multimode fiber (iv) within it, (v) a sample consisting of a single fluorescent 10 μm bead (spatial density < 1 bead/cm²), and (vi) a customized titanium tweezer (YMETRY®) to hold the ferrule. (c) Scattering fingerprint patterns at the proximal end (bottom row) depending on the radial position d of the single-bead at the distal end. Position d is indicated on the axis at the top of the figure, and is represented as a red arrow on the distal end pictures (with the bead indicated as a blue dot). Each pattern acquisition in the proximal end corresponds to 10 μm steps from the fiber central axis (black dot in the center at distal end images). The bigger the distance d , the wider the diameter of the bright spiral-ring pattern (of radius ρ in the proximal end, white arrow). The diagonal white dashed line is the azimuthal orientation of the vector d , which always coincides with the alignment angle of the 2 central bright points of the fingerprint patterns in the proximal end (see supp info Figure S03-S04 for details). The highest LED power values measured at the distal end of the fiber (whose core is 200 μm in diameter) were around 9.5 μW , which yields an excitation intensity of 0.3 mW/mm² at the output of the fiber core, and 2.4×10^{-5} mW excitation power per bead area. Exposure time: 100 ms (Miniscope FPS = 10 Hz). For more details, see Figures S03 and S04 in the supporting Information. (d) The concept of doing experiments with a MiniDART device, which combines a miniscope and a short implantable multimode fiber. For future *in vivo* experiments, the MMF and miniscope baseplate should be glued on the mouse skull with dental cement in the same way typical miniscope experiments are performed with GRIN lenses.

Fundamentally, the MiniDART is not designed for imaging neurons or localization (like in other works that used learning algorithm methods^{61,62}). In many experiments, the relevant biological information does not depend on the shape or local position of the neurons, but mostly on the activity of each of them and their number. To extract this information, just demixing fluorescence time trace signals with NMF would be enough for relevant applications, since the number of neurons (NMF rank) could be obtained by counting the

number of unique MMF fingerprints, and possibly confirmed by a *post-mortem* evaluation of the brain region right below the thin hole made by the MMF. In addition, recording the spatial fingerprints of each source would be useful for chronic experiments (to match the sources from one session to the next). Nevertheless, as we can also see in Figure 04, the morphology of short MMF fingerprints provides some interesting insights into the point source position at the fiber distal end - without the need for any computational learning method. As we move a single bead laterally in a radial manner (in the x,y-plane at the fiber's distal end), a few easily interpretable geometrical properties of the fluorescence patterns systematically change in the fiber's proximal end (Figure 04d). More specifically, when the bead is displaced from the center towards the fiber border (of a distance d) a bright ring (of radius ρ) with some spiral ramifications is deterministically formed (see supp info for more details). Larger d distances yield wider rings (i.e., larger ρ , see Figure 04d, and supp info video of miniscope and single-bead). Thus, each fingerprint's bright ring diameter is encoding radial information about the bead lateral localization at the distal end. The dependence of fingerprint shape features on the individual point source position is further discussed in the supplementary information.

3 Discussion

Multimode fibers are well known to be minimally invasive microendoscopic probes that could be promptly combined with optogenetics manipulation of neuronal activity for behavioral neuroscience studies in living mice^{15,27,28,46,63}. It is well known from the literature that long multimode fibers (MMF length > 100 mm) could be used to transmit fluorescence activity signals and that would naturally generate a speckle wavefront due to internal multimodal mixing^{30,38,70,71}. However, as well described in wavefront shaping experiments, speckle wavefronts are extremely sensitive to fiber bending, torsion movements, and temperature changes along the fiber, which demands a long and meticulous wavefront propagation characterization (e.g., calibration using spatial light modulators, SLM) to compensate for all the changes in spatial properties of the speckles^{36,47,48}. In other words, there would be many experimental conditions to take into account to guarantee that the speckle patterns from each source would remain the same over time when using a long MMF as a photometric probe in freely-behaving mice experiments. That is why using only a short and stable multimode fiber for this type of application could be a very pragmatic solution.

To this end, we designed an experiment with a known ground truth excitation to be able to evaluate if NMF could demix the individual spatio-temporal readouts characteristic of short MMFs and GECI recordings. In this paper, we demonstrate that it is possible to demix such spatio-temporal signals *in vitro*, using a simple and general unconstrained NMF algorithm on the video data recorded in our proof-of-principle experiment. We designed *in vitro* samples to mimic as much as possible the real brain: we used tens of sources embedded in agarose (where a few of them are touching each other), with multiple overlapping temporal transient peaks signals, and we chose one source to mimic fluorescent neuropil. In one experiment, we added a scattering layer between the sources and the fiber, with scattering properties equivalent to that of a 120 μ m brain layer. In all of these experiments, we demonstrate that we are able to successfully demix most of the sources. In the most extreme case where sources are touching one another below a scattering layer, we show that we retrieve 20 of the 26 sources with high fidelity. It is the first time, to the best of our knowledge, that NMF is used to demix fluorescence fluctuating signals transmitted by a multimode fiber. In particular, the present work presents the proof of concept on how to obtain fluorescence activity readouts reaching single-source resolution with short multimode fibers. Therefore, this work opens a promising direction to improve fiber photometry fluorescence experiments by reaching single-source temporal activity resolution.

We suggest that this method could be applied *in vivo* in freely behaving animals by coupling the short implanted fiber with a miniscope (MiniDART concept). Indeed, we showed that patterns measured with a miniscope for single sources are very similar to patterns measured with the benchtop microscope used in our *in vitro* experiments. Therefore, one could benefit from the short MMF's scattering fingerprint patterns and rigidity by directly imaging the proximal end of the short (implantable) MMF with a miniscope. That would be different from the typical scheme in fiber photometry, where there is an optical coupling between the transmitted light from the implantable MMF to another long MMF (relay). In this sense, we tested and confirmed that even a low-cost miniscope would have enough LED power and CMOS speed/sensitivity to image the intricate scattering patterns transmitted by short MMFs emitted from just a single source. Both the multimode fiber and the miniscope (Open Ephys Miniscope-v4.4) are affordable and available in the market to carry out experiments in living mice. Therefore, in this paper, we show a low-cost and simple idea to expand the capacity of fiber photometry methods in resolving neuronal activity circuitry (that have already been used to investigate deep brain regions in chronic behavioral experiments in freely-behaving mice). In addition, as a minor result, we point out in Figure 04 that the short MMF scattering fingerprint morphology can have some interpretable geometry that has a relation with the source ($\approx 10\ \mu$ m size) localization at the distal end of the fiber. The relationship between the source localization and its fluorescence pattern shape is discussed in the supp info Figures S03 and S04, but the key message for demixing is that the scattering fingerprint patterns do not seem to be ambiguous depending on the source lateral position from the fiber axis.

To apply this method *in vivo*, a few difficulties could arise, but we think they can be circumvented:

1- Fluorescence background. In calcium imaging experiments, there are two types of background: a static background (corresponding to the neurons resting fluorescence F_0) and a dynamic background (typically the activity of the neuropil). In our experiments, we didn't model the resting fluorescence of the neurons ($F_0=0$). However, new GECI indicators such as GCaMP8 have low resting fluorescence and show large transient signals, with a $\Delta F/F_0$ corresponding to one action potential ranging between 40% and 100% depending on the variant used⁸⁰. Therefore, this static background should remain moderate, and we expect NMF to be able to extract it (for example using rank-1 matrix factorization, see supp info of ⁷⁹). On the other hand, dynamic background should be less straightforward to subtract. In this work, to evaluate if NMF could find and remove a non-sparse dynamic background component from our current signal, we included an additional source to model a neuropil signal (Figure 02.2 and Figure 02.3). This source (bead #20 in Figure 02.2, and bead #13 in Figure 02.03) was chosen to have a spatial fingerprint overlapped with many other sources in the FoV, and to exhibit a non-sparse, fast oscillating signal, with amplitudes on the same order of magnitude as the transient peaks of the other sources. In both experiments, we showed that a simple NMF algorithm could successfully retrieve more than 20 out of 26 spatiotemporal sources from the sample, including the neuropil source.

In addition, previous work from the team also addressed the case of NMF performance depending on a fluorescence background^{50,51}. NMF performance was evaluated by quantifying the cross-correlation statistics of the retrieved time traces over different experimental background conditions. Typically, NMF performance starts to slowly get impaired when the max value of the background signal is 1.5x bigger than the max value of the sources' activity time trace signal. In this case, the median temporal cross-correlation gets lower than 80%, with the first quartile of ~65%. Nevertheless, even when the max background over the max activity ratio is of 2.0, the median cross-correlation in the time trace is still above 70%, with the first quartile above 60%⁵⁰. Moreover, the performance of NMF could be improved compared to what has been shown here. Indeed, our team has already shown that the cross-correlation between NFM and GT traces increases with the number of frames in the recording⁵⁰, thus longer recordings are preferable for noisier data. In addition, it has been shown that for cases in which the background is larger than the signal from the somata, constrained NMF could retrieve well the time traces from neurons recorded with wide-field microscopy^{59,60}. In our case, we could apply similar spatiotemporal constraints (adapted to the fingerprint patterns we see here), which should allow significant improvement of demixing performances. Finally, when designing *in vivo* experiments, we would advise using GCaMP8 indicators targeted to the soma⁸¹ to minimize the neuropil component and therefore facilitate signal analysis.

2- Sample motion. In the case of 2-photon imaging experiments in the cortex with a cranial window, motion artifacts were 2-4 μm at z distances shorter than 150 μm from the optical window^{1,76}. In our case, we expect similar motion artifacts when exploring shallow regions of the brain, and smaller artifacts for deep regions. Indeed, this is what has been observed for 2-photon imaging with GRIN lenses^{77,78}. In addition, since in our experiments the patterns smoothly change upon source motion in the distal FoV (see Figure 04 and supplementary information Figure S03), we expect that motion artifact to remain small, periodic, and restricted in space, and we expect NMF to extract an average pattern for each source.

3- Fiber bending. Typical studies on multimode fiber bending effects are done with relatively long fibers (> 100 mm, typically around 300 mm long), which are quite flexible to be bent (Thorlabs manufacturer recommends bending fibers until a maximum of 21 mm of radius of curvature for 200 μm diameter core fibers). However, light propagation studies dealing with extreme bending cases of fibers with similar core as the one we used (200 μm diameter) display typical smallest bending radius of around 5 mm, which is the typical length of the short MMF we use⁴⁷. Like any other solid material, shorter multimode fibers (~10 mm) are way stiffer to bending than long fibers (> 100 mm) (Euler–Bernoulli beam theory of solid materials mechanics)^{72–75}. Typically, even long fibers have critical ~6 mm bending radius (with typical bending stress of ~700 MPa), where the Young modulus of multimode fibers changes very little (less than 1%) and its value is for practical purposes considered constant⁷². Therefore, short fibers as the ones we used (~ 8mm long) are significantly rigid and very difficult to be bent. This is particularly true for in living mouse experiments, where one end of the fiber (proximal) will be glued on the mouse's skull, and only the distal end of the fiber will be "free" to be bent (i.e., this end will be actually be surrounded by the mouse brain, dumping the small internal movements^{77,78}). In fact, most of the fiber length is rigidly glued within the ferrule, letting only a small portion of the fiber "free" to be bent (typically, in between ~1mm to ~4mm long sticking out of the ferrule, which is below the critical length of the fiber). Therefore, we expect very little bending of the fiber during *in vivo* recordings.

4- Bit depth of the miniscope camera. The current 8-bit depth CMOS camera of the miniscope might experimentally limit the potential of the method in probing a large number of sources because the miniscope camera can get more easily saturated due to the current short dynamic range (shallow bit depth, see Figure 04d and Figure S03). Saturated camera pixels should be avoided during the video recording because they do not allow one to distinguish GECI dynamics within the saturated frames. Probably, when N number of

pixels are saturated over a finite number of F frames, it might create a cross-talk in all retrieved time traces over the F frames whose fingerprint signals depend on those N saturated pixels. In our tabletop experiment, the sCMOS camera we used had a larger bit depth (16-bit dynamic range) and we demonstrated that a simple unconstrained NMF was able to demix more than 20 sources with a significant spatiotemporal overlap with other sources and non-sparse neuropil activity. In our experiments the camera dynamic range (DR) in the ensemble time trace were around: DR = 10.000 for Figure 02.1 (Proof-of-principle with 6 beads), DR = 1.500 for Figure 02.2 and Figure 02.3 (Proof-of-principle with 26 beads with and without Parafilm M®), DR = 450 for Figure 03 (Proof-of-principle with 50 μ m thick brain slice). Therefore, most of the experiments used a moderate dynamic range compared to the available 16-bit. We provide all the tiff files of the videos in the supporting information.

Regarding the current literature, previous works have demonstrated methods to obtain some degree of readout specificity in photometry experiments. For example, in Bianco M. *et al.* APL Photonics (2022) <https://doi.org/10.1063/5.0073594>, the authors have tapered the end of a multimode fiber so that fluorescence light coming from different depths of the taper is spatially separated in the far field of the optical fiber, at a camera. Although this technique is a nice improvement of fiber photometry, it does not give single source specificity, but rather it allows to obtain signals from spatial ensembles located at different depths in the tissue. Our approach is very different: we are not relying on spatial information only to separate the sources, but we take advantage of the temporal fluctuations of each source to extract both the spatial fingerprint and the temporal trace corresponding to each source, using a NMF algorithm. As a consequence, we manage to reach single source specificity. Moreover, in our approach we show that the raw video data doesn't need to be transformed or pre-process to obtain more specificity in the photometric readouts, although we could promptly do it as an extra strategy to improve its performance. It is worth noting that the actual implementation is performed with a cylindrical MMF, which gives ring patterns resembling that of Bianco *et al.*, but our method would also work with other types of fibers (for example square core fibers) as long as patterns corresponding from different sources are different. Lastly, multimode fiber modal dispersion doesn't necessarily limit our method, but it can be engineered to tune our method performance.

Moreover, computational learning tools have already been applied on short MMF scattering fingerprints to retrieve back the image of deep brain neurons from a fixed thick brain slice^{53,54}. However it is not yet proven that this approach could correctly assign the neuronal activity in living mice or any artificial condition. On the temporal resolution side, the authors tracked the movement of a fluorescently labeled worm in 2D with a framerate of 2 Hz, which is relatively low for typical calcium imaging experiments performed in living mice. In the latter case, experiments are typically carried out with a framerate of at least 10 Hz (such as the one available in the miniscope DAQ software). Besides, any learning algorithm depends on the specific conditions of the training set (fiber properties, imaging optical components properties, etc.), which is less general and therefore less applicable to any other new neuroscience experiment.

In our case, we used a simple unconstrained NMF, which is a general mathematical method that simply decomposes a matrix into a product of two matrices where all the entries are non-negative. This has been applied in many different fields, such as astronomy, audio processing or computer vision^{52,54,56–58,68,69}. In particular, we transformed our recordings into this matrix form where the columns (rows) represent spatial (temporal) information, but the method is blind to this physical interpretation and just operates numerically. Importantly, we wanted to establish as clearly as possible a general proof-of-principle for the technique, focusing on a solid ground truth, keeping the algorithms as “vanilla” as possible, so as to underlay the physical concepts. As we previously mentioned, a more tailored NMF implementation, for example using sparsity or other image-based and/or temporal constraints based on the specific nature of our experiments, would probably yield better results in terms of fidelity or achieving a higher number of retrieved traces^{59,60}. On the optical engineering side, one could tailor new miniscopes for this specific method or conveniently explore different multimode fibers types for the optical recordings. Regarding the miniscope potential improvements, when we spatially binned the video recorded by our high-end sCMOS camera (tabletop experiment) until we get a similar number of FoV pixels used in the miniscope, the retrieved results of NMF fingerprints and traces were visually indistinguishable (see supp info) compared to a non-binned analysis. This finding reinforces the idea that the current default design of the miniscope (LED power, camera speed/sensitivity, and FoV magnification) might be already enough to perform a living mouse experiment, although most pixels of the miniscope's camera chip was not used in our case (less than 1/9 of the FoV pixels were used to image a single MMF proximal end tip), and could be explored by simply changing the current magnification lens of the miniscope.

4 Conclusion

In this paper, we demonstrated for the first time how one could obtain single-source optical recording resolution in fiber photometry experiments that use thin multimode fibers as a microendoscopic probe. Besides, we show that the currently available low-cost miniscope has enough sensitivity to image directly MMF scattering fingerprints from individual sources, suggesting that this

experimental configuration could be advantageous for future long-term microendoscopic studies in freely-behaving animals due to the intrinsic rigidity of short fibers (< 10 mm). Therefore, we believe that this work can open a whole new avenue for novel and affordable minimally invasive deep brain optical microendoscopic studies to probe (potentially several) deep brain regions simultaneously in freely-behaving animals, including experiments that could be conveniently coupled with optogenetics tools to photoactivate or inhibit neurons which are already a routine in many neuroscience labs.

5 Methods

Proof-of-principle setup:

The proof-of-principle setup is visually illustrated and fully described in the supp info.

Fiber-ferrule preparation:

The multimode fiber was purchased from Thorlabs (FT200UMT, NA = 0.39, 200 ± 5 μm core diameter, 225 ± 5 μm cladding diameter). Around 10 cm of the fiber was initially cleaved with a ruby blade (Thorlabs, S90R), and the quality of the cleaved edge was inspected with a stereomicroscope (LEICA A60F, maximum magnification 30x). The fiber was glued within a 1.25 mm wide and 6 mm long stainless-steel ferrule (Thorlabs SFLC230-10, 230 ± 10 μm bore diameter) using an ultraviolet curing glue (Norland optical adhesive 81) so that the cleaved end was chosen to be the distal end of the fiber (with 2mm of it sticking out of the ferrule). The excess of the fiber on the other end (proximal end) was cut close to the ferrule edge and then sequentially polished (KRELLTECH NOVA device) with 3 different silicon carbide polishing disks with gradually descending roughness (30 mm, 3 mm, 0.3 mm, PSA 4" polishing disks from KRELLTECH). The quality of the polished end (proximal end of the fiber) was verified with the LEICA A60F stereomicroscope. We used a customized titanium tweezer and baseplate to hold the ferrule and the miniscope respectively (YMETRY®).

Preparation of the fluorescent bead sample:

In the proof-of-principle experiments, the samples consisted of randomly distributed fluorescent beads on borosilicate glass (22x40 mm cover glass, thickness Nb.1.5, purchased from VWR). An aliquot (100x diluted in milli-Q water) of the polystyrene (PS) particles aqueous suspension (PS - FluoGreen - Fi226 – 1mL, 10.23 ± 0.13 μm size, abs/em = 502/518 nm, purchase from microParticles GmbH, Germany) was used to randomly distribute the beads on the cover glass. The beads' size was chosen to have similar size to typical neuron soma probed in calcium imaging experiments. Besides, the emission spectrum of the beads is close to the common GFP calcium indicators. For the single-bead sample, a more diluted aliquot (from 10^6 to 10^7 times dilution) was used to guarantee a very spatially sparse bead sample with density ≤ 1 bead/ cm^2 , so that there would be only a single bead throughout the Fiber FoV whenever translating the bead laterally in the miniDART experiment (easily inspected by the miniscope itself without the fiber). The sample with high spatial density of beads was done by mixing concentrated bead aliquot with 5% Agarose aqueous solution with proportion 1:1 in volume (Sigma-Aldrich product# A2576, ultra-low gelling temperature, biology grade).

Preparation of the fixed brain slice sample:

The work includes data from one GAD65-EGFP transgenic mouse (heterozygote; male; aged 6 months) expressing EGFP in Gad65-positive interneurons in the brain and spinal cord. All procedures involving this animal complied with French and European legislations relative to the protection of animals used for experimental and other scientific purposes (2010/63/UE) and were approved by the "Charles Darwin" institutional ethics committee under the direction of the French National Committee of Ethical Reflection on Animal Experimentation under authorization number APAFIS 26667. The mouse was euthanized by cervical dislocation performed on the terminally anesthetized animal (5% isoflurane for 5 minutes in an induction chamber) and the brain was quickly removed from the skull and immediately transferred into a fixation solution (4% paraformaldehyde; pH 6.9 buffered; Sigma-Aldrich #1004965000). After 12 h at 5° the brain was transferred into phosphate-buffered saline (PBS) and cut into tangential slices of 50 to 100 μm thickness using a vibratome (Leica VT1000). Obtained slices were stored in multi-well plates with PBS and assessed with a fluorometric microscope before the experiment with the DMD.

NMF Analysis in Python:

The raw video data [2D image, time] was reshaped to a 2D matrix [1D image, time] to fit the input format of NMF. We used the scikit-learn decomposition NMF package freely available online (Python) ^{44,60}. In the code pipeline, an optional pre-processing step was added, which included an option for pixel binning (see supp info). The NMF parameters chosen ignored the additional parametric terms that are introduced to account for the sparsity of the data. The parameters chosen were: *init* = 'nndsvd', *random_state* = 0, *max_iter* = 3000, *solver* = 'cd', *l1_ratio* = 1, *beta_loss* = 2, *alpha_W* = 0, *alpha_H* = 0. The parameter *n_components* (which is the chosen NMF rank) changes depending on the experiment and a more detailed discussion about how to choose this value can be found in the supp info. In particular, the rank used in Figure 02.1 was rank_{Fig2}=9 (explained in the supp info), and the rank for Figure 03 was rank_{Fig3} = 5. The results of Figure 02.1 with different ranks are illustrated in the supp info.

The non-diagonal coefficients mean and standard deviation of the temporal correlation results:

The matrix of the non-diagonal elements $\zeta = \zeta_{i \neq j}$, where each element is the mean absolute error value between GT-NMF and GT-GT coefficients is detailed described in the supp info. The mean absolute error (MAE) value of a given element in $\zeta_{i \neq j}$ is given by:

$$MAE_{i,j} = |v_{i,j} - \gamma_{i,j}|$$

Where, $v_{i,j}$ is the (i,j) non-diagonal coefficient of GT-NMF temporal correlations, and is $\gamma_{i,j}$ the corresponding (i,j) non-diagonal coefficient of the GT-GT temporal correlations. The average value (ζ_{avg}) of all these non-diagonal elements and the standard deviation (σ) is given by:

$$\zeta_{avg} = mean(\zeta_{i \neq j}) = \frac{1}{2(N_s - 1)} \left(\sum_{i \neq j}^{N_s-1} |v_{i,j} - \gamma_{i,j}| \right)$$

$$\sigma_{\zeta} = std(\zeta_{i \neq j})$$

Where N_s is the total number of sources. These two values ($\zeta_{avg} \pm \sigma_{\zeta}$), together with the diagonal values ($\delta_{avg} \pm \sigma_{\delta}$), give us an estimation of whole experiment quality since ($\zeta_{avg} \pm \sigma_{\zeta}$) should ideally approach to zero.

6 Acknowledgments

The authors are grateful to Serena Bovetti, Stefano Zucca, and Laurent Bourdieu for productive discussions about the applications of the concept to in-vivo imaging. We are very thankful to Walther Akemann for the mouse brain extraction and fixation. In addition, we are grateful to Guillaume Dugué, Thomas Pujol, Arnaud Leclercq, and Maurice Debray for the fiber-ferrule assembly discussions and technical support (Lab. Kastler Brossel and IBENS' FabLab facilities, the latter which received support from the Fédération pour la Recherche sur le Cerveau - Rotary International France (2018)). The authors acknowledge the funding sources HFSP, SMARTIES, and France's Agence Nationale de la Recherche (ANR). The project is funded thanks to HFSP project N°RGP0003/2020. S.G. acknowledges support from H2020 European Research Council (724473 SMARTIES). C.V. acknowledges support from ANR (ANR-19-CE37-0007-02).

7 Author contributions

C.V.R. adapted the previous setup and performed the optical experiments, prepared the samples, adapted the code, performed the NMF analysis, and wrote the article. C.M. built the excitation ground-truth part of the setup (DMD alignment) and wrote the Matlab control code. F.S. wrote the core code in Python for the NMF analysis. E.B. and C.V.R. assembled fiber-ferrules and performed experiments with the MiniDART. C.V. and S.G. supervised and initiated the project. C.M. and S.G. conceived the idea. All authors discussed the results and commented on the paper.

Supp info 01: the proof of principle optical setup

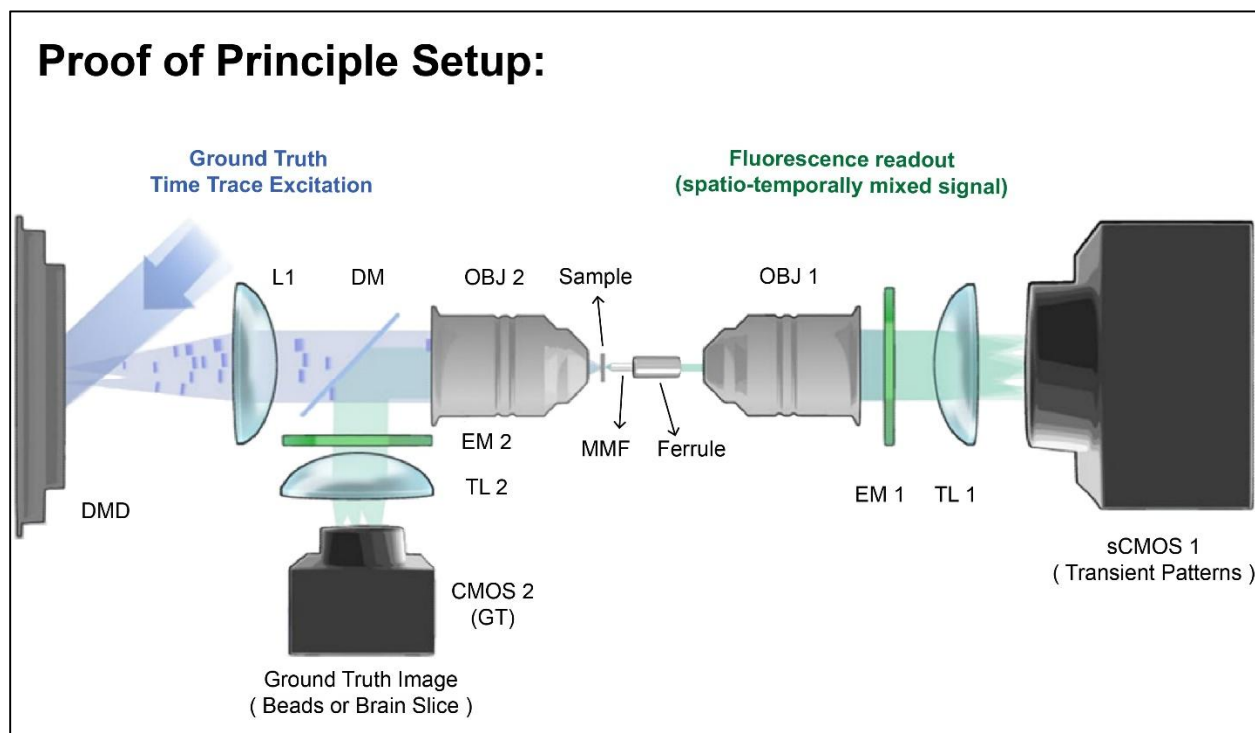

Figure S01 - The proof of principle optical setup. A 473 nm blue laser (LSR-0473-PFM-00100-01, Laserglow Technologies) illuminates a digital micromirror device surface (DMD from Texas Instruments: DLP LightCrafter 6500, same as «), that was used to create the ground truth (GT) excitation of each fluorescence source present in the sample plane (see sample details in the methods). A tube lens (L1, LA1708-A, Thorlabs) and the lower objective OBJ 2 (Plan-NEOFLUAR × 20, 0.5 NA, Zeiss) were used in the excitation path. For the ground truth excitation, genetically encoded calcium indicator (GECI) traces were obtained from neuronal recordings available in the literature, as we did before in previous

experiments^{43,57}. After excitation, the fluorescent signal propagated through the short multimode fiber (see fiber-ferrule preparation details in the methods) and the fluctuating fluorescent scattering fingerprints on the tip of the fiber were imaged onto a scientific complementary metal-oxide-semiconductor (sCMOS) camera (Iris 15 sCMOS, Teledyne Photometrics) by a microscope objective (OBJ 1, RMS10X PLAN ACHROMAT 0.25NA, Olympus) and a tube lens (TL 1). An emission bandpass filter (MF530-43, Thorlabs) was used in the detection path to block the blue excitation light. In addition, the system has a control path to image the fluorescence sample directly, so that it would be possible to obtain the ground truth image of the sample without passing through the fiber. This is done by imaging the backpropagating fluorescent light from the sample in reflection mode. For this path, a dichroic beam splitter (DM, FF496-SDi01, Semrock) was used to collect the fluorescent signal in reflection and the sample plane was imaged onto a CMOS camera (ACE2014-55um, Basler) after another tube lens (TL 2). We typically used a laser power of $3.0 \cdot 10^{-8}$ W per $10 \mu\text{m}$ diameter area (bead size), resulting in a local intensity of $3.8 \cdot 10^{-2}$ W/cm². Synthetic fluorescence traces were generated like previous work from our team, using the spike activity dataset from real available datasets acquired in mouse visual cortex, and converting them into calcium (excitation) traces (MLSpikes from Vanzetta's group: Deneux, T., *et al.* Accurate spike estimation from noisy calcium signals for ultrafast three-dimensional imaging of large neuronal populations *in vivo*. *Nat Commun* 7, 12190 (2016). <https://doi.org/10.1038/ncomms12190>) using a GCaMP6s physiological model and resampled at 10 Hz. The analog calcium transient profiles were designed by changing the dwell time of the excitation in relation to a longer, but constant, detection window time - similarly to previous works from our team. The DMD can control the excitation beam fast ($>10\text{kHz}$) concerning the detection window, allowing it to mimic an analog time trace profile very smoothly in the video recording. A higher (resp. lower) fluorescence intensity from a given bead corresponds to a longer (shorter) excitation dwell time during a given detection window. The detection window in the experiments were: 500 ms (Figure 02.1 - the 6 bead experiment, camera dynamic range of $\sim 10,000$), 1000 ms (Figure 02.2 - the 26 bead embedded in $50 \mu\text{m}$ thick agarose layer sandwiched between coverslips, camera dynamic range of $\sim 1,500$), 2000 ms (Figure 02.3 - the 26 bead embedded agarose layer sandwiched between coverslips + single Parafilm M[®] layer on top, camera dynamic range of $\sim 1,500$), 4000 ms (Figure 03 - 4 neurons in $50 \mu\text{m}$ brain tissue slice of the Gad-EGFP labeled neurons from the cortex, camera dynamic range of ~ 450). Therefore, most of the experiments used a moderate dynamic range compared to the available 16-bit.

Supp info 02: estimating the number of fluorescence sources with NMF: the NMF rank study

The rank of NMF sets the number of components the NMF will demix from the video data (number of fingerprints and their corresponding time traces)^{42-44,48}. In the experiment of Figure 02, we probed 6 beads in the FoV. In such case, because we know the number of sources, an expected good rank number (R_{expected}) as an input in NMF would be: $R_{\text{expected}} = 7$, because there were 6 beads + 1 background signal ($R_{\text{expected}} = N_{\text{beads}} + 1_{\text{bgd}}$). In a neuroscience experiment, one might not know *a priori* the number of the sources (neurons) one is probing, hence the input rank value on the NMF algorithm is not evident. However, one could still evaluate how well NMF performs to minimize the difference between the product of the two factorized spatial (W) and temporal (H) matrices and the original video matrix (X) with different rank values. The fidelity plot is shown in Figure S02-i. There, the residual error gradually decreases until reaching stabilized values, similar to a plateau (e.g., for rank values higher than 9). The curve profile changes more drastically its curvature around rank 4 and starts to stabilize around the expected rank $R_{\text{expected}} = 7$. Therefore, one could immediately make a rough estimation of the number of sources by just calculating the fidelity of NMF.

Figure S02-i – Residual error estimation (fidelity plot) for NMF with different factorization ranks. The sample used here is the same as in Figure 02 and contains 6 beads. One might see that the fidelity curve changes its curvature when the tested rank values gets closer to the GT expected rank (6 beads + 1 background). After that, the NMF performance slowly reaches a plateau. For large NMF rank values, the extra fingerprints and time traces obtained are replicas of the GT signal. NMF model parameters were the same as methods, only changing the rank value. Mean value and standard deviations (std) over 5 realizations with 3000 interactions.

However, by investigating more closely these NMF results for ranks between 4 and 10, one might be able to count the number of individual sources with more precision. This is because the extra components are due to NMF forcing to split a single signal (fingerprint and time trace) into two or more positive signals. As a consequence, we expect to obtain fingerprint replicas of the bead patterns and background. For lower ranks, signal from individual sources can be superimposed with data from other sources or with the background. For example, in when we chose rank $R=4$, the background signal is still mixed with some of the fluorescent bead signal (see Figure S02-ii). In such case, we retrieved relatively well the signal of 3 sources (there is some cross talk between bead 3 and the bead 4), but we lost the remaining ones.

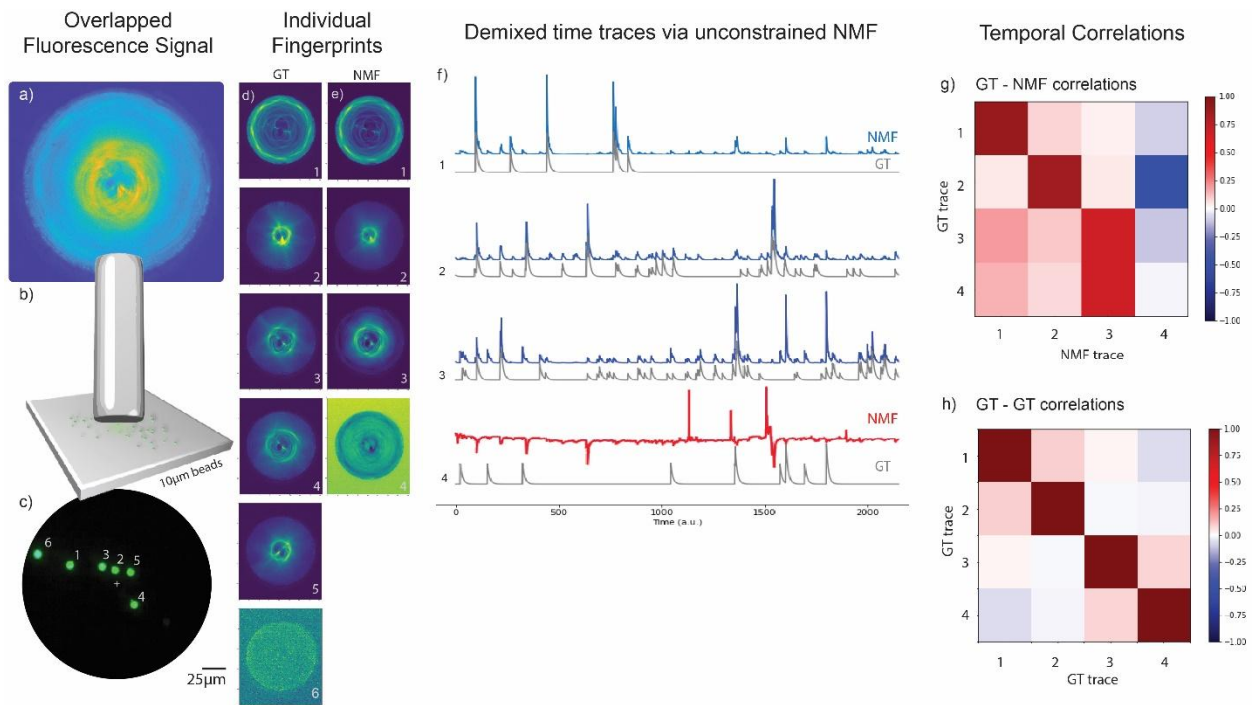

Figure S02-ii – Results of the proof of principle experiment, analyzed when we the input rank of NMF is $R = 4$. From (a) to (c) we have: (a) the fiber proximal end image of 6 fluorescent bead fingerprint patterns overlapped on the sCMOS camera chip; (b) the short MMF located at a distance of $60 \pm 10 \mu\text{m}$ from the fluorescent beads; (c) a CMOS Basler camera with the ground truth image of the sample. (d) The ground truth (GT) fingerprint patterns. (e) The fingerprint patterns obtained via NMF with rank 4. (f) The individual temporal activity traces of the sources obtained with NMF (blue) and their corresponding GT traces (gray). The red NMF trace (#4) is mainly background superimposed with the time trace activity of the other sources. (g) The Ground truth (GT) – NMF time trace correlations. The average diagonal value of the first 3 beads was $\langle \delta_{g,n} \rangle = \delta_{avg} = 81.3\%$ with standard deviation of $\sigma_\delta = 8.9\%$. (h) The GT-GT temporal trace correlations coefficients.

For rank $R = 7$, we did retrieve well 5 unique fingerprints and their corresponding time traces, but we did not retrieve well the signal from bead #6 mostly due low SNR ratio. When using a higher rank and sorting the most correlated NMF time traces to the GTs, the background temporal correlations were higher than the time trace signal of the bead itself (see red time trace NMF curve in Figure S02-iii). This result suggests that bead #6 was still embedded in the background for rank $R=7$.

For higher ranks than the expected one ($R > 7$), we start to split the signal of the source time traces, but also from the background (see replicas in Figure S02-iv). For NMF rank #9 (see Figure 02) and beyond, NMF always managed to find the hidden signal of bead #6 in the background component, which was correlating more with the GT of bead #6 than the background itself.

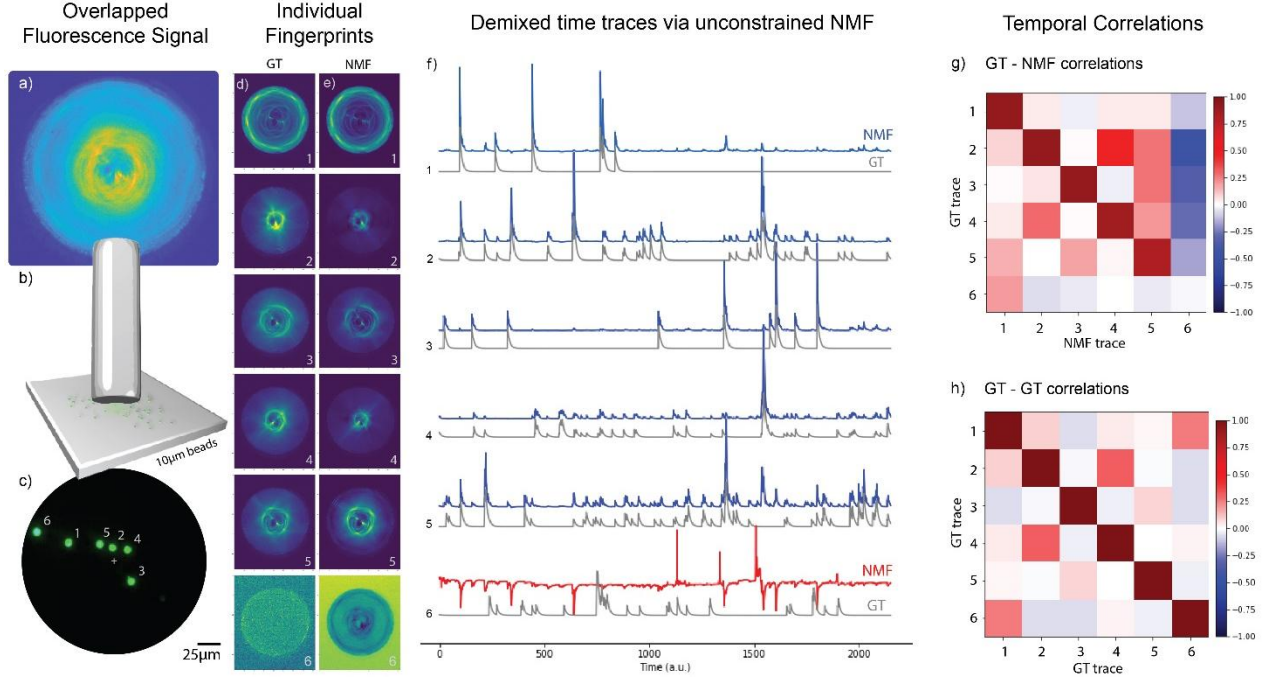

Figure S02-iii – Results of the proof of principle experiment, when NMF rank $R = 7$. From (a) to (c) we have: (a) the fiber proximal end image of 6 fluorescent bead fingerprint patterns overlapped on the sCMOS camera chip; (b) the short MMF located at a distance of $60 \pm 10 \mu\text{m}$ from the fluorescent beads; (c) a CMOS Basler camera with the ground truth image of the sample. (d) The ground truth (GT) fingerprint patterns. (e) The fingerprint patterns obtained with the NMF. (f) The individual temporal activity traces of the sources obtained with NMF (blue) and their corresponding GT traces (gray). The red NMF trace (#6) was not recovered well by NMF since bead #6 was localized very close to the fiber core edge, therefore yielding low signal/contrast of its pattern (see GT scattering fingerprint of bead #6 in d). (g) The Ground truth (GT) – NMF time trace correlations. The average diagonal value of the first 5 beads was $\langle \delta_{g,n} \rangle = \delta_{\text{avg}} = 88\%$ with standard deviation of $\sigma_{\delta} = 4\%$. (h) The GT-GT temporal trace correlation coefficients. The GT-GT correlation coefficients show that GTs from different sources were not fully uncorrelated, although each GT trace was unique in time (singular). For example, GT traces of beads #2 and #4 were fairly temporally correlated ($\gamma_{2,4} = \gamma_{4,2} = 31.2\%$, in (h)) and had a very clear spatial overlap (see GT and NMF scattering fingerprints #2 and #4 in (d) and (e)).

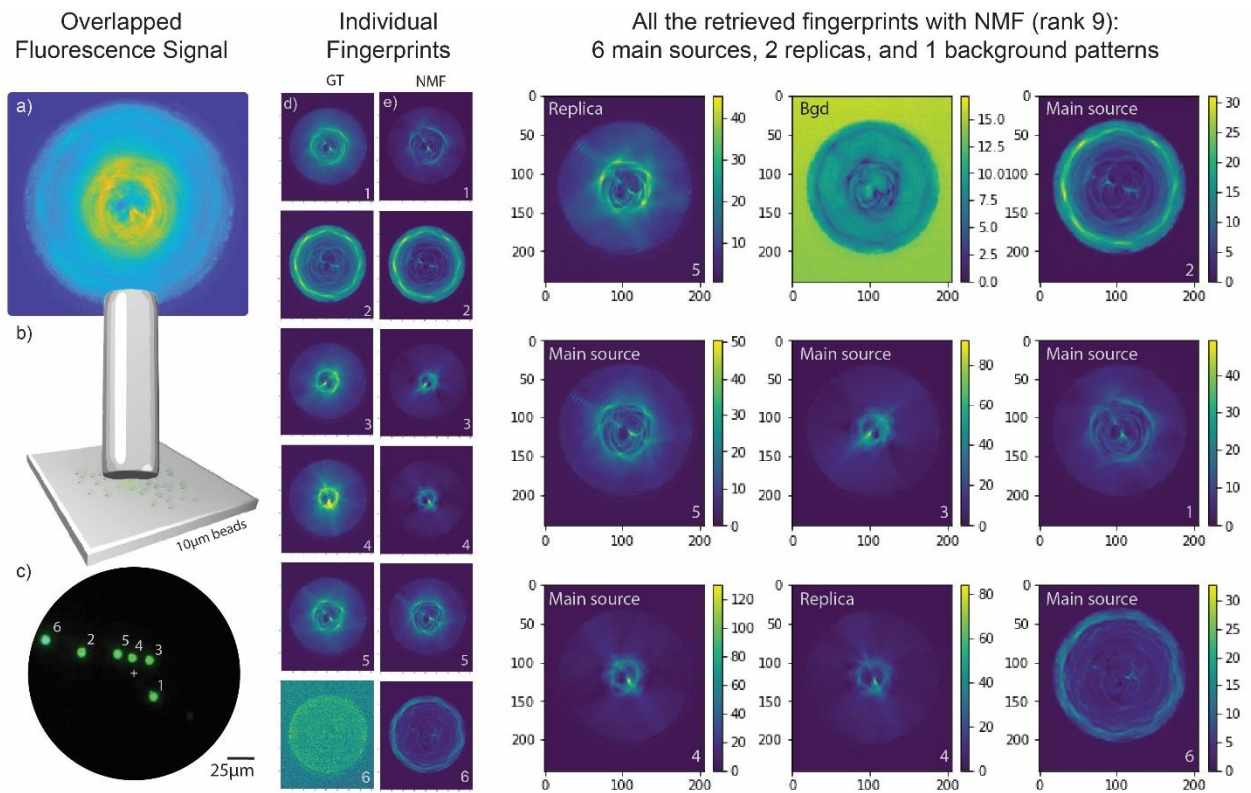

Figure S02-iv – All the fingerprint results of the proof of principle experiment, when NMF rank $R = 9$ (same as Figure O2). When rank is $R = 9$, the NMF demixes the data video in 6 main sources, 2 replicas, and 1 background (bgd).

Supp info 03: the miniscope detection sensitivity to a single source

Supp info 04: pattern shape dependence on symmetrically positioned beads (with miniscope)

Figure S04 – Beads at different azimuthal orientational positions display rotated patterns in relation to each other. In (a) the white x and y arrows are the main axis of the miniscope optics. The flat gray circles on the top of the patterns illustrate the corresponding distal end of the fiber, where the blue dot represents the 10 μ m fluorescent bead, and the black dot represents the center of the fiber core. Below each distal end cartoon, there are the corresponding proximal end data images (fluorescence patterns) obtained with the miniscope. Note that, the central structure of the fingerprint patterns (the core area within the bright ring with ramifications) contains bright and dark spots which rotate accordingly to the azimuthal orientation of the single source (blue dot) at the distal end. Yellow arrows point to some subtle bright features (ripples) at the patterns (d) and (h) that can possibly distinguish fingerprints generated from symmetrically positioned beads along one given direction if SNR is good enough. The very subtle shape differences between such two similar patterns from symmetric beads along one direction needs further investigation to confirm that they are really different, which is far from the scope of this work. In most cases, fingerprint pattern shapes seem to be different (not ambiguous) from beads localized at different orientations. Miniscope settings for these measurements were: LED = 30%, transmitted power was $P_{MMF} = 13.1 \pm 0.8 \mu\text{W}$, and detection parameters of FPS = 20 Hz, Gain = 1.

Supp info 05: the binning test

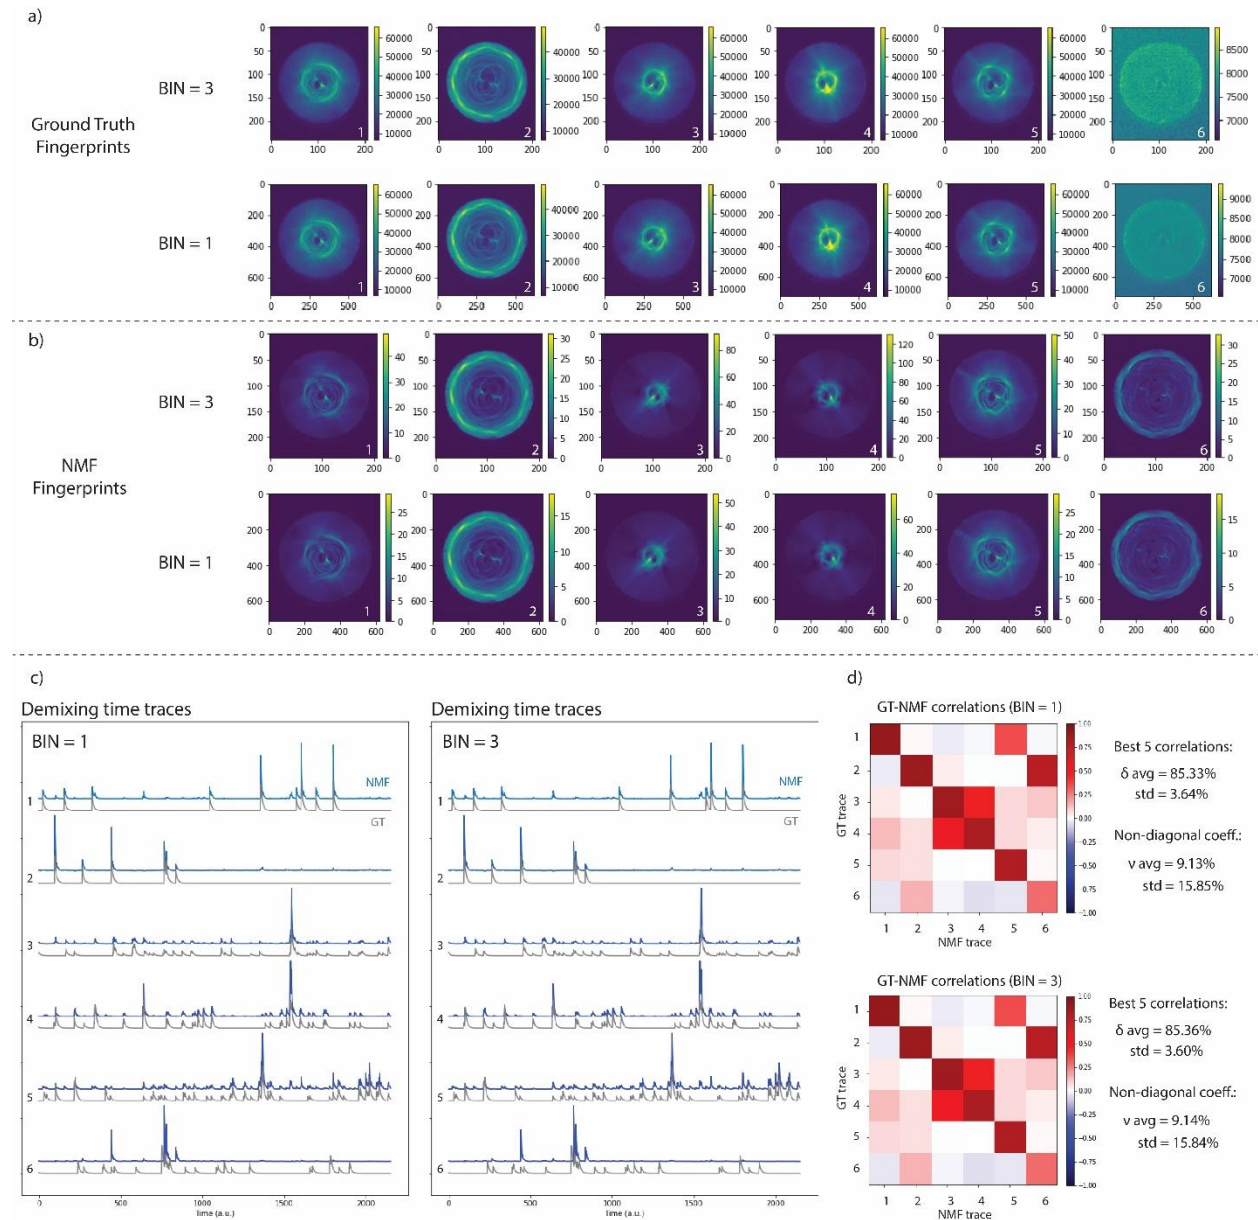

Figure S05 – Testing the results for NMF when spatially binning the recorded video. The tested binning value was bin = 3. Comparison of the results when BIN = 1 and BIN = 3 for ground truth fingerprints (a), NMF retrieved fingerprints (b), obtained time traces with NMF (c), and GT-NMF time trace correlations. NMF rank = 9, displaying the selected 6 best time traces. Analogous results were also obtained for different rank values. Overall results BIN = 3 are virtually identical to BIN = 1.

Supp info 06: comparing GT-NMF and GT-GT time trace correlation coefficients

The reason why we performed element-wise subtraction between GT-NMF and GT-GT correlation coefficients to evaluate the off-diagonal components is because the GT-GT time traces have some similarity among themselves, i.e., the non-diagonal GT-GT coefficients are not zero ($v_{i,j}^{GT-GT} \neq 0$). Consequently, it is expected that the non-diagonal elements of GT-NMF do not reach zero, but values close to the GT-GT coefficients. Let's consider the following notation for the time traces correlation coefficients:

- *GT-NMF time trace correlation coefficients:*

GT-NMF diagonal coefficients = $\delta_{i,i}$

GT-NMF non-diagonal coefficients = $v_{i,j}$

For example, when the total number of sources $N_s=6$:

$$R_{GT-NMF} = \begin{pmatrix} \delta_{1,1} & v_{1,2} & v_{1,3} & v_{1,4} & v_{1,5} & v_{1,6} \\ v_{2,1} & \delta_{2,2} & v_{2,3} & v_{2,4} & v_{2,5} & v_{2,6} \\ v_{3,1} & v_{3,2} & \delta_{3,3} & v_{3,4} & v_{3,5} & v_{3,6} \\ v_{4,1} & v_{4,2} & v_{4,3} & \delta_{4,4} & v_{4,5} & v_{4,6} \\ v_{5,1} & v_{5,2} & v_{5,3} & v_{5,4} & \delta_{5,5} & v_{5,6} \\ v_{6,1} & v_{6,2} & v_{6,3} & v_{6,4} & v_{6,5} & \delta_{6,6} \end{pmatrix}$$

- *GT-GT time trace correlation coefficients:*

GT-GT non-diagonal coefficients = $\gamma_{i,j}$

For example, when the total number of sources $N_s=6$:

$$R_{GT-GT} = \begin{pmatrix} 1 & \gamma_{1,2} & \gamma_{1,3} & \gamma_{1,4} & \gamma_{1,5} & \gamma_{1,6} \\ \gamma_{2,1} & 1 & \gamma_{2,3} & \gamma_{2,4} & \gamma_{2,5} & \gamma_{2,6} \\ \gamma_{3,1} & \gamma_{3,2} & 1 & \gamma_{3,4} & \gamma_{3,5} & \gamma_{3,6} \\ \gamma_{4,1} & \gamma_{4,2} & \gamma_{4,3} & 1 & \gamma_{4,5} & \gamma_{4,6} \\ \gamma_{5,1} & \gamma_{5,2} & \gamma_{5,3} & \gamma_{5,4} & 1 & \gamma_{5,6} \\ \gamma_{6,1} & \gamma_{6,2} & \gamma_{6,3} & \gamma_{6,4} & \gamma_{6,5} & 1 \end{pmatrix} \text{ symmetric}$$

To better evaluate how well were the obtained time traces by the NMF, one should compute the absolute mean error between the non-diagonal elements of the GT-NMF and GT-GT values:

$$\zeta = \zeta_{i \neq j} = \begin{pmatrix} s_1 & |v_{1,2} - \gamma_{1,2}| & |v_{1,3} - \gamma_{1,3}| & |v_{1,4} - \gamma_{1,4}| & |v_{1,5} - \gamma_{1,5}| & |v_{1,6} - \gamma_{1,6}| \\ |v_{2,1} - \gamma_{2,1}| & s_2 & |v_{2,3} - \gamma_{2,3}| & |v_{2,4} - \gamma_{2,4}| & |v_{2,5} - \gamma_{2,5}| & |v_{2,6} - \gamma_{2,6}| \\ |v_{3,1} - \gamma_{3,1}| & |v_{3,2} - \gamma_{3,2}| & s_3 & |v_{3,4} - \gamma_{3,4}| & |v_{3,5} - \gamma_{3,5}| & |v_{3,6} - \gamma_{3,6}| \\ |v_{4,1} - \gamma_{4,1}| & |v_{4,2} - \gamma_{4,2}| & |v_{4,3} - \gamma_{4,3}| & s_4 & |v_{4,5} - \gamma_{4,5}| & |v_{4,6} - \gamma_{4,6}| \\ |v_{5,1} - \gamma_{5,1}| & |v_{5,2} - \gamma_{5,2}| & |v_{5,3} - \gamma_{5,3}| & |v_{5,4} - \gamma_{5,4}| & s_5 & |v_{5,6} - \gamma_{5,6}| \\ |v_{6,1} - \gamma_{6,1}| & |v_{6,2} - \gamma_{6,2}| & |v_{6,3} - \gamma_{6,3}| & |v_{6,4} - \gamma_{6,4}| & |v_{6,5} - \gamma_{6,5}| & s_6 \end{pmatrix}$$

So, the mean of all the non-diagonal values would be:

$$\zeta_{avg} = \text{mean}(\zeta_{i \neq j}) = \frac{1}{2(N_s - 1)} \left(\sum_{i \neq j}^{N_s-1} |v_{i,j} - \gamma_{i,j}| \right)$$

And the standard deviation (std) of all non-diagonal elements would be:

$$\sigma_\zeta = \text{std}(\zeta_{i \neq j})$$

Where N_s is the total number of sources. These two values ($\zeta_{avg} \pm \sigma$) give us an estimation of the whole experiment quality since they should approach to zero.

Supp info 07: NMF denoising effect on spatial fingerprints

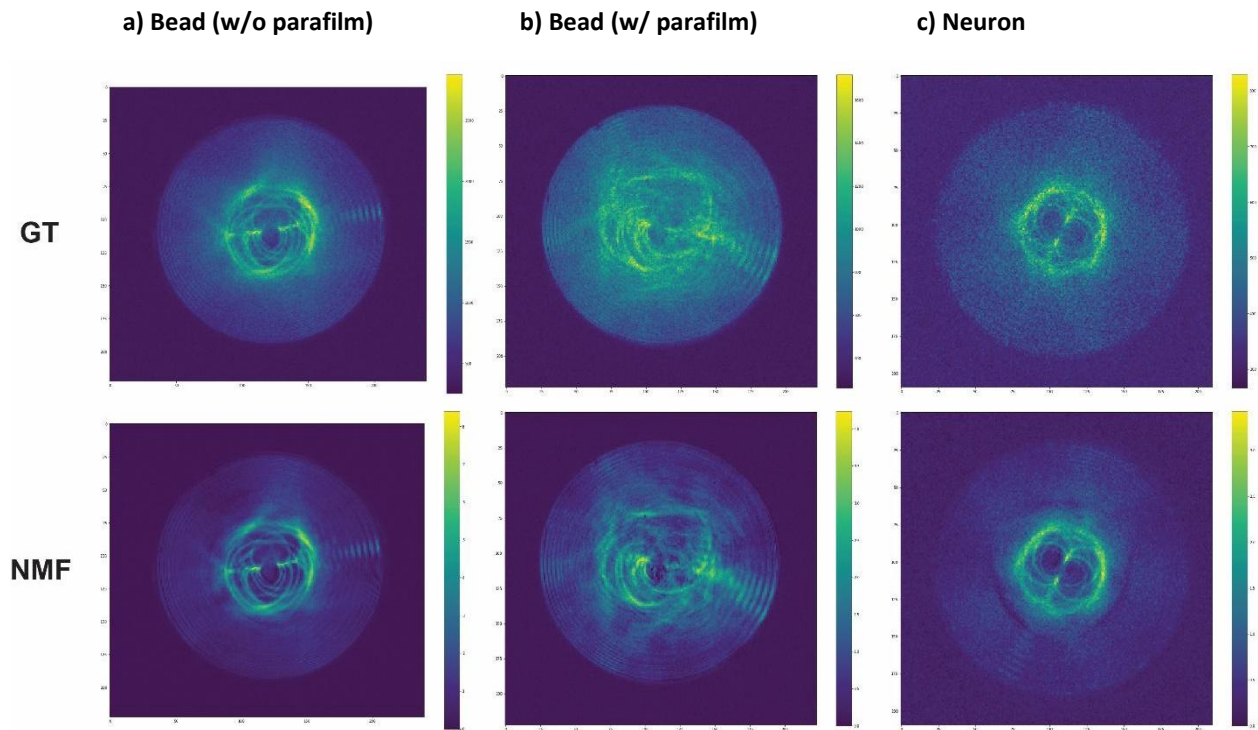

Figure S07 – NMF denoising effect on the retrieved spatial signal. Top: the ground-truth (GT) images. Bottom: the respective NMF fingerprint pattern. (a) Left column: GT-NMF patterns from bead #10 of Figure 02.2 (experiment without Parafilm M®). (b) Central column: GT-NMF patterns from bead# 09 of Figure 02.3 (experiment with Parafilm M®). (c) Right column: GT-NMF patterns of neuron #03 of Figure 03 from the main text (fixed brain slice experiment with Gad EGP labeled neurons). It is well-documented in the literature that NMF can denoise image data and we hypothesize that a long video recording can help NMF in denoising the pattern photometry data (Aonishi, T. et al. Neuroscience Research (2022); Varghese, K. et al. 3rd International Conference for Convergence in Technology (2018); Lin, B. et al. IEEE International Geoscience and Remote Sensing Symposium, (2018)). Importantly, NMF has already been used to simultaneously denoise, deconvolve and extract time traces from calcium imaging experiments (Pnevmatikakis, E.A. et al. Neuron (2016)).

Supp info 08: Scattering properties of Parafilm M®

Parafilm M® is a well-known scattering media and it has similar scattering properties as the brain tissue [Boniface A. PhD dissertation (2020), Boniface A. Optica 2019]. One layer of Parafilm M® is approximately 120 μm thick, having a scattering mean free path of around $l_s \approx 170 \mu\text{m}$ and its transport mean free path close to $l^* \approx 0.7 \mu\text{m}$, which leads to an anisotropy factor of $g \approx 0.8$ for green light (532 nm). These values are comprehensively detailed in Antoine Boniface's PhD dissertation (2020) from our team and are very close to the values obtained in biological tissues, such as the brain tissue. Thus, one layer of Parafilm M® is assumed to possess scattering characteristics comparable to 120 μm of brain tissue.

Supp info 09: Number of available scattering fingerprints (sources) to be demixed

We show in Figure 4 how patterns depend on the position of the source for a unique source. Patterns from 2 sources that are displaced by 10 μm along a radius of the fiber are already very different. In addition, we show that patterns of 2 sources that are localized with similar radial distances but different azimuthal angles around the fiber axis are also different (see patterns of beads 14 and 16 in Figure 02.2), and are well-demixed. In general, we show in Figure 02.2 that we can demix 10 μm diameter sources

that are touching each other, indicating that their corresponding patterns are sufficiently different. Therefore, the number of available “scattering fingerprints” should be on the order of hundreds for fiber lengths of 5-15 mm whose fiber core has a similar area as the one we used. With this type of fiber, we show that we are already able to demix more than 20 sources, with and without a scattering layer between the sources and the fiber tip, because their spatial fingerprints are sufficiently different (Figure 02.2 and Figure 02.3). Interestingly, however, we demonstrate that the presence of a scattering layer changes the spatial features of the fingerprint patterns, making them less similar to each other (less symmetric). This result suggests that sources at different depths in the brain can be demixed even if they overlap in x and y coordinates. In addition, this feature could facilitate our method in demixing time traces and suggests that it is possible to tune the total number of the probed sources if one decides to change the optical propagation properties of the system by engineering the implantable fiber. For example, one could add a scattering layer on the fiber distal end (the tip that faces the brain) by controlling its degree of polishment, or by simply choosing a fiber with different intrinsic propagation properties, such as NA, core geometry, etc. In theory, an infinitely long recording would be able to demix all the probed sources with unique spatial and temporal signatures. In practice, the maximum number of sources one can demix will depend on the unique features of the activity for each source, the signal-to-noise ratio, and the length of the recordings. Here, we use very short recordings (3000 frames), and the activity rate is the one observed in the mouse cortex.
