ABSTRACT

Dual super massive black holes at sub-kpc to kpc scales, the product of galaxy mergers, are progenitors of eventually coalescing binary SMBHs. If both or one of the dual SMBHs are accreting, they may appear as dual AGNs or off-nucleus AGNs. Studying such systems is essential to learn the dynamical evolution of binary SMBHs as well as the process of galaxy merging. Recently a novel astrometry-based method named varstrometry has been put forward to search for dual SMBHs at high redshift, as the unsynchronized flux variability of dual AGNs (or off-nucleus AGNs) will cause astrometric jitters detectable by Gaia without spatially resolving them. Based on Gaia varstrometry we select a rare sample of 5 radio loud quasars with clear Gaia astrometric jitters. With e-MERLIN observations we have revealed a single compact radio source for each of them. Remarkably all but one exhibit clear Gaia-radio offsets of $\sim 9 - 60$ mas. The observed Gaia jitters appear consistent with the expected values. These detected Gaia-radio offsets suggest these candidate dual SMBHs may have projected separations as small as $\sim 0.01 - 0.1''$ (~ 0.1 kpc, depending on the optical flux ratio of two SMBHs). Meanwhile, this work highlights the remarkably high efficiency of Gaia varstrometry selection of jittering sources.

Key words: quasars: general – quasars: supermassive black holes – radio continuum: galaxies – astrometry

1 INTRODUCTION

Dual super massive black holes (SMBH) may appear in the postmerger stage of galaxies, which could play a key role in galaxy formation and evolution (e.g. Jaffe & Backer 2003; Hughes 2009). As time goes by, dual SMBHs may get closer to each other due to dynamical friction, form binary SMBHs with a compact orbit < 10 pc in its own potential, and finally coalesce (e.g. Blaes et al. 2002; Khan et al. 2013). Searching for close (~ kpc or sub-kpc) dual SMBHs, the progenitors of coalescing SMBHs, thus are essential to probe their dynamical evolution as well as the process of galaxy merging (De Rosa et al. 2019), especially at high redshifts when galaxy mergers occurs much more frequently. Such dual SMBHs may appear as a dual AGN if both SMBHs are accreting, or an off-nucleus AGN if only one SMBH is active. A number of dual AGNs have been reported in literature (e.g. Woo et al. 2014; Li et al. 2016; Ellison et al. 2017; Shen et al. 2021; Chen et al. 2022; Mannucci et al. 2022; Koss et al. 2023), the majority of which (as shown in Fig. 1 of Chen et al. 2022, hereafter C22) however are at low redshifts and/or have separations > 10 kpc.

Along with Gaia's outstanding astrometric performance and full

sky coverage, a novel astrometric method to search for \sim kpc scale dual SMBHs at high redshifts has been proposed (Hwang et al. 2020), which is named as varstrometry. Considering a pair of closely tied active SMBHs with small angular separation, the photocenter of the unresolved system is dependent of the relative brightness of each component. Owing to the unsynchronized stochastic flux variation of each AGN, the photocenter may change its location noticeably enough for Gaia's detection without spatially resolving the pair. For off-nucleus AGNs, the photocenter of the variable AGN emission and the stable host galaxy flux may change as well. The changing photocenter can be well quantified by the parameter astrometric excess noise (Lindegren et al. 2018), calculated by Gaia's astrometric solution to describe the disagreement between observations and the best-fitting standard astrometric model. Meanwhile, due to unequal optical path for each lensed quasar image, unresolved lensed quasars may result in the same observational effect (astrometric jittering) as dual and off-nucleus AGNs do. Similarly quasar-star superpositions in optical image may also yield astrometric jitters (Shen et al. 2021; Lemon et al. 2017; Chen et al. 2022).

Recently C22 presented HST snap images of 56 Gaia-unresolved candidates dual quasars selected with varstrometry (based on Gaia DR2, Gaia Collaboration 2018), 18 of which show two or multiple sub-arcsecond cores (with separations as small as 0.2") in HST images, confirming the remarkable efficiency of the varstrometry

Figure 1. Gaia G-band magnitude versus *astrometric_excess_noise* of SDSS quasars (grey scale image). Our varstrometry selection criteria for candidate dual and off-nucleus AGNs are shown as blue dashed lines. The z > 0.5 candidates are shown as blue dots, among them five with FIRST 1.4 GHz flux above 5 mJy are our selected targets for e-MERLIN observations (blue triangles). Known lensed quasars from Williams et al. 2017 at z > 0.5 are plotted as orange dots. The varstrometry selection criteria of C22 using Gaia DR2 are drawn as red dashed lines, and their varstrometry selected quasars (but now plotted using *astrometric_excess_noise* from Gaia EDR3 instead of DR2) are marked as red dots with 18 HST resolved ones marked as red crosses.

approach. While a significant fraction of the resolved pairs could be physical quasar pairs or lensed quasars with separations of ~ several kpc (C22), the nature of those HST unresolved candidates is unclear but also attractive. Are they reliable jittering sources? If yes, some of them are likely dual or off-nucleus AGNs with even smaller separations (sub-kpc), for which resolving the pair or detecting the small offset between the active SMBH and the host galaxy could be beyond the ability of current optical instruments.

In this letter, we choose varstrometry selected candidate dual and off-nucleus quasars utilizing Gaia EDR3 (Gaia Collaboration et al. 2021), which provide significantly better astrometric measurements compared with earlier releases (Lindegren et al. 2021). We present radio (e-MERLIN) observations of five radio loud candidates. We show that high resolution radio interferometric observations (of radio loud candidates) can robustly confirm the remarkable efficiency of the varstrometry selection, and dramatically help us to dive deeper into the nature of the selected candidates. In §2, we present our candidates selected from Gaia EDR3 and SDSS DR16Q. We obtain e-MERLIN observations on five candidates, with the analyses and results given in §3, followed by a discussion on §4. Through out this work, we adopt a flat Λ CDM cosomology with $\Omega_m = 0.31$, $\Omega_{\Lambda} = 0.69$, $H_0 = 67.7$ km s⁻¹ Mpc⁻¹ (Planck Collaboration et al. 2020).

2 TARGET SELECTION

Here we first describe our procedures to select candidate dual and offnucleus AGNs based on Gaia varstrometry. Firstly, we perform a cross match between Gaia EDR3 (Gaia Collaboration et al. 2016, 2021) and SDSS DR16Q (Lyke et al. 2020) with a radius of 3", and pick the closest match when multiple Gaia EDR3 matches are found. It has been proposed that *astrometric_excess_noise* > 1 is a good criterion to select jittering sources (Lindegren et al. 2018; Hwang et al. 2020). However, in Fig. 1 we show that *astrometric_excess_noise* shows clear dependence on Gaia magnitude, indicating a dominant fraction of the large *astrometric_excess_noise* values (> 1) of faint sources are likely artificial ¹. We optimize the criteria to select candidates: 1) z > 0.5, to eliminate the strong effect of extended host emission on the accuracy of astrometric variability (Hwang et al. 2020); 2) a magnitude-dependent threshold of *astrometric_excess_noise* (see Fig. 1); 3) Gaia G-band magnitude brighter than 20. 111 quasars satisfy our criteria.

In Fig. 1 we over-plot the 56 varstrometry selected quasars of C22 with followup HST observations, 18 of which are spatially resolved into dual or multiple cores by HST. Our criteria could include 16 of the candidates of C22, 14 out of which have been resolved by HST images. This indicates while our criteria is highly effective in selecting jittering sources (likely with a success rate of 14/16 = 87.5%), the current selection region could be expanded in the future to include more candidates. Meanwhile, although the selection criteria of C22 (see Fig. 1) is more conservative than ours, a significant portion of their candidates show rather low *astrometric_excess_noise* in Gaia EDR3. This is because the selection of C22 was based on Gaia DR2 while EDR3 we utilized provides significantly better astrometric measurements (Lindegren et al. 2021). As an illustration, using the same selection criteria we adopted in this work but Gaia DR2 data, we would select 5147 candidates (instead of 111).

Only 7 candidates out of the 111 selected ones have FIRST 1.4 GHz radio flux larger than 5 mJy. The cut is applied to select radio bright sources for follow up high-resolution observations to accurately locate their radio core(s). Among them, J0749+2255 has been confirmed as double quasars by Shen et al. (2021) with HST and VLBA images (also included in C22); and J1415+1129 has been identified as a lensed quasar (Chartas et al. 2004). We selected the rest 5 sources as our e-MERLIN observation targets (see Table 1). Assuming a radio spectra index of 0.5, their radio loudness $R = f_{5GHz}/f_{2500A}$ range between 33 and 197. Note one of the targets, J1325+0412, is a type 2 AGN with a spectral redshift of 0.73.

3 E-MERLIN OBSERVATIONS

We observed the 5 sources with e-MERLIN in C-band between 2021.8.15 and 2021.9.6 (CY12207). MK2, Kn, De, Pi and Cm were used for observations with 3 spectral windows of 128 MHz centering at 5 GHz. The observations were performed in phase-reference mode and lasted for ~ 6 hours on each source. Radio images were calibrated with standard e-MERLIN pipeline. We cleaned the radio images using *tclean* task in CASA (CASA Team et al. 2022) with multi frequency synthesis and Briggs weighting. We set the robust parameter to 0.5 to reach a balance between spatial resolution and sensitivity. The clean beam size is $0.09'' \times 0.03''$ in average. The radio images of 5 sources are shown in Fig. 2.

We detect one compact radio core close to the optical position for each target. Fitting the compact radio core in each radio image with a two-dimensional Gaussian function using *imfit* task in CASA,

¹ As noted in Hwang et al. (2020), the reliability of *astrometric_excess_noise_sig* (an indicator of whether *astrometric_excess_noise* is statistically significant) however is yet unclear. We would like to defer the discussion and use of *astrometric_excess_noise_sig* to a future work.

Table 1. Five candidates of off-nucleus or dual quasars with e-MERLIN observations

Name	Redshift	Gaia position (ICRS)	Radio position (ICRS)	Separations [mas]	Gaia RA error [mas]	Gaia dec error [mas]	Radio RA error [mas]	Radio dec error [mas]	astrometric_excess_noise [mas]	Core flux density mJy/beam

Figure 2. e-MERLIN images of the 5 sources. The left panel for each source shows the radio images with the primary beam shown on the bottom left. The contour levels are $(3,6,12,24,32) \times 3.05$ mJy/beam (rms, the same below) for J1044+2959, $(3,5,7,9) \times 0.04$ mJy/beam for J1325+1042, $(2.5,5,10,20) \times 0.14$ mJy/beam for J1433+4342, $(3,6,12,24) \times 0.16$ mJy/beam for J1733+5520 and $(3,6,12,24) \times 0.12$ mJy/beam for J2109+0656. The right panel shows the zoom-in radio image centering at each sources. The positions of compact radio cores are drawn as crosses and the positions of Gaia optical centers are drawn as stars, which are connected with red lines. Significant Gaia-radio offsets are revealed in all sources but J1433+4842.

we obtain the positions and positional uncertainties² of radio core (see Table. 1). We use normalized separations (Mignard et al. 2016; Gaia Collaboration et al. 2022) to evaluate the significance of Gaiaradio offsets, taking account of the positional uncertainties of RA and Dec and their covariance, for both Gaia and radio coordinates. The covariance between RA and Dec uncertainties of the compact radio core is calculated using the position angle of the best-fit two-dimensional Gaussian from *imfit*. All but one of five candidates (J1433+4842) have normalized separations > 24, reaching a confidence level of $1 - 10^{-125}$.

On the other hand, for J1433, considering the 1σ confidence range of the best-fit positional angle, its normalized separation could be as low as 1.83 (corresponding to a confidence level of 81.3%). It indicates that the Gaia-radio offset of J1433+4842 is relatively small and statistically insignificant. We found there is an extra source in Gaia EDR3 near J1433+4842 within 1.09". As Mannucci et al. 2022 pointed out, the elongated photometric window on Gaia allowed pair of sources with separations near or closer than 1.1" to be recorded as a single entry, possibly causing strange astrometric solutions and enlarging the *astrometric_excess_noise*. The non-zero *ipd_frac_multi_peak* of J1433+4842 supports this scenario as well. Therefore, although can not be ruled out (see further discussion in §4), the observed jittering of J1433+4842 is possibly artificial due to the contamination of the nearby source. Note for each of the rest 4 targets, there is only a single Gaia match within 3".

As shown in the upper panel of Fig. 3, all but one of our five candidates show significant and large Gaia-radio offsets (as large as 64 mas). This is highly remarkable as the comparison between VLBI and Gaia astrometry of a control sample of quasars (see Fig. 3) revealed > 10 mas offsets only in 3.7% sources. The lower panel of Fig. 3 also shows that most quasar in the control sample have small *astrometric_excess_noise* (only 0.4% have *astrometric_excess_noise* > 1.614, which is the minimum value of our five targets). Clearly, the observed large Gaia-radio offsets of our candidates are associated with their large *astrometric_excess_noise* values.

The large Gaia-radio position offsets and large *astrometric_excess_noise* of our small sample indicate we have obtained a distinct and rare population of quasars with clear Gaia astrometry jitters, and with the radio-loud AGN offset from the optical center of the system, as expected in dual AGNs or off-nucleus AGNs.

4 DISCUSSION

Suppose the mean optical flux and its variation (standard deviation) for each quasar in dual quasars, or for the off-nucleus quasar and its host galaxy, are f_1 , σ_1 and f_2 , σ_2 , respectively ($\sigma_2 = 0$ for the host galaxy for off-nucleus quasar), and the projected distance between two components is *D*. The total optical flux and its standard deviation

 $^{^2}$ All the phase calibrators we used have position uncertainties less than 0.2 mas thus their uncertainties are ignored, and the stochastic contribution from atmospheric phase fluctuations are also negligible.

Figure 3. Top: Gaia-radio offsets of our five candidates of dual and offnucleus quasars, and the reverse-cumulative histogram of a control sample (red line). The control sample is derived through cross-matching the VLBIbased Radio Fundamental Catalogue rfc_2022d with Gaia EDR3 and the Million Quasars catalog (Flesch 2021), with only sources with z < 0.5and Gaia G-band magnitude < 20 selected (similar with our targets). See http://astrogeo.org/sol/rfc/rfc_2022d/ for rfc catalog. Bottom: Gaia-radio offsets - *astrometric_excess_noise* diagram of our candidates and the control sample.

of the system is $f = f_1 + f_2$ and $\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$. The positioning uncertainty of the optical center could be calculated as following, corresponding to *astrometric_excess_noise* (Hwang et al. 2020).

$$\sigma_c = \frac{D}{(f_1 + f_2)^2} \sqrt{\sigma_1^2 f_2^2 + \sigma_2^2 f_1^2} \tag{1}$$

The Gaia-radio offset is the projected distance between the radio core (source 1) and optical center of the system:

$$d_{GR} = \frac{f_2}{f_1 + f_2} D$$
 (2)

Combining these equations, we get the predicted *astrometric_excess_noise* as:

$$\sigma_c = \frac{d_{GR}}{f} \sqrt{\sigma_1^2 + \sigma_2^2 f_1^2 / f_2^2}$$
(3)

Assuming that our candidates are off-nucleus quasars, or dual quasars but optical flux variation in one of them is negligible, i.e., $\sigma_2 = 0$, or dual quasars with $f_1 \sim f_2$ (assuming the host galaxy contribution is negligible), we may calculate the predicted *astrometic_excess_noise* as

$$\sigma_c = d_{GR} \frac{\sigma}{f} \tag{4}$$

where σ is the flux variation³ of our candidates, and compared it with observed value (see Fig. 4).

Figure 4. Observed and predicted *astrometric_excess_noise* for each candidates assuming they are all off-nucleus quasars. The blue line is the linear regression of the sample (excluding J1433+4842) with the 1σ area of the regression filled with light blue.

A correlation (with coefficient *R* of 0.853 and p-value of 0.147) is found between the observed and predicted *astrometric_excess_noise*, and the best-fit linear regression line is close to 1:1. This is similar to Fig. 6 of Hwang et al. (2020), who calculated the expected *astrometric_excess_noise* for a small sample of Gaia unresolved pre-main sequence binaries (but resolved by other facilities, thus with the measurements of *D* instead of d_{GR}).

Our Fig. 4 thus provides new and remarkable support to the varstrometry approach that the observed *astrometric_excess_noise* provides a reasonable measurement of the astrometric jittering in quasars. We note that though the observed Gaia-radio offset in J1433+4842 is statistically insignificant, its observed *astrometric_excess_noise* also appears consistent with the expected value, suggesting its jittering could be physical real. Therefore we keep this source as a possible candidate of dual or off-nucleus quasars, and await future deep radio images to confirm its Gaia-radio offset.

Furthermore, we may calculate the projected distance between two quasars (or between the off-nucleus quasar and its host galaxy center) in our candidate systems assuming hypothetical brightness ratio $q = f_1/f_2$ ranging from 1:10 to 10:1 (assuming quasar 1 is the radio detected one):

$$D = \frac{f_1 + f_2}{f_2} d_{GR} = (1+q) d_{GR}$$
(5)

Note the brightness ratio of the HST resolved pairs in C22 is between 1.0 and 8.7 with a median of 2.1 (the flux ratio of the brighter source to the fainter one).

The results are presented in Fig. 5. We over-plot the 16 varstrometry selected quasars of C22 which fall in our selection region (see Fig. 1), 14 of them are resolved with HST.

Compared to the sample of C22, though to be statistically confirmed with larger sample, our sample tends to have considerably

Gaia G band exposures, both given in Gaia EDR3. The intrinsic flux variation σ is then obtained through subtracting in quadrature the expected Gaia photometric uncertainty per exposure. The expected Gaia photometric uncertainty per exposure as a function of magnitude is calculated using the tool provided by Gaia DPAC to reproduce the Gaia (E)DR3 photometric uncertainties described in the GAIA-C5-TN-UB-JMC-031 technical note using data in Riello et al. (2021). See https://www.cosmos.esa.int/web/gaia/fitteddr3-photometric-uncertainties-tool. For all of our 5 quasars, the photometric uncertainties only make small contribution to the observed variation.

³ For each Gaia source, its observed flux variation could be derived as $phot_g_mean_flux_error * \sqrt{phot_g_n_obs}$, where $phot_g_mean_flux_error$ is the mean Gaia G band flux uncertainty and $phot_g_n_obs$ the number of

smaller projected distances. One possibility is due to the difference in the selection between C22 and this work, and in the measurements of *astrometric_excess_noise* between Gaia DR2 and EDR3. As shown in Fig. 1, the selection of C22 appears more conservative, thus favors targets with larger *astrometric_excess_noise* (thus larger projected distance). Meanwhile, Gaia DR2 provides less reliable measurements of small *astrometric_excess_noise*, thus is less efficient in selecting sources with small projected distances. Since we have demonstrated the remarkably high efficiency of varstrometry selection of jittering sources based on Gaia EDR3, HST followup observations on a sample uniformly selected based on Gaia EDR3 or later releases are thus essential to statistically study the population, and HST unresolved candidates among them could consequently be considered as reliable jittering sources, thus potential dual and offnucleus AGNs at smaller scales.

Alternatively, varstrometry selected radio loud quasars may intrinsically be different. Through matching Gaia DR2 with the VLBIbased Radio Fundamental Catalog, Plavin et al. (2019) found radio AGNs with clear Gaia-VLBI offsets often have the direction of offset aligning with the jet, indicating strong optical jet contamination to Gaia astrometry could cause Gaia-radio offset and possibly also jittering (see also Kovalev et al. 2017; Petrov & Kovalev 2017). As shown in the lower panel of Fig. 3, while our candidates have both large Gaiaradio offsets and astrometric_excess_noise, most of the VLBI control sample have rather small offsets and *astrometric_excess_noise*. We further find that Gaia-radio offsets of the control sample barely change with increasing astrometric excess noise. This suggests our small sample is physically distinct from the control sample, and the physical origin of their jitter and Gaia-radio offset is unlikely due to jet contamination. Meanwhile, except for J1044+2959, our sources have rather low radio core fluxes (0.4 - 6 mJy), considerably fainter than the VLBI C-band fluxes (with a median of 69 mJy) of the control sample at similar Gaia G magnitude. Furthermore, we only detected compact radio cores (but not extended jet like structure) in e-MERLIN images of our five targets. This suggests our sources do not have jet as strong as RFC sources, thus the optical jet contribution to Gaia astrometry of them is expected to be weak. Future deep radio images could put further constraints to the existence of strong jets in our targets.

A more interesting possibility is that varstrometry selected radio loud quasars do intrinsically have smaller projected distances. If future deep radio images (e.g. SKA) could confirm that radio loud varstrometry selected dual and off-nucleus quasars preferentially have smaller projected distances (sub-kpc vs kpc) compared with radio quiet ones, this could interestingly implies that dual SMBHs or offset SMBH at sub-kpc scales are more likely to trigger jet launching compared with those at kpc scales.

A considerable fraction of varstrometry selected quasars could be quasar-star pairs or lensed quasars (e.g. Shen et al. 2021; Chen et al. 2022). As Fig. 5 shows, our small sample seems to have shorter projected separations ($\leq 0.1''$) compared to the "dual/lensed quasars" in C22 (~ 0.5''), resulting in 25 times lower possibility of finding close quasar-star pairs. Among the 16 targets of C22 which satisfy our selection criteria, 9 are identified as "quasar-star" pairs, thus for our small sample with much smaller predicted separations, the fraction of quasar-star pairs is expected to much lower (9/16/25 = 2.25%).

On the other hand, while lensed quasars can not be completely ruled out, our high resolution e-MERLIN observations revealed no evidence of lensed signals (arcs, rings, or multiple images), though this possibility could be further testified with future deep radio images. Furthermore, Shen et al. (2021) stated that the abundance of

Figure 5. The expected projected separation of our 5 candidate dual quasars, in comparison with the HST measured projected separation of the varstrometry selected quasars of C22 which also satisfy our selection criteria based on Gaia EDR3 (an upper limit of 0.18", the smallest resolved separation in C22, is assigned to the two HST unresolved ones). For our targets, the expected separation is calculated from the measured Gaia-radio offset assuming the optical flux ratio of the two quasars (of the e-MERLIN detected quasar to the other) of 1:10, 1:1 and 10:1 (the lower limits of the blue error bars, blue dots, and upper limits, respectively). One of two other varstrometry selected radio quasars, J0749+2255, which is also included in C22, in marked as an open blue circle. The other one, J1415+1129, a lensed quasar with four images spacing in ~ 1 ", is omitted in this figure.

high-redshift sub-arcsecond gravitational lens is insufficient to account for their varstrometry selected resolved pairs.

It is also interesting to note that numerical simulations (e.g. Blecha et al. 2018) have suggested that AGNs in the sub-kpc merger stage should be heavily obscured. Varstrometry selected sub-kpc dual AGNs seems contradict this scenario, or we are selecting a sub-population of them in which at least one AGN is unobscured. Further note one of our candidate J1325+0412 is indeed a type 2 AGN. If it is in a dual AGN system, its jitter and flux variability measured with Gaia shall be caused by the other unobscured AGN in the system (which however was not seen in SDSS spectrum), unless itself changed to type 1 during Gaia observations. Followup spectroscopic observation is required to verify if this sources is a changing-look quasar (e.g. LaMassa et al. 2015) in dual or off-nucleus AGN system.

Besides *astrometric_excess_noise*, other criteria may also reveal candidate dual quasars out of Gaia unresolved sources. As Fabricius et al. (2021) presented, *ruwe* (renormalised unit weight error) which describes the goodness of fit with standard astrometric model similar to reduced χ^2 , could be utilized to select candidate dual quasars (normal stars and quasars with good astrometric behaviour should have *ruwe* close to 1, and sources with *ruwe* > 1.4 are possibly dual quasar candidates). Four of our five e-MERLIN target fullfilled this criteria except J1044+2959 (whose *ruwe* is 1.34, also close to 1.4).

Additionally, Mannucci et al. (2022) proposed the GMP (Gaia Multi-Peak) method and successfully found dual/lensed AGN candidates at sub-arcsec separations by looking for multiple peaks in the light profiles observed by Gaia. As mentioned in §2, close pairs with separations $\leq 1.1''$ may be observed and recorded by single elongated photometric window of Gaia, whose size is as large as $0.71'' \times 2.1''$. In this case, multiple peaks can be seen in the compressed 1-D light profile, and *ipd_frac_multi_peak* is the fraction of Gaia observations with multiple peaks detected. A quasar with large *ipd_frac_multi_peak* is likely to be a dual/lensed quasar. Among our five targets, only J1733+5520 shows a large *ipd_frac_multi_peak* of 20%. As J1733+5520 is unresolved by Gaia, its possible separation is likely between 0.11'' (Gaia's PSF) and 0.35'' (Mannucci et al.

2022), consistent with the range of 0.028-0.28'' we derived based on its Gaia-radio offset.

Moreover, Wu et al. (2022) selected abnormal Gaia unresolved quasars (e.g. quasar pairs. Makarov & Secrest (2022) yielded a sample of 152 quasars with excess proper motions, which were candidates of dual/multiple AGNs, or lensed quasars. Note two of our candidates (J1733+5520 and J2109+0656) do exhibit highly significant Gaia DR3 proper motions, with covariance-normalized values of 16.0 and 11.8 respectively, and J2109+0656 has an uncertainty-normalized parallax of +4.3. Such proper motion and parallax should be artificial due to the jittering of the sources. For instance, a monotonic flux increasing of one quasar in dual AGN system could cause artificial proper motion signal. Further crossmatch studies of the parent sample in this letter (111 varstrometry selected quasars) with those samples aforementioned, and extensively exploring the efficiencies of these various selection criteria is deferred to a future work, better with later Gaia data releases when epoch astrometry is available.

ACKNOWLEDGEMENTS

We thank the anonymous referee for constructive comments which have significantly improved the manuscript. This work was supported by the National Science Foundation of China (No. 1890693, 12033006 & 12192221), and Cyrus Chun Ying Tang Foundations. MFG acknowledges support from the National Science Foundation of China (grant no. 11873073), Shanghai Pilot Program for Basic Research Chinese Academy of Science, Shanghai Branch (JCYJ-SHFY2021-013), the National SKA Program of China (Grant No. 2022SKA0120102), the Original Innovation Program of the Chinese Academy of Sciences (E085021002), and the science research grants from the China Manned Space Project with No. CMSCSST-2021-A06. e-MERLIN is a National Facility operated by the University of Manchester at Jodrell Bank Observatory on behalf of STFC, part of UK Research and Innovation. This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.
