ABSTRACT

While in massive galaxies active galactic nuclei (AGN) feedback plays an important role, the role of AGN feedback is still under debate in dwarf galaxies. With well spatially resolved data obtained from the Multi-Unit Spectroscopic Explorer (MUSE), we identify a spatially extended (~ 3 kpc) and fast ($V_{80} \sim 471 \text{ km s}^{-1}$) AGN-driven outflow in a dwarf galaxy: SDSS J022849.51-090153.8 with $M_* \sim 10^{9.6} \text{ M}_{\odot}$ that host an intermediate-mass black hole of $M_{BH} \sim 10^5 \text{ M}_{\odot}$ and $L_{AGN}/L_{Edd} \sim 0.15$. Through the measurement of the rotation curve, we estimate the escape velocity of the halo and the ratio of the outflow velocity to the halo escape velocity to be 1.09 ± 0.04 , indicating that the outflow is capable of escaping not only the galaxy disk but the halo. The outflow size of our AGN is found to be larger than AGN in massive galaxies at the given AGN [O III] luminosity, while the size of the photo-ionized narrow-line region is comparable. These results suggest the important role of AGN feedback through outflows in dwarf galaxies when their central intermediate-mass black holes accrete at high-Eddington ratios.

Key words: galaxies: active, galaxies: dwarf, galaxies: Seyfert

1 INTRODUCTION

Observations have shown that there are correlations between the physical properties of supermassive black holes (SMBH) and their host galaxies (Kormendy & Ho 2013). By accreting the surrounding gas material, SMBHs shine as the active galactic nuclei (AGN), meanwhile, their feedback processes affect the evolution of host galaxies (King & Pounds 2015). In the theoretical framework of galaxy formation and evolution, such feedback brings simulated galaxy properties in agreement with observations by suppressing star formation in massive galaxies (Vogelsberger et al. 2014; Dubois et al. 2016; Pillepich et al. 2018; Puchwein & Springel 2013; Khandai et al. 2015; Schaye et al. 2015).

The AGN-driven outflow is proposed to be an effective way to affect the physical properties of host galaxies (King & Pounds 2015). Observational evidence has shown that the presence of AGN-driven outflow in massive galaxies represents an ongoing AGN feedback process (Rupke & Veilleux 2011, 2013, 2015; Liu et al. 2013a,b; Harrison et al. 2014; Rupke et al. 2017; Ramos Almeida et al. 2019). Through such powerful and spatially extended outflow, AGN feedback is sufficient to affect the baryonic matter of galaxies out to their circumgalactic media (CGM) (Veilleux et al. 2014; Lau et al. 2018).

In dwarf galaxies, a common picture holds that stellar feedback

is the primary feedback mechanism (Heckman & Thompson 2017; Martín-Navarro & Mezcua 2018; Shi et al. 2021a), while the role of AGN feedback is still under debate. New simulations from Koudmani et al. (2019, 2021) pointed out that AGN may play an indirect role in regulating the baryonic matter cycle in dwarf galaxies. Meanwhile, other simulations also rise the possibility of direct AGN feedback in dwarf galaxies via gas ejection (Dashyan et al. 2018; Barai & de Gouveia Dal Pino 2019; Koudmani et al. 2022; Sharma et al. 2022). With the development of observational techniques, ones have detected more and more AGN activities in dwarf galaxies (Shi et al. 2008; Baldassare et al. 2016; Chilingarian et al. 2018; Bohn et al. 2021; Salehirad et al. 2022). Penny et al. (2018) presented that the AGN feedback may affect the quenching process of dwarf elliptical galaxies in the MaNGA survey. Manzano-King et al. (2019) observed 29 dwarf galaxies with AGN through the Keck LRIS long-slit spectroscopy. Nine of their 29 objects show spatial extended and fast AGN-driven outflows, which suggests that AGN feedback may play an important role in their dwarf galaxy sample. Liu et al. (2020) selected eight AGN in dwarf host galaxies from Manzano-King et al. (2019) and drew similar conclusions through integral field spectroscopy (IFS) observations with Keck KCWI and Gemini GMOS.

By assuming a simple density profile, such as an isothermal sphere model, the escape velocity is often derived from the circular velocity, i.e., $V_{esc} \approx (2.6-3.3) V_{circ}$ (Veilleux et al. 2020). In massive galaxies, cool outflows (atomic and molecular outflow) are hard to escape

⁵Department of Astronomy, Xiamen University, Xiamen, Fujian 361005, China

 ^{*} E-mail: yong@nju.edu.cn

from the halo (Schroetter et al. 2015, 2016; Tamhane et al. 2022). The situation does not become better in warmer material, since the outflow velocity of ionized gas is not always larger than the neutral gas (Rupke et al. 2017; Veilleux et al. 2020).

However, the situation in dwarf galaxies may be quite different. In some objects where the ionized gas outflow is detected, the ratio of outflow velocity and escape velocity (i.e. V_{out}/V_{esc}) decreases with the galaxy mass (Arribas et al. 2014; Rodríguez del Pino et al. 2019), and drops to a unity around the stellar mass of $4 \times 10^9 M_{\odot}$ so that $V_{out} > V_{esc}$ (Schroetter et al. 2019). These results indicate that the outflow escapes easier in dwarf galaxies, at least for the ionized gas. However, the escape velocity is difficult to measure in dwarf galaxies, usually based on indirect methods such as the abundance matching (Manzano-King et al. 2019). The direct method with the rotation curve requires data reaching the flat part of the rotation curve, which is sometimes hard especially in dwarf galaxies where AGN-driven outflow is detected (Manzano-King & Canalizo 2020; Liu et al. 2020).

In this work, we carry out detailed studies of AGN in a dwarf galaxy SDSS J022849.51-090153.8 (SDSS J0228-0901) with Multi-Unit Spectroscopic Explorer (MUSE) on Very Large Telescope (VLT) to probe properties of its outflows. It hosts an intermediate-mass black holes with $M_{\rm BH} \sim 3.7 \times 10^5 {\rm M}_{\odot}$ (Chilingarian et al. 2018). Benefiting from the large field of view of MUSE, we have a chance to measure the escape velocity more precisely. This paper is organized as follows. In § 2, we introduce the basic properties of SDSS J0228-0901 and our observations. Then the data analysis is presented in § 3. Our investigation results and understandings are described in § 4. Finally, § 5 gives a summary. We assume a Λ CDM cosmology of $H_0 = 67.4 {\rm km s}^{-1} {\rm Mpc}^{-1}$, $\Omega_{\rm m} = 0.315$ and $\Omega_{\Lambda} = 0.685$ (Planck Collaboration et al. 2020).

2 OBSERVATION AND DATA REDUCTION

The galaxy SDSS J0228-0901 is first identified as an AGN in Greene & Ho (2007). As listed in Table 1, its black-hole mass of $(3.7 \pm 0.3) \times 10^5 M_{\odot}$ is measured through a single-epoch broad line width by Chilingarian et al. (2018). In order to search for and study outflows in this galaxy hosting such an intermediate-mass black hole, we carry out the MUSE IFU observations (PID: 0104.C-0181(C), PI: F. Bian). Figure 1 (a) shows the white image of our object. The red box in this panel marks the region that we used to do spectral analysis.

We use the well-known method to classify AGN region in the optical band: the BPT diagram (Baldwin et al. 1981; Kewley et al. 2001; Kauffmann et al. 2003; Schawinski et al. 2007). This diagram uses several emission line ratios in the optical band: $log([N II]\lambda 6583/H\alpha)$ vs. $log([O III]\lambda 5007/H\beta)$ to classify galaxies into Seyfert, LINER, star-forming and composite regions. Therefore, we classify each spaxel by the [N II]-BPT diagram in panel (b) and (c) of Figure 1. As indicated by panel (c), the central regions of SDSS J0228-0901 are classified as Seyfert. As shown later in this study, the Seyfert regions overlap more or less with the outflow regions.

2.1 MUSE Data Reduction

MUSE (Bacon et al. 2010) is one of the instruments onboard VLT. It has a spatial sampling of 0.2'' and a field of view of $1' \times 1'$ under the Wide Field Mode (WFM). This mode covers the wavelength range from 4650 to 9300, with a spectral resolution of about 2800. The observations with the WFM-NOAO-N mode were carried out on October 8, 20, and 21, 2019. The total on-source exposure time is

2400 sec. The typical seeing is around 1.4". We adopt the standard ESO Reflex environment (Freudling et al. 2013) to produce the IFS datacube. Briefly, the science frames are first calibrated by bias, dark, and flat frames. Next, the arc frames are used for wavelength calibrations. After the sky subtractions, flux calibrations, and telluric corrections, the single science exposures are combined into the final datacube. The default settings of the pipeline are adopted during the data reduction processes.

2.2 SDSS Data

We also retrieve the broad band images from the Sloan Digital Sky Survey Data Release 15 (SDSS DR15, Aguado et al. 2019). These images were taken on November 18, 2006, with a total exposure time of 53.9 secs and a seeing of 1.2". We further decompose the galaxy into bulge and disk components through the GALFIT software (Peng et al. 2010). The uncertainties of the photometry include the read noise and the sky background.

3 DATA ANALYSIS

3.1 Voronoi Binning

To improve the signal-to-noise ratio (SNR) of our datacube, we rebin the spaxels by the VorBin software (Cappellari & Copin 2003). The datacube is binned according to the SNR of the H α emission line. To ensure sufficient SNR, we adopt a threshold of 10.

3.2 Spectrum Fitting

There is a strong blue-shifted wing in $[O III]\lambda\lambda4959$, 5007 emission line as shown in Figure 2, indicating an ionized outflow in SDSS J0228-0901. Before measuring the emission line, we first employ the penalized Pixel-Fitting (pPXF; Cappellari 2017) software to fit the underlying stellar continuum. We adopt the single stellar population model MILES (Vazdekis et al. 2010) and a 4th-order polynomial. To align the spectral wavelength intervals with the model spectrum, we limit the wavelength range from 4800Å to 7409Å.

For each emission line with a potential broad line component after subtracting the stellar continuum, we fit it with a single Gaussian model and multi-Gaussian model, respectively, through Python code Scipy.curve_fit. If the former has a χ^2 more than 20% larger than the latter (Salehirad et al. 2022), we define that there is a broad component in this emission line. Through the above method,

Figure 1. White image and BPT map of SDSS J0228-0901. (a): The white image of SDSS J0228-0901, which is taken from MUSE observation. The FOV of MUSE is $1' \times 1'$, SDSS J0228-0901 is boxed by the red square with a size $10'' \times 10''$. (b): BPT diagram. Here we use the $\log([O \, \text{m}]/\text{H}\beta) \text{vslog}([N \, \text{n}]/\text{H}\alpha)$ diagram to distinguish the type of each spaxel. The red pixels above the blue solid curve and the green dot-dash line represent the Seyfert region, the orange dots above the blur solid curve but below the green dot-dash line are the LINER regions, the blue pixels below the orange dashed curve mark the star-forming region, and the green pixels between the two curve is the composite region (Kewley et al. 2001; Kauffmann et al. 2003; Schawinski et al. 2007). We only classify the spaxels whose signal-to-noise ratio (SNR) of H α emission line larger than 10 (i.e. $\text{SNR}_{H\alpha>10}$). (c): Two-dimensional BPT map. The color represents the same region as panel (b).

Figure 2. Spectrum fitting results of the central spaxel. (a): The black line shows the observational data, the red line represents the stellar continuum fitted by pPXF software, and the green dots in the middle plane show the residuals. (b)-(d) is the H β region, H α region, [S II] doublet fitting results. Same as (a), the black line represents the observational data, the orange line is the best fit of the emission line, the blue dot-dashed line is the narrow component and the magenta dashed line is the broad component.

we fit a total of eight emission lines for our IFS datacube, including: $H\alpha\lambda 6563$, $H\beta\lambda 4861$, $[N II]\lambda\lambda 6548$, 6583, $[O III]\lambda\lambda 4959$, 5007, $[S II]\lambda\lambda 6717$, 6731. For the $[O III]\lambda 4959$ and $[O III]\lambda 5007$ doublet, we tied the line width and set the flux ratio of 1:3 (Dimitrijević et al. 2007).

As shown in Figure 2, the best fitting results are dominated by polynomials and do not show any strong absorption lines for the central spaxel, indicating the dominance of AGN power law emission over the stellar continuum emission at the center. As shown in Figure 2 (b)-(d), there is a clear broad component in H α , H β , and [O III] doublet.

3.3 Dust Attenuation

We correct the dust attenuation based on the Balmer decrement and the attenuation curve from Calzetti (2001), with an assumption of $A_V/E(B - V) = 3.1$. For SDSS J0228-0901, we adopt the intrinsic ratio between the narrow components of H α and H β to be 2.86 for star-forming regions and 3.1 for AGN regions (Kewley et al. 2006).

3.4 Outflow Velocity

For the broad component in [O III] emission lines, we not only calculate its line center velocity (i.e. V_{50}) but also use the non-parametric approach from Harrison et al. (2014) to evaluate the outflow velocity (i.e V_{80}). Where the V_{80} represents at least 20% of the flux of the emission line moving at this speed. In the non-parametric approach, we consider W_{80} as the width which contains 80% of the total flux of the broad component of the emission line. And then we use the equation from Manzano-King et al. (2019) to define:

$$V_{80} = -V_0 + \frac{W_{80}}{2},\tag{1}$$

where V_0 is the line center velocity offset between narrow and broad components, and for a single Gaussian profile: $W_{80} = 1.09$ FWHM.

3.5 Rotation Curve

To evaluate if the outflow can escape the galaxy gravitational potential well, we measure the total rotation curve from the line center velocity map of the H α narrow component. Here the H α velocity map includes the narrow line region (NLR) of AGN. We estimate the inclination angle by measuring the ellipticity through fitting the surface brightness image with the python package photutils (Bradley et al. 2022). Figure 3 (a) shows the velocity map, and we measure the total rotation curve of the galaxy along its major axis which is the black dashed line in this figure.

The observed rotation curve contains contributions from the gravity of stars, gas, and dark matter. We measure the stellar contribution from the stellar mass surface density profile that is based on the SDSS DR15 g and r band images through the aperture photometry. As the bulge and disk have different 3-D structure and thus different gravitational potential well for a given surface density. We first adopt GALFIT (Peng et al. 2010) to decompose the image data by fitting g and r images with a bulge of Sérsic index 2 and an exponential disk model while estimating the error as described in § 2.2. Afterward, we use the python package photutils to perform aperture photometry on two decomposed components, while setting the outer boundary of the photometry around 8 kpc. We then estimate the stellar mass profile from the surface brightness profile of the g, r band with the equation from Shi et al. (2018) that are based on the SDSS galaxies:

$$\log M_* + M_{\rm r-band}/2.5 = 1.13 + 1.49 \times (g - r), \tag{2}$$

Figure 3. (a): Line center velocity map of H α narrow components, the black dashed line along the major axis. Setting the H α emission line SNR threshold to 10. (b): The contribution of different components to the total rotation curve. The blue line shows the circular velocity profile which is from the rotation curve from the H α velocity with the correction of asymmetric drift. The green dotted line represents the contribution of the stellar component, while the red dot-dashed line of the gas component.

where M_{r-band} is the *r*-band absolute magnitude in AB, and g - r is color in AB. Figure 4 (a)-(c) shows the *r*-band image, the stellar mass profile of bulge and disk, respectively, where the orange ellipse in panel (a) marks the outer boundary and reaches about 8 kpc. To measure the stellar contribution to the rotation curve, we use the ROTMOD task of GIPSY (Casertano 1983) by assuming a "SECH-SQUARED" vertical distribution with a scale height of 0.2 kpc. The error of the stellar rotation curve is dominated by the uncertainties of stellar mass distribution, and this effect is simulated through the Monte-Carlo method. As a result, the green dashed curve in Figure 3 (b) is the stellar rotation curve, its inner most radius reaches about 1.2 kpc as limited by the spatial resolution of the SDSS image.

It is out of the current capability to obtain both spatially-resolved H_I gas and molecular gas kinematics for this dwarf galaxy with a luminosity distance of about 300 Mpc. As a result, we estimate the total gas surface density through the star formation law, especially the extended Schmidt law that shows a tight relationship between star formation rate (SFR), gas, and stellar mass down to very low

Figure 4. Optical *r*-band image and H α integrate flux map of SDSS J0228-0901. (a), (d): The *r*-band image from SDSS DR15 and the H α integrate flux map from MUSE observation. The orange ellipse represents the outer bounds of aperture photometry. (b), (c): Radial profile of stellar mass surface density of galaxy bulge and disk components. (e): Radial profile of star formation rate, the sky-blue dots are the star formation rate surface density that we measure from the H α luminosity, the black dashed line is the best-fit exponential model, and the red points are obtained by extrapolation from the exponential model. The orange dots are presented as the model that there is no star formation in the inner regions. (f): Radial profile of total gas mass surface density derive from the extended Schmidt law. The sky-blue dots mark the exponential star formation model, and the orange dots show the model that no star formation in the inner regions.

gas densities (Shi et al. 2011, 2018; Du et al. 2022). To estimate the SFR surface density, we first draw the flux map of H α emission line narrow component. To exclude the effect of AGN, we mask the regions which are classified as AGN in the BPT map. Figure 4 (d) shows the H α narrow component flux map, where the orange ellipse represents the outer boundary. We then estimate the SFR through the equation from Kennicutt (1998):

$$SFR(M_{\odot}yr^{-1}) = 7.9 \times 10^{-42} L(H\alpha) (\text{ergs s}^{-1}), \qquad (3)$$

where $L(H\alpha)$ is the flux of the H α narrow component in ergs s⁻¹.For the inner region, we assume two models to evaluate the SFR in the bulge: (1) no star formation in the bulge regions. (2) we adopt a gas disk model so that the SFR surface density follows an exponential model from the inner regions to the outer regions. Figure 4 (e) shows the SFR surface density evaluated from the two models above, where the error is mainly from the flux error of the H α emission line. With the derived SFR and stellar mass distribution, we measure the gas mass distribution from the equation from Shi et al. (2018):

$$\Sigma_{\rm SFR} = 10^{-4.76} (\Sigma_{\rm star}^{0.5} \Sigma_{\rm gas})^{1.09}, \tag{4}$$

where the Σ_{SFR} is the SFR surface density in M_{\odot} yr⁻¹ kpc⁻², Σ_{star} and Σ_{gas} are the stellar and gas mass surface densities in M_{\odot} pc⁻², respectively. As a result, the gas distribution is shown in Figure 4 (f), where the error contains the error from SFR, stellar mass profiles and the intrinsic scatter of around 0.23 dex for the extended Schmidt law. We then use the same method to measure the gas contribution to the rotation curve as we measure the stellar rotation curve. The most significant difference between the gas rotation curve measured by the two models is that the rotation velocity of the first method is much slower than the gas disk model in the inner bulge regions. The overall gas contribution to the circular velocity from the two models is minimal, so we ensure that the dark matter halo (DMH) rotation curve also becomes flat when the total rotation curve is flattened.

To evaluate the escape velocity of the gravitational potential of the galaxy, we also need to measure the circular velocity. However, as the gas collision, part of the gravitational potential of the galaxy is consumed by the random motion of gas referred to as the asymmetric drift effect (Oh et al. 2015). We follow the method of Shi et al. (2021b) to correct the effect of asymmetric drift. For a hydrostatic equilibrium disk, the circular velocity satisfies:

$$V_{\rm circ}^2 = V_{\rm rot}^2 + V_{\rm P}^2,\tag{5}$$

where V_{rot} is the rotation velocity from observations and V_{P} is the velocity related to the gas random motion as driven by pressure. The V_{P} is related to the gas density and gas dispersion:

$$V_{\rm P}^2 = -R\sigma_{\rm v}^2 \frac{\partial \ln(\rho \sigma_{\rm v}^2)}{\partial R}.$$
(6)

If adding another assumption that the scale height (z_0) of the gas disk is a constant, i.e. $dln(z_0)/dR = 0$, then the equation will become:

$$V_{\rm P}^2 = -R\sigma_{\rm v}^2 \frac{\partial \ln(\sigma_{\rm v}^2 \Sigma_{\rm obs} \cos i)}{\partial R},\tag{7}$$

where Σ_{obs} is the gas surface density from the observation, σ_v is the gas velocity dispersion as obtained from the narrow component of the H α emission line, and *i* is the inclination angle. The final rotation curve after correcting the pressure support is shown in Figure 3 (b). Recently, Downing & Oman (2023) investigated the relationship

between the measured rotation curve and circular velocity in dwarf galaxies by simulations. They pointed out that the environmental effects can cause significant differences between the two, which may not be corrected fully by the asymmetric drift effect. However, the optical image of SDSS J0228-0901 shows that it is an isolated dwarf galaxy that lacks obvious merging or interacting features. On the other hand, we are mainly interested in the flat part of the circular velocity that infers the escape velocity. In their sample, the rotation curve and circular velocity do show a better agreement in the flat part. Therefore, these environmental effects should not affect our results significantly.

4 RESULTS AND DISCUSSION

4.1 Spatial Distributions and Kinematics of Outflow

We estimate the kinematic properties of the ionized gas outflow as shown in Figure 5 (b) and (c). The outflow regions are almost all blue-shifted and their velocities (V_{50} and V_{80}) do not decrease with the radius. Figure 6 compares the radial profiles of two outflow velocities with the rotation curve. The V_{80} remains almost constant with radius, and it is much larger than the circular velocity.

We also use the ratio of outflow velocity and the halo escape velocity (V_{80}/V_{esc}) to evaluate if the outflow can escape from the gravitational potential of the host galaxy. We select a total of 23 sources that include both dwarf galaxies and massive galaxies for comparison. Five dwarf galaxies with AGN are from Manzano-King et al. (2019) and Liu et al. (2020). They have available SMBH mass, V80, and halo escape velocity measurements. Massive galaxies with AGN are from McElroy et al. (2015). We list a series of physical properties of SDSS J0228-0901 and comparison samples in Table 2.

We estimate the escape velocity of SDSS J0228-0901 through two methods. (1) By assuming the density profile of both baryonic and dark matter with an isothermal sphere model which truncates at a radius r_{max} , the escape velocity is related to V_{circ} and r_{max}/r as described in Veilleux et al. (2020):

$$V_{\rm esc}(r) = V_{\rm circ} \sqrt{2 \left[1 + \ln(\frac{r_{\rm max}}{r}) \right]}.$$
(8)

For different r_{max}/r , the $V_{\text{esc}}/V_{\text{circ}}$ can vary from 2.6 to 3.3 with different r_{max}/r . We use the mean factor of 3 to estimate the escape velocity to be about 427.2 km s⁻¹, i.e. $V_{\text{esc}} = 3V_{\text{circ}}$. (2) The escape velocity can also be derived from the gravitational potential directly:

$$V_{\rm esc}(r)^2 = 2 \times |\Phi(r)|. \tag{9}$$

Here we assume the DMH as a Navarro-Frenk-White (NFW) halo model (Navarro et al. 1997), and estimate the halo mass from maximum circular velocity (Klypin et al. 2011). As a result, the estimated halo mass (M_{200}) is around $10^{11.95}$ M_{\odot} and the escape velocity is around 435 km s⁻¹ at $R = R_{out}$ (R_{out} : the radius of the outflow region.). Finally, we take the average of the two methods as the result, i.e. $V_{esc} = (431.4 \pm 17.9)$ km s⁻¹. We notice that both methods produce a consistent escape velocity, indicating that the NFW DMH model is reasonable to describe the dark matter distribution in SDSS J0228-0901. In Figure 6, the dark orange curve represents the circular velocity profile of the NFW DMH. We calculate this profile through the derived NFW circular profile(Shi et al. 2021b):

$$V_{\rm NFW}(R) = V_{200} \sqrt{\frac{\ln(1+cx) - cx/(1+cx)}{x[\ln(1+c) - c/(1+c)]}},$$
(10)

where V_{200} is the velocity at R_{200} , i.e. $V_{200} = R_{200}h$, c represent the concentration with $c = R_{200}/R_s$, and $x = R/R_{200}$. The halo concentration parameter (c) is estimated from its halo mass (M_{200}) following the approximation for distinct halo (Klypin et al. 2011):

$$c(M_{200}) = 9.60(\frac{M_{200}}{10^{12}h^{-1}M_{\odot}}).$$
(11)

As for the subsample of massive galaxies, the circular velocity is determined by a kinematic parameter $S_{0.5}$ that is the combination of the regular rotation (V_{rot}) and random motion (σ_{gas}). To measure the kinematic parameter $S_{0.5}$, we adopt a tight correlation between $S_{0.5}$ and stellar mass (M_*) (Kassin et al. 2007):

$$\log(M_*/M_{\odot}) = 1.93 \log S_{0.5} + 0.30.$$
(12)

Then, according to the stellar mass from McElroy et al. (2015), the circular velocity is estimated as $V_{\text{circ}} = \sqrt{2}S_{0.5}$. In the subsample of dwarf galaxies, Manzano-King et al. (2019) used the abundance matching method (Moster et al. 2013) to estimate the mass of DMH and assume an NFW dark matter density profile (Łokas & Mamon 2001) to derive the escape velocity.

The escape velocity error of SDSS J0228-0901 is mainly from the error of the circular velocity profile which is described in § 3.5. For the escape velocity estimated from the kinematic parameter, the scatter of the relation between $S_{0.5}$ and M_* dominates the error of the velocity. For dwarf galaxies, assuming a standard deviation of 0.2 dex for the abundance-match based log M_{200} (Xu et al. 2022a), the uncertainty of V_{circ} is derived from the relation between $V_{\text{circ},\text{max}}$ and M_{200} (Klypin et al. 2011), which gives a fractional error of $\Delta V_{\text{circ}}/V_{\text{circ}} \approx 0.7$. Errors of outflow velocity and W80 in the total 23 sources are from the spectral fitting.

Figure 7 (a), (b) show V_{80}/V_{esc} as a function of the AGN luminosities and SMBH masses. The V_{80}/V_{esc} of SDSS J0228-0901 is 1.09 ± 0.04, larger than most massive galaxies. These results suggest that the AGN-driven outflow in dwarf galaxies is able to escape from the gravitational potential of the dark matter halo. This result is consistent with Liu et al. (2020) although their escape velocity measurements have much larger errors. Figure 7 (c) shows V_{80}/V_{esc} as a function of the Eddington ratios. Although there is a significant selection bias in dwarf galaxies toward higher Eddington ratios as compared to massive galaxies, no clear trend is seen that the AGN-driven outflow escapes more easily in AGNs with high Eddington ratios. Figure 7 (d) shows V_{80}/V_{esc} as a function of the ratio between the SMBH mass and stellar mass of hosts. There is no clear trend suggesting that the AGN-driven outflow escape more easily in more massive SMBHs at a given stellar mass.

Besides Figure 7, we also compare other properties among these samples in Table 2. For the environments, we further check the optical image in SDSS. Dwarf galaxies are all isolated and lack merging or interacting features. While about half of massive galaxies show clear merging or interacting features, galaxies with interacting pairs or tidal tails do not show significantly higher outflow velocity (McElroy et al. 2015). On the other hand, these merging or tidal features may affect the estimation of stellar mass and escape velocity. For the SFR, Liu et al. (2020) estimated the SFR upper limit from the [O II] luminosity, which indicated that their dwarf galaxies span a large range from green-valley galaxies to starburst galaxies. McElroy et al. (2015) provided the total H α luminosity data, from which we convert to the SFR following the method in Kennicutt (1998), and find that these massive galaxies have slightly higher SFRs consistent with the SF main sequence and starburst galaxies.

Other studies of outflows in larger samples also show V_{out}/V_{esc} as

Table 2. Comparison of physical properties between SDSS J0228-0901 and other samples from literature.

Figure 5. The spatially resolved physical properties of galaxy SDSS J0228-0901. (a): The [O III] total flux map with the correction of dust attenuation, we use the same SNR cut as described before. Due to the weak emission and seeing smearing effect, we can not reach the threshold $(10^{-16} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2})$ of the extended narrow line region (ENLR) size measured in Chen et al. (2019). Hence we plot half of the FWHM of PSF as the red circle in panel (a) to represent the upper limit of the ENLR size. (b) The line center velocity (V_{50}) of the broad component of [O III] emission line, and the blue color represent the blue shifted velocity, the maximum V_{50} reach to around -200 km s^{-1} . (c): The outflow velocity (V_{80}) map defined as V_{80} which is calculated by the same method in Manzano-King et al. (2019), the maximum V_{80} along minor axis reach to 471 km s⁻¹. Both the V_{50} and V_{80} do not decrease with the radius, and the outflow can extend to galactic scale with a size of around 3 kpc by rough estimation.

Figure 6. The spatially extended outflow velocity vs total rotation curve in log space. The blue curve is the total rotation curve, the pink diamonds mark the line center velocity (V_{50}) while the brown squares are the outflow velocity (V_{80}). The dark orange curve represents the circular velocity profile of an NFW DMH.

a function of the stellar mass, indicating that ionized gas outflows in dwarf galaxies are more likely to escape from their hosts (Arribas et al. 2014; Rodríguez del Pino et al. 2019; Schroetter et al. 2019; Xu et al. 2022b). While this conclusion is supported by current observations, it is important to note that AGNs in dwarf galaxies are selected to have high Eddington ratios. It is unclear whether outflow can be launched to a similar velocity when the accretion rate is low in dwarf galaxies.

4.2 Outflow size vs. AGN luminosity

In addition to the outflow velocity, the size of the outflow region is another indicator to reflect how the AGN exerts feedback on its host galaxy. Numerous works have studied outflow sizes using spatially resolved data, revealing that outflow sizes range from the sub-kpc (Kawaguchi et al. 2018; Baron & Netzer 2019) to several kpc (Harrison et al. 2014; McElroy et al. 2015; Kang & Woo 2018). Two types of methods have been used to measure outflow sizes. One is to define the outflow region based on the line fluxes such as signal-to-noise ratio or surface brightness thresholds. The second is based on the kinematics of emission lines, e.g. the outflow region is identified as the presence of a broad line component whose $\sigma_{\rm emline} > 250 \,\rm km \, s^{-1}$, or as the velocity dispersion of the emission line equal to the stellar velocity dispersion, i.e. $\sigma_{\rm emline} = \sigma_*$ (Kang & Woo 2018).

Previous works have compared the outflow size using different methods, and pointed out that the flux based method may significantly over-estimate the outflow size (Fischer et al. 2018; Kang & Woo 2018). Therefore we estimate the outflow size of SDSS J0228-0901 by using the kinematic edge in Kang & Woo (2018). They studied 23 luminous ($L_{O III} > 5 \times 10^{41}$ erg s⁻¹) type 2 AGN that host relatively massive SMBH in the local universe ($M_{BH} \sim 10^{6.2-9.3} \text{ M}_{\odot}$) and defined the ionized gas outflow region as where the velocity dispersion of [O III] λ 5007 emission line is larger than the stellar velocity dispersion. The derived outflow sizes of their samples cover from 0.60 to 7.45 kpc. We use the same method to estimate the outflow size for SDSS J0228-0901. However, since we do not detect any absorption line in the spectrum of SDSS J0228-0901, it is impossible to

Figure 7. Outflow capability vs. AGN properties. We utilize the ratio between the maximum outflow velocity and the escape velocity (V_{80}/V_{esc}) to describe the escape capability of outflow. (a): V_{80}/V_{esc} as a function of AGN luminosity, (b): V_{80}/V_{esc} as a function of SMBH mass. (c): V_{80}/V_{esc} as a function of Eddington ratios. (d): V_{80}/V_{esc} as a function of the ratio between SMBH mass and stellar mass

. In each subplot, the pink hexagon represents the galaxy SDSS J0228-0901, the sky-blue cross is the dwarf galaxies from Manzano-King et al. (2019) and Liu et al. (2020), and the brown square mark the massive galaxies from McElroy et al. (2015). The gray dashed line represents where $V_{80}/V_{esc} = 1$.

obtain the stellar velocity dispersion directly. Fortunately, previous works proposed to use the flux weighted velocity dispersion of the narrow component of the emission line as the proxy of stellar velocity dispersion, such as H α or [O III] (Woo et al. 2016; Kang et al. 2017; Kang & Woo 2018). Here, we substitute the stellar velocity dispersion with the flux weighted velocity dispersion of the narrow component of [O III] λ 5007, and convert $\sigma_{[O III]narrow}$ to σ_* by dividing with a factor of (1.09 ± 0.32) , to give σ_* of around 63 kms⁻¹. We note that this correction factor has a slight effect on the outflow size measurement but does not change our results. The AGN luminosity are converted from [O III] luminosity (Lamastra et al. 2009)

The upper panel of Figure 8 shows the two-dimensional spatial distribution of $[O ext{ III}]\lambda 5007$ velocity dispersion distribution that is normalized with the stellar velocity dispersion, while the bottom panel shows the normalized $[O ext{ III}]\lambda 5007$ velocity dispersion along the major axis. We estimate the outflow size of $R_{\text{out}} = 2.45 \pm 0.44$ kpc by subtracting the PSF size (black dashed line). Kang & Woo (2018) obtains a good relation between the outflow size and $[O ext{ III}]$

luminosity:

$$\log(R_{\rm out}) = (0.28 \pm 0.03) \log L_{\rm [O\,III]} - (11.27 \pm 1.46). \tag{13}$$

Figure 9 (a) clearly shows that the kinematic outflow size of SDSS J0228-0901 locates above the relationship.

Furthermore, to compare the outflow size among galaxies with different sizes, we normalize the outflow size by the effective radius (R_e) of galaxies. Here we use photutils to measure the surface brightness profile from the SDSS r band image by aperture photometry. Then the surface brightness profile is fitted by an Sérsic model (Sérsic 1968) which contains R_e :

$$I(R) = I_{\rm e} \exp\left\{-b_{\rm n}\left[\left(\frac{R}{R_{\rm e}}\right)^{1/n} - 1\right]\right\}.$$
(14)

During the fitting, we free three parameters: I_e , R_e , and Sérsic index n, where b_n is tied with n as $b_n \approx 1.9992n - 0.3271$ (Graham 2019). Given that the average FWHM of PSF is 1.26'', if the effective radius

Figure 8. Upper: Spatial distribution of [O III] velocity dispersion which is normalized by the stellar velocity dispersion, the ionized gas outflow size is indicated by the red circle with 1σ error. Bottom: the normalized [O III]velocity dispersion profile along the major axis, here we adopt the same cut as the rotation curve, i.e. SNR of H α larger than 10. The green line and light green region represent the stellar dispersion with 1σ error, the vertical red line is the outer boundary of the outflow region, the two vertical dashed red lines and the pink area show the 1σ error, while the vertical black dashed line represents the PSF size (FWHM/2). After subtracting the seeing smearing, we obtain the final outflow size: $R_{out} = (2.45 \pm 0.44)$ kpc.

is smaller than the PSF size, we then use the PSF size as the upper limit of the effective radius. Figure 9 (b) shows the result where we exclude sources classified as quasars in archive data. Finally, we plot 17 galaxies together with SDSS J0228-0901. It seems the normalized outflow size of SDSS J0228-0901 is not so stand out from the other galaxies but is slightly larger than other AGN in the low [O III] luminosity regime. The above two results indicate that the mechanical feedback from the central AGN is more substantial in SDSS J0228-0901.

Since the AGN feedback is not only through the mechanical process (i.e. jets and outflows) but also via the radiative process i.e. photoionization regions as excited by AGN (King & Pounds 2015). The size of the extended narrow line region (ENLR) is an indicator of the radiative effect. Similar to the size measurements of outflow

Figure 9. Upper: Outflow size vs [O III] luminosity, both the blue dots and the best-fit relation with the dark blue line are from Kang & Woo (2018), the pink marker is galaxy SDSS J0228-0901. The outflow size of SDSS J0228-0901 is significantly larger than predicted by the relation. Bottom: Normalized outflow size by effective radius (R_{out}/R_e) vs [O III] luminosity, the symbols are same as the upper panel. The dark blue line marks the best-fit relation of the sky-blue data points.

regions, there are also different methods to determine the size of ENLR. For the Seyfert galaxies, we follow the method in Chen et al. (2019), and use the same threshold of 10^{-16} erg s⁻¹ cm⁻² arcsec⁻². However, Figure 5 (a) indicates that the surface brightness across the whole galaxy is all below this threshold, indicating a tiny size if adopting the above threshold. In Figure 10, we adopt half of the PSF FWHM as the upper limit of the ENLR size and found that its upper limit does not deviate significantly from the relation.

Owing to the difference in gas motion, there is a large difference between outflow size and ENLR size. From observations, the outflow size is always smaller than the size of ENLR (Fischer et al. 2018; Kang & Woo 2018). This indicates that the mechanical feedback is weaker than the radiative feedback in most Seyfert galaxies. However, for SDSS J0228-0901 we find a larger outflow size than the ENLR size, which indicates the mechanical feedback is stronger than the radiative feedback in this object.

Figure 10. Extended Narrow Line Region size vs [O III] luminosity. All the background dots are same as the Figure 6. in Chen et al. (2019), the best-fit relation with a slope of (0.42 ± 0.02) . The pink hexagon represents the upper limit ENLR size of SDSS J0228-0901, we set the upper limit as half of the FWHM of median PSF as 1.1 kpc.

4.3 Gas phase metallicity of star-forming region and AGN NLR

Metallicity is an important property of ionized gas in galaxies. However, the metallicity of gas that is ionized by the AGN radiation is difficult to measure. This is because most of the emission line diagnostics are usually adapted for star-forming regions. Therefore we estimate the gas-phase metallicity through 3 different methods. (1) N2 calibrator which is used in Seyfert 2 AGNs and proposed by (Carvalho et al. 2020):

$$12 + \log\left(\frac{O}{H}\right) = 8.69 + \log\left(\frac{Z}{Z_{\odot}}\right),\tag{15}$$

where $Z/Z_{\odot} = 4.01^{N2} - 0.07$, and $N2 = \log([N \, \text{II}]\lambda 6584/\text{H}\alpha)$. This calibrator is also adopted to AGN NLRs and LINERs for $0.3 < (Z/Z_{\odot}) < 2.0$. (2) O3N2 calibrator which is used in diffused ionized gas and LINERs as proposed by (Kumari et al. 2019):

$$12 + \log\left(\frac{O}{H}\right) = 7.673 + 0.22 \times \sqrt{25.25 - 9.072 \times O3N2} + 0.127 \times O3,$$
(16)

where $O3N2 = \log([O \ m]\lambda 5007/H\beta \times H\alpha/[N \ m\lambda 6584])$, and $O3 = \log([O \ m]\lambda 5007/H\beta)$. (3) HII-CHI-MISTRY (HCM) software that uses multiple strong collisionally exciting lines in the optical band and combines them with photo-ionized models to calculate the gasphase metallicity (Pérez-Montero 2014). We adopt the HCM software to obtain the spatially resolved gas-phase metallicity of SDSS J0228-0901 from the inner AGN regions to outer star-forming regions. Within the wavelength coverage of MUSE, we have five emission lines: $[O \ m]\lambda\lambda4959, 5007$, $[N \ m]\lambda6584$, $[S \ m]\lambda\lambda6715, 6731$, and $[S \ m]$ lines for which we sum them together as $[S \ m]\lambda6725$. The fluxes of all these emission lines are normalized by the flux of the narrow component of H β emission line. To adapt the photoionized model better, we exclude the broad component from the H α and H β emission line and the blue-shifted wing of $[O \ m]$ doublet.

Figure 11 shows the metallicity distribution estimated by the three methods above. SDSS J0228-0901 shows an overall flat radial metallicity distribution, a general property seen in dwarf galaxies. Even

in AGN NLRs, the metallicity is not apparently elevated. However, there is a significant difference between the two optical line calibrators and the HCM software. As shown in Figure 11 (a), (b), both N2 and O3N2 show weak or no negative gradients along the major and minor axis and do not present metal enrichment around outflow edges on the minor axis direction. But in Figure 11 (c), along the minor axis, regions that are outside the galaxy disk but within the outflow regions have enhanced metallicity. In these regions, gas may be dominated by outflowing gas that is more metal rich. The HCM software is also adopted to various galaxies, including the star-forming galaxies, Seyfert 2 AGNs, and LINERs (Pérez-Díaz et al. 2021). In that work, their Seyfert 2 AGN and LINER sub-samples do not show a clear mass metallicity relation (MZR), and the metallicity in their star-forming galaxies also presents a significant deviation in the low mass end in MZR. As for SDSS J0228-0901, a dwarf galaxy with a Seyfert 1 AGN, the metallicity inferred from the HCM software also shows a large deviation in MZR (according to the MZR, the metallicity is about 8.7 as stellar mass is around 9.6). As a result, we prefer results from the two emission line calibrators, suggesting that AGN does not launch metal rich outflowing gas in our object.

4.4 Electron Density of star-forming region and AGN NLR

The electron density (n_e) of ionized gas can be derived from the ratio between $[O ext{ II}]\lambda\lambda3726, 3729$ or $[S ext{ II}]\lambda\lambda6717, 6731$ doublets (Sanders et al. 2016), which covers a n_e range of 50 – 5000 cm⁻³. Here we estimate the electron density of NLR through the flux ratio of $[S ext{ II}]$ doublet. As shown in Figure 12, the n_e along the major axis exhibits a shallow negative gradient with the best fit slope of (-0.15 ± 0.08) .

Some previous studies about the AGN-driven ionized gas outflow assume n_e as a constant in the outflow regions (Harrison et al. 2014; McElroy et al. 2015; Kakkad et al. 2016), but the electron density is very different between the NLR and the outflow regions. While other works with IFS data confirm that the gas in the outflow regions is denser than in the NLR, and the electron density in NLR also decreases with radius (Arribas et al. 2014; Kakkad et al. 2018; Baron et al. 2020). Our result gives a conclusion that the electron density in NLR decreases with radius too. However, due to the lack of the broad component of [S II] emission line, we can not obtain the electron density of the outflow regions. The result also shows that the n_e of NLR is not much different from normal galaxies which indicates the outflow may not affect the electron density of NLR distribution of the host galaxy.

5 CONCLUSIONS

With VLT-MUSE observations, we discover a fast AGN-driven outflow in a dwarf galaxy SDSS J0228-0901 that hosts an intermediatemass black hole ($M_{\rm BH} \sim 10^5 {\rm ~M}_{\odot}$). By comparing with other galaxies that host AGN-driven outflows, we find that the outflow in dwarf galaxies can escape when their central black-holes accrete at high rates. And here are our main conclusions.

(1) In the BPT diagram and BPT map, the detected outflow regions largely overlap with the AGN NLR regions, which supports that the outflow is driven by the central AGN.

(2) The outflow in SDSS J0228-0901 is blue-shifted, with the outflow velocity (V_{80}) of 471 km s⁻¹, while the escape velocity is around 431 km s⁻¹. This indicates that the outflow will escape from the gravitational potential of the galaxy and dark matter halo.

(3) To further investigate how AGN feedback affects its host galaxy

Figure 11. Two-dimensional gas-phase metallicity map of SDSS J0228-0901. We estimate the gas-phase metallicity through three methods. (a) The N2 calibrator proposed by Carvalho et al. (2020). (b) The O3N2 calibrator proposed by Kumari et al. (2019). (c) The python script HII-CHI-MISTRY (HCM) from the photoionized model (Pérez-Montero 2014). In each panel, the red circle represents the size of outflow regions with 1σ error.

Figure 12. The electron density along the major axis. The electron density is estimated by the ratio of [S n] doublet. While the dark blue solid line is the best fit line of the electron density gradient with a slope of -0.15 ± 0.08 .

in our case. We estimate the outflow size and extended narrow line region (ENLR) size, and find that the outflow size is larger than the ENLR size, indicating the mechanical feedback process is stronger than the radiative feedback process.

(4) From the two-dimensional distribution of gas-phase metallicity, we do not find the metallicity enhancement in the outflow regions.

(5) Due to the lack of the broad component in [S II] $\lambda\lambda 6717, 6731$, we cannot obtain the electron density of the outflow regions. But we do calculate the electron density of the NLR by using the narrow component of [S II] doublet and find a negative gradient along the major axis with the best-fit slope of -0.15 ± 0.08 .

ACKNOWLEDGEMENTS
