ABSTRACT

We present Balmer decrement $H\alpha/H\beta$ measurements for a sample of 51 galaxies at redshifts $z = 4-7$ observed with the *JWST*/NIRSpec MSA, as part of the JADES survey. Leveraging 28-hour long exposures and the efficiency of the prism/clear configuration (but also using information from the medium-resolution gratings), we are able to probe directly the low-mass end of the galaxy population, reaching stellar masses M_\star as low as $10^7 M_\odot$. We find that the correlation between Balmer decrement and M_\star is already established at these high redshifts, indicating a rapid build up of dust in moderately massive galaxies at such early epochs. The lowest-mass galaxies in our sample ($M_\star = 1-3 \times 10^7 M_\odot$) display a remarkably low Balmer decrement of 2.88 ± 0.08 , consistent with case B, suggesting very little dust content. However, we warn that such a low observed Balmer decrement may also partly be a consequence of an intrinsically lower $H\alpha/H\beta$, resulting from the extreme conditions of the ionized gas in these primeval and unevolved systems. We further compare the Balmer decrement to continuum-derived star-formation rates (SFR), finding tentative evidence of a correlation, which likely traces the underlying connection between SFR and mass of cold gas. However, we note that larger samples are required to distinguish between direct and primary correlations from indirect and secondary dependencies at such high redshifts.

Key words. Galaxies: high redshift – Galaxies: evolution – Galaxies: ISM – ISM: dust extinction

1. Introduction

The Balmer recombination lines are an efficient probe of star-forming regions. They are the brightest non-resonant series (enabling efficient escape, unlike the intrinsically brighter Lyman

series) and they are less affected by dust attenuation compared to probes at shorter wavelengths. The Balmer series is therefore the brightest measure of the flux of hydrogen-ionising continuum emitted by massive, short-lived (< 10 Myr) stars. These lines therefore provide the most direct measure of the current rate of

* E-mail: ls861@cam.ac.uk

star formation, on timescales of 3–10 Myr (Flores Velázquez et al. 2021; Tacchella et al. 2022).

Because of the wavelength-dependent attenuation from dust, the observed flux ratio between the Balmer lines (Balmer decrement) provides a direct measure of the optical depth towards star-forming regions. This measurement is essential to complement alternative probes such as the attenuation of the optical and UV stellar continuum (e.g., Galliano et al. 2018; Salim & Narayanan 2020), which probe different optical depths (e.g., Calzetti et al. 1994).

While this measurement requires knowledge of the intrinsic ratio, the latter value is known from atomic physics and is relatively insensitive to a broad range of different physical conditions commonly found in star-forming regions (Osterbrock & Ferland 2006; Smith et al. 2022). In particular, variations of the gas temperature between 5,000–20,000 K and of the density between 100–10,000 cm^{-3} can change the Balmer decrement by less than 10 per cent.

Leveraging these advantages, the ratio of the two brightest lines – $\text{H}\alpha/\text{H}\beta$ – has been used to estimate the dust content of star-forming regions (Reddy et al. 2015; Nelson et al. 2016; Matharu et al. 2023), the amount of gas present (e.g., Piotrowska et al. 2020), and their relation with other galaxy properties (e.g., Groves et al. 2012). Maheson et al. (2023) show that the Balmer decrement correlates with stellar mass M_\star , with secondary dependencies on gas metallicity and velocity dispersion. One should however also take into account that the geometry of the dust distribution also plays a role in the observed Balmer decrement. Specifically, very dusty and optically thick systems can potentially result in a low Balmer decrement, as the Balmer lines may trace only the outer, optically thin regions of the galaxy.

However, as we strive to observe galaxies further away, at earlier cosmic times, the Balmer series is redshifted towards near-infrared (NIR) wavelengths, where atmospheric absorption, as well as thermal and telluric emission from the atmosphere, make ground-based observations difficult. Despite that, in recent years, ground-based NIR surveys have revealed how the Balmer decrement evolves up to Cosmic Noon, at redshifts $z = 2$ – 3 (Kriek et al. 2015; Reddy et al. 2015; Curti et al. 2020; Lorenz et al. 2023). Yet, at $z > 3$, $\text{H}\alpha$ is redshifted beyond 2.6 μm , where ground-based observations of faint distant galaxies are prohibitively expensive. This meant that, at these high redshifts, dust could only be probed using sub-mm observations (Watson et al. 2015; Laporte et al. 2017; Witstok et al. 2022), which is feasible only for relatively high stellar masses.

The start of *JWST* science operations in July 2022 opened for the first time a view into $\text{H}\alpha$ at redshifts $z > 3$ (Gardner et al. 2023). Early results using data from the Cosmic Evolution Early Release Science Survey (CEERS; Finkelstein et al. 2023) have shown that the correlation between Balmer decrement and stellar mass is already established at $z = 4$ – 6 (Shapley et al. 2023). In particular, low-mass galaxies are confirmed to have low Balmer decrement – suggesting low dust content. At the same time, studies of collisionally excited lines have shown that the star-forming regions of early galaxies were hotter than in the local Universe, with electron temperatures of $\approx 20,000$ K (e.g., Schaerer et al. 2022; Curti et al. 2023a,b) and possibly denser, with electron densities $n_e \approx 500 \text{ cm}^{-3}$ (Reddy et al. 2023). These differences mean that the intrinsic Balmer decrement should also be slightly different, requiring a correction to our methods to estimate dust attenuation.

In this work, we leverage the unprecedented depth of the *JWST* Advanced Deep Extragalactic Survey (JADES; Eisenstein et al. 2023) to probe dust attenuation in the star-forming regions

of galaxies at redshifts $z = 4$ – 7 . In § 2 we introduce the data and sample and describe the measurements we use. Our results are presented in § 3 and we conclude the article with a discussion of the implications (§ 4) and a summary (§ 5).

Throughout this work, we assume a flat Λ CDM cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$. For the initial mass function we assume the functional shape of Chabrier (2003).

2. Data / Sample Selection

2.1. Data

We use data from the JADES survey (Bunker et al. 2023; Eisenstein et al. 2023), obtained as part of programme ID 1210 (PI: N. Lützgendorf). The targets were selected from the GOODS-South field (Giavalisco et al. 2004), as described in Bunker et al. (2023). *JWST*/NIRSpec was configured to use the micro-shutter assembly (MSA; Jakobsen et al. 2022), with the prism/clear disperser/filter combination to obtain low-resolution spectroscopy (nominal $R = 30$ – 100) for 253 targets between $0.6 < \lambda < 5.3 \mu\text{m}$. An example spectrum (JADES-GS+53.16904-27.77884) is shown in Fig. 1.

Each target was assigned to an array of 3×1 micro-shutters, forming an effective slit of 0.2 arcsec width and ≈ 1.3 arcsec length. We used three dither positions and three nods, for a total integration time of up to 28 hours. The data reduction was performed using the pipeline developed by the ESA NIRSpec Science Operations Team and the NIRSpec GTO Team. We use the publicly available data products v3.0, which include a wavelength dependent slit-loss correction, assuming all sources are unresolved. We refer to Carniani et al. (in prep) and to (Cameron et al. 2023; Curti et al. 2023b; Curtis-Lake et al. 2023) for more information on the data reduction process.

In addition to prism spectroscopy, JADES also provides medium-resolution (nominal $R = 1000$) spectroscopy covering the full 0.6–5.3 μm range, combining the three disperser/filter configurations: g140m/f070lp, g235m/f170lp and g395m/f290lp. This dataset is less deep than the prism observations, owing to shorter exposure times (≈ 7 hours). Moreover, medium-resolution observations do not cover the entire sample.

2.2. Target selection and redshift determination

The target selection was based on the photometric Lyman-break technique, as described in Bunker et al. (2023). With the sensitivity of our observations, we probe stellar masses down to $10^6 M_\odot$ (but in this work we are limited to $10^7 M_\odot$ due to additional requirements in the emission-line signal-to-noise ratio; S/N).

Galaxy redshifts were obtained with an iterative procedure. We use BAGPIPES (Carnall et al. 2018) to infer the spectroscopic redshift from the prism observations. This redshift is subsequently refined by visual inspection of the medium- and high-resolution spectra (if available) and by fitting the emission lines with a Gaussian. In this work, we always require detection of at least two emission lines ($\text{H}\beta$ and $\text{H}\alpha$), therefore the redshifts are always determined well, within the accuracy of the spectroscopic data (Bunker et al. 2023, Jakobsen et al., in prep).

At redshifts $z < 4$ the spectral resolution of the prism is unable to resolve the 0.1 μm gap between $\text{H}\beta$ and $[\text{O III}]\lambda 4959$. Noting that $\text{H}\alpha$ is redshifted beyond 5.3 μm at redshift $z = 7$, we apply a redshift cut of $4 < z < 7$, reducing our sample size to 58 (out of 253) objects.

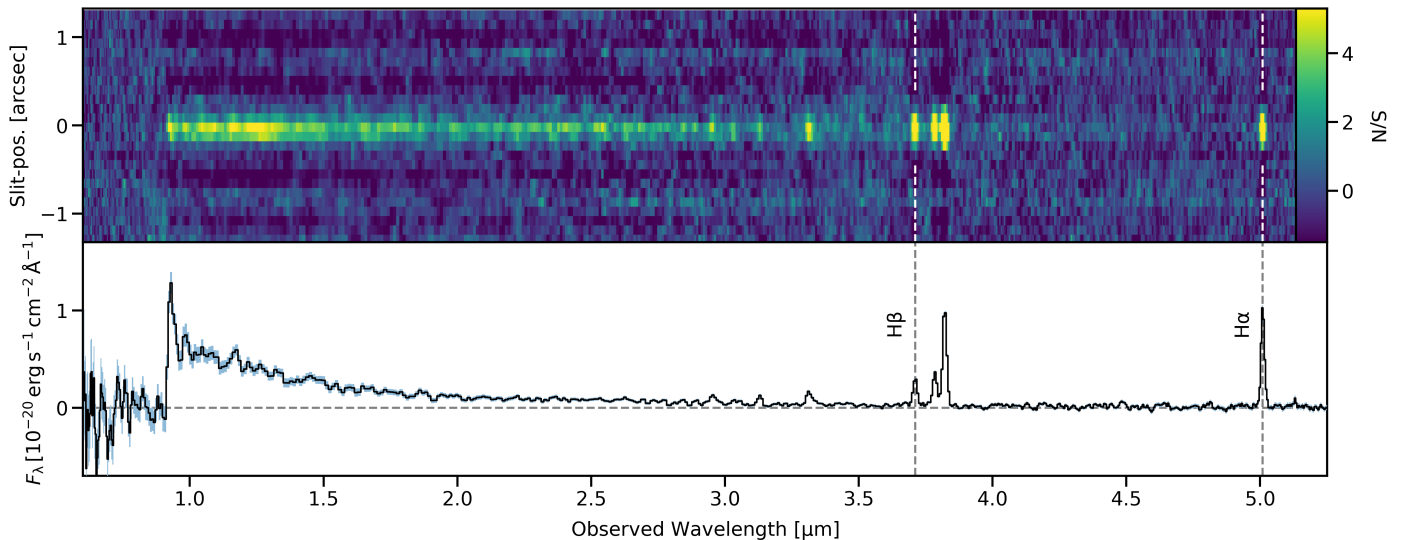

Fig. 1: NIRSpec low-resolution spectrum of JADES-GS+53.16904-27.77884 with a redshift of $z = 6.6$. The top panel shows the 2D spectrum colour coded by the signal-to-noise ratio; S/N. The bottom panel shows the extracted 1D flux density versus observed wavelength.

2.3. Emission-line measurements

Emission-line fluxes are measured using simultaneous fitting of the stellar continuum and nebular emission with the software `PPXF` (Cappellari 2017, 2022).

The stellar continuum is modelled as a non-negative linear superposition of single stellar population templates (SSP). The SSP spectra use C3K synthetic model atmospheres (Conroy et al. 2019) and MIST isochrones (Choi et al. 2016; Dotter 2016), which we convolve with a wavelength-dependent Gaussian kernel corresponding to $0.5\times$ the nominal spectral resolution of the NIRSpec prism. This is to provide a first-order correction to the increased spectral resolution for sources that are smaller than the micro-shutter width. Any flux blueward of Ly α is set to zero, because we do not model foreground absorption due to neutral-gas. In addition to the SSP spectra, the continuum also includes a 5th-order multiplicative Legendre polynomial, to model the effect of dust and the possible damping wing at rest-frame $0.12\ \mu\text{m}$. In this work we focus on rest-frame $0.4\text{--}0.7\ \mu\text{m}$, where the effect of these modelling choices is negligible.

Emission lines are modelled as Gaussians, with a reduced set of parameters to maximise S/N; in particular, for this study, we tie together the velocity and velocity dispersion of the H β –[O III] λ 4959,5007 complex and of the H α –[N II] λ 6548,6584 complex (hereafter, we always refer to the [O III] λ 4959,5007 and [N II] λ 6548,6584 doublets as [O III] and [N II]). When fixed by atomic physics, the ratio of emission-line doublets is constrained, which in this paper is relevant for both the [O III] and [N II] doublets. A critical aspect of these emission-line measurements is that – by simultaneously modelling the stellar continuum – our algorithm includes a correction for stellar-atmospheric absorption.

Using low-resolution instead of medium-resolution spectroscopy presents advantages and disadvantages. In medium resolution, we always resolve the H β –[O III] and the H α –[N II] complexes, giving more accurate measurements. However, medium-resolution observations are less deep and cover a smaller sample than the low-resolution observations. This means using low-resolution increases the precision at the expense of accuracy.

Within this context, we note that the H α and [N II] lines are blended in the prism. Therefore, in order to measure H α , we first measure the total H α + [N II] flux from the prism. For five objects in our sample, we detect [N II] in the corresponding medium-resolution spectra (S/N > 3). For these objects we multiply the total low-resolution H α + [N II] flux by the medium-resolution corrective factor: H α /(H α + [N II]). For the remaining objects, we use a constant correction of H α /(H α + [N II]) = 0.96 determined from the stack of all $z > 4$ medium-resolution spectra.

From our sample of 58 galaxies ($4 < z < 7$), we remove seven objects with H β S/N < 3: three of which also had an H α S/N < 3; one of which has a ‘blocky’, asymmetric H α profile (probably resulting from a noise spike not reflected in the noise array) and for the remaining three, we are able to calculate 3σ lower limits to H α /H β . Our final sample then consists of 51 galaxies, for which the Balmer decrement is measured as the ratio between H α and H β .

2.4. Stellar mass and star-formation rate measurements

Stellar masses (M_\star) and star-formation rates (SFR) are obtained again from `PPXF`, but using a separate, continuum-focused pipeline. The procedure is described in detail in Looser et al. (2023); here we report only a brief summary. As input we use the same C3K/MIST SSP library, with a logarithmic grid of ages spanning between 10^6 yr and the age of the Universe at the redshift of the target. The effect of dust is modelled using the Calzetti law (Calzetti et al. 2000). The star-formation history (SFH) is reconstructed using a combination of low regularisation and wild bootstrapping, following the approach of Looser et al. (2023). Stellar masses are defined as the total mass formed, by integrating the SFH. The SFR is measured as the time-averaged SFH over the last 10 Myr. This value is derived purely from the rest-frame UV stellar continuum (i.e., nebular emission is marginalised over), but Looser et al. (2023) show these measurements trace the SFR derived combining H α and the Balmer decrement from medium-resolution spectroscopy (Curti et al. 2023b), with a scatter of 0.4 dex and an offset of -0.1 dex. Assuming measurement uncertainties are equal between the H α - and continuum-based SFRs,

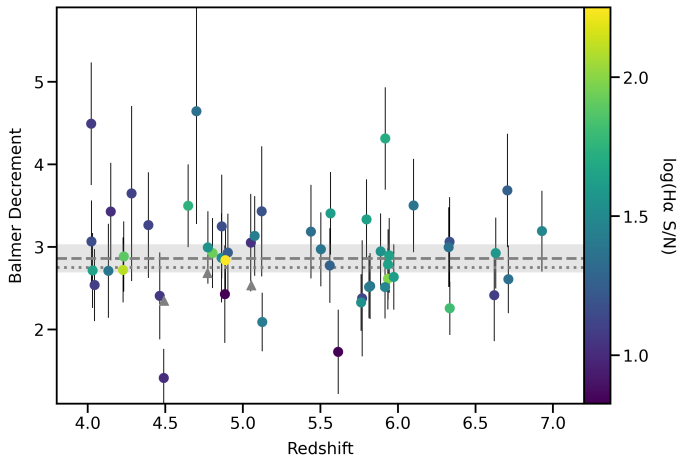

Fig. 2: Balmer decrement $H\alpha/H\beta$ plotted against redshift for our sample of 51 galaxies. The points are colour coded by their corresponding $H\alpha$ S/N. The errorbars combine the random measurement uncertainties on the line fluxes with a systematic uncertainty of 10 per cent. Three lower limits are shown as grey triangles. The horizontal dashed grey line corresponds to a Balmer decrement of 2.86, appropriate for local star-forming regions. The grey shaded region represents the 6 per cent range of $H\alpha/H\beta$ corresponding to $5,000 < T_e < 30,000$ K and $10 < n_e < 500$ cm $^{-3}$. The horizontal dotted grey line corresponds to a Balmer decrement of 2.75.

we obtain a median uncertainty of 0.3 dex on the SFR. Similarly, Looser et al. (2023) derived a median uncertainty on M_\star of 0.2 dex comparing their measurements to the M_\star values from BEAGLE SED models (Chevallard & Charlot 2016, Chevallard et al., in prep). Crucially, the PPXF-derived SFR are not directly coupled with the Balmer decrement (even though we cannot rule out a small correlation due to stellar absorption) therefore we can study the relation between these two galaxy observables with negligible correlated noise, compared to the $H\alpha$ -derived SFR.

3. Results

In Fig. 2 we show the Balmer decrement as a function of redshift. Circles represent individual galaxies, colour coded by the S/N of the $H\alpha$ emission line. The errorbars combine the random measurement uncertainties on the line fluxes as well as a systematic uncertainty of 10 per cent due to flux calibration; grey triangles are 3σ upper limits. The horizontal dashed line traces the intrinsic (unattenuated) $H\alpha/H\beta$ ratio of 2.86, appropriate for Case B recombination, temperature $T_e = 10,000$ K and density $n_e = 100$ cm $^{-3}$ (e.g., Osterbrock & Ferland 2006). Changing these assumptions within the range typical for star-forming regions ($5,000 < T_e < 30,000$ K and $10 < n_e < 500$ cm $^{-3}$) changes the Balmer decrement by 5–6 per cent.

The distribution of measured Balmer decrements is highly scattered, also reaching values below the Case B limit of 2.86. However, within the uncertainties, almost all galaxies below the dashed horizontal line are consistent with a Balmer decrement of 2.86 or higher. The exception are the two galaxies with the lowest Balmer decrements, which have values clearly deviating from the common assumptions valid in local star-forming regions ($\gtrsim 2\sigma$ below the unattenuated value of 2.86). We note, however, that these two galaxies are also the ones with the lowest $H\alpha$ S/N (as highlighted by the colour coding in Fig. 2), suggesting that the

low ratio is due to contamination of $H\beta$ and their uncertainties may be underestimated.

We do not find a clear correlation with redshift, suggesting that the dust content of galaxies does not evolve significantly between the end of reionisation at $z = 7$ –6 and the epoch immediately before Cosmic Noon ($z = 4$), and likely neither the dust properties evolve (consistent with recent findings based on the far-IR/submm properties of galaxies in this redshift range Witstok et al. 2023a). However, the sample selection criteria prevent us from drawing general conclusions about evolution.

In the left panel of Fig 3 we study the Balmer decrement as a function of M_\star . We detect a statistically significant Spearman’s rank correlation ($r = 0.32$, $p < 0.05$; traced by the moving mean, horizontal red lines in Fig. 3), as already found at lower redshifts (e.g., Groves et al. 2012; Shivaee et al. 2015, 2020; Maheson et al. 2023). We note, however, that the average Balmer decrement is very low – particularly so at the low-mass end. For stellar masses $M_\star < 3 \times 10^7 M_\odot$ we find a median decrement of 2.88 ± 0.08 , very close to the unattenuated value of 2.86 and therefore leaving little room for any dust attenuation. The three lower limits are not constraining (i.e., they are consistent with any amount of dust). This underscores that – with the depth of JADES – we do not miss significant numbers of highly obscured objects due to quality selection cuts.

In the right panel of Fig 3 we study the Balmer decrement as a function of the continuum-inferred SFR, averaged over the last 10 Myr. The symbols and colours are the same as in the left panel. In this case, we do not find a statistically significant Spearman’s rank correlation ($r = 0.18$, $p > 0.05$). However, we do find a correlation for galaxies with $\log(\text{SFR}/M_\star \text{ yr}^{-1}) > -0.5$ dex ($r = 0.48$ and $p = 0.001$). Note this result is not driven by the high-SFR outliers: removing also galaxies with $\log(\text{SFR}/M_\star \text{ yr}^{-1}) > 1$ dex we obtain $r = 0.44$ and $p = 0.004$.

At this stage, we cannot say whether the Balmer decrement correlates more tightly with M_\star or with SFR. A comparison of the PPXF-derived stellar masses to their BEAGLE-inferred equivalents suggests a mean uncertainty of 0.2 dex (accounting for both random noise and systematics due to different SFH assumptions, e.g., Carnall et al. 2019; Leja et al. 2019; Sandles et al. 2022). For the SFR, a comparison between PPXF and the $H\alpha$ derived values suggests a scatter of 0.4 dex. If we assume that the SFR from PPXF traces accurately the SFR on 10 Myr timescales, then the measurement uncertainties on SFR are larger than on M_\star . This would make the *intrinsic* correlation between Balmer decrement and SFR stronger (i.e., higher correlation coefficient) and more significant than the correlation between Balmer decrement and M_\star . More data and a better characterisation of the systematic uncertainties could help address which of these two correlations is strongest.

4. Discussion

Empowered by the combination of the exquisite sensitivity of JWST/NIRSpec with the unprecedented depth of JADES, we can probe for the first time the low-mass end of the galaxy distribution beyond Cosmic Noon, with tens of galaxies in the range 10^7 – $10^8 M_\odot$. In this mass regime, we find no evidence of high-attenuation galaxies, consistent with the overall trend of increasing Balmer decrement with increasing M_\star , already reported by numerous authors for the local Universe (Groves et al. 2012), Cosmic noon (Domínguez et al. 2013; Reddy et al. 2015; Nelson et al. 2016; Lorenz et al. 2023; Matharu et al. 2023) and redshifts 3–6 (Shapley et al. 2023). The lack of objects with significant nebular attenuation is also confirmed by the lack of constraining

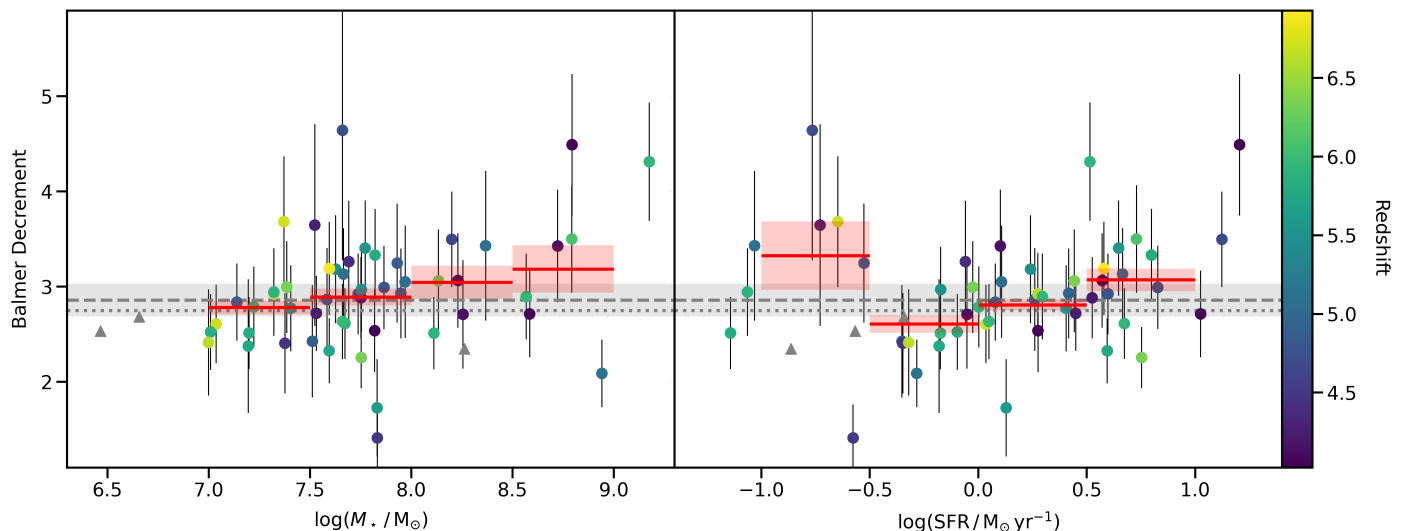

Fig. 3: Balmer decrement $H\alpha/H\beta$ as a function of M_* (left panel) and SFR (right panel), both derived from the stellar continuum. Circles represent individual galaxies, colour coded by their spectroscopic redshift. Three lower limits are shown on each panel as grey triangles. The median uncertainties on M_* and SFR are 0.2 and 0.3 dex, respectively. The horizontal dashed grey line corresponds to a Balmer decrement of 2.86, appropriate for local star-forming regions. The grey shaded region represents the 6 per cent range of $H\alpha/H\beta$ corresponding to $5,000 < T_e < 30,000$ K and $10 < n_e < 500$ cm $^{-3}$. The horizontal dotted grey line corresponds to a Balmer decrement of 2.75. The horizontal red lines and shaded regions represent the running mean and error on the mean. The Balmer decrement shows statistically significant correlation with M_* . For SFR, we find an increasing trend from $\log(\text{SFR}/M_* \text{ yr}^{-1}) > -0.5$ dex. Because we measure both M_* and SFR from PPXF (Section 2.4), the $H\alpha$ and $H\beta$ emission lines do not enter these two measurements, meaning the observed correlations with the Balmer decrement are not due to correlated noise.

lower limits. Part of the reason we find no galaxies with high Balmer decrement could be due to sample bias, because our primary targets were selected to be UV-bright objects with strong Ly α drops (Bunker et al. 2023). However, secondary targets are not selected to be as UV bright, therefore selection criteria alone may be insufficient to explain the observed dearth of galaxies with high Balmer decrement. Indeed, our results are consistent with the shallower measurements from the CEERS survey. In the sample of Shapley et al. (2023), there are six galaxies with $5 < z < 6$ and $M_* < 10^8 M_\odot$; of these, two imply Balmer decrements larger than 3. The only measurement with a Balmer decrement uncertainty smaller than 1 is fully consistent with our median Balmer decrement in the same mass range.

These findings suggest that, similar to the low-redshift Universe, even in the young Universe before cosmic noon, more massive galaxies produced more dust and/or could retain more dust. As discussed in Maheson et al. (2023), this might be partly due to the mass-metallicity relation (and the fact that dust content scales with metallicity). Retention of dust due to the gravitational potential seems to also play a role in the mass dependence. However, in addition to these two secondary correlations, dust attenuation is also found to have an intrinsic dependence on stellar mass. This is likely a consequence of the direct correlation between stellar mass and gas mass (Lin et al. 2019; Baker et al. 2023). At the high redshifts of our sample, disentangling the dependencies on these individual parameters requires more statistics than currently available (the multi-parameter dependencies found in local galaxies by Maheson et al. 2023 required a sample of thousands of galaxies).

Interestingly, we find evidence of extremely low Balmer decrements at the low-mass end (2.88 ± 0.08 for $M_* < 3 \times 10^7 M_\odot$). With the physical conditions of local star-forming regions (i.e., $T_e = 10,000$ K and $n_e = 100$ cm $^{-3}$), the intrinsic Balmer decrement is 2.86. This means our measurement leaves

little or no room for *any* ISM dust towards the H II regions (although dust might be present inside H II regions, while absorbing UV photons; Charlot et al. 2002). For example, assuming the Milky Way extinction law with $R_V = 3.1$ (Cardelli et al. 1989, hereafter, CCM89) and an intrinsic $H\alpha/H\beta$ ratio of 2.86, the observed Balmer decrement yields $A_V = 0.02$ mag, meaning very little dust is present. This is a finding that was also inferred by the blue slopes of the spectra of galaxies at such high redshifts (Fiore et al. 2023) and is in agreement with current theoretical models (which predict a drop of the dust-to-stellar mass ratio by a factor of 2 between $z = 0$ and $z = 4-7$; Popping et al. 2017).

However, other studies have found evidence for some dust attenuation at such high redshifts in low-mass galaxies, e.g. through the detection of the UV carbonaceous dust absorption dip (Markov et al. 2023; Witstok et al. 2023b) and through SED modelling (e.g., Tacchella et al. 2023, although these authors explore a mass at least $2-3\times$ larger than here).

An interesting possibility is that the low Balmer decrement might be associated with ‘non-standard’ physical conditions in the ISM. In fact, our findings would be consistent with the hypothesis that at $z = 4-7$, star-forming gas in low-mass galaxies had higher T_e (Schaerer et al. 2022; Curti et al. 2023a) and/or higher n_e (Reddy et al. 2023). Qualitatively, this is consistent with lower metallicity stars being the primary source of photoionisation, and with the prediction of higher gas densities from numerical simulations (e.g. Ceverino et al. 2018; Lovell et al. 2022). For example, assuming $T_e = 20,000$ K and $n_e = 300$ cm $^{-3}$, the intrinsic $H\alpha/H\beta$ ratio drops to 2.75. However, comparing this value to the observed decrement of 2.88, the CCM89 law gives $A_V = 0.14$ mag – still indicating the presence of only a modest amount of dust.

In any case – at the low-mass end – there seems to be very little room for interstellar dust, even taking into account the possible effect of the extreme gas conditions which might lower the intrinsic

sic Balmer decrement. Part of the difference compared to higher-mass galaxies is the lower metallicity. Several authors (Curti et al. 2023b; Nakajima et al. 2023) report the mass-metallicity relation is already in place at $z > 4$ – albeit with a large intrinsic scatter. Lower ISM metallicity implies lower dust content in the ISM (especially taking into account that the dust-to-gas ratio drops more than linearly at low metallicities; De Cia 2018). In addition, low-mass galaxies could also be more efficient at removing dust. Numerical simulations (Ceverino et al. 2018; Ma et al. 2018; Lovell et al. 2022; Dome et al. 2023) predict that galaxies with stellar masses $M_\star \lesssim 0.5\text{--}5 \times 10^8 M_\odot$ have ‘burstier’ SFHs; their SFR varies rapidly on timescales of 10 Myr, modulated by rapid gas accretion and efficient star formation. This phase is accompanied by gas depletion and strong, efficient feedback which removes any leftover gas (see also discussion in Fiore et al. 2023). Burstier SFHs at low mass and high redshifts seem confirmed by a comparison between the SFRs averaged over 0–10 and 10–90 Myr (Looser et al. 2023, but see Rezaee et al. 2022 for a different view); our work presents a consistent picture from the point of view of the ISM attenuation. Finally, in terms of dust production timescales, the low dust content may reflect also the fact that low-mass galaxies have younger ages (Looser et al. 2023), hence less time to produce dust through the AGB channel (whereas dust production from SN acts on very short time scales).

Regarding the possible correlation of the Balmer decrement with SFR, we note that the lower metallicity and the burstiness of the SFH require a different calibration of the $H\alpha$ -based SFR indicator, as already recognised by several authors (e.g., Hao et al. 2011; Reddy et al. 2018; Shivaei et al. 2022; Tacchella et al. 2022; Curti et al. 2023b; Shapley et al. 2023). Metallicity enters the SFR calibrators through the production rate of hydrogen-ionising photons. Using a solar-metallicity calibrator in a low-metallicity galaxy leads to an overestimate of the SFR by a factor of 2–3. The burstiness of the SFH implies that the often adopted standard linear relation between $H\alpha$ luminosity and SFR, which assumes constant SFR, cannot be really applied. Additionally, the SFR inferred from $H\alpha$ cannot be used for exploring the relation with the Balmer decrement because the $H\alpha$ flux would enter in both quantities and introduce spurious correlations.

Therefore, we have leveraged on the continuum-based SFR from PPXF to quantify the correlation between Balmer decrement and SFR (right panel Fig. 3) and compared it to the well-known correlation with M_\star (left panel Fig. 3). The correlation with M_\star is statistically significant, while for SFR we find a correlation only for $\text{SFR} > 0.3 M_\odot \text{ yr}^{-1}$. We are unable to determine if, for these distant galaxies, any of the two is a secondary correlation, as inferred for local galaxies (Maheson et al. 2023). In fact, because of the star-forming main sequence – i.e., the empirical correlation between M_\star and SFR – it is unclear if and to what extent the correlation between Balmer decrement and SFR reflects the combination of the known correlation between Balmer decrement and M_\star (e.g., Groves et al. 2012; Maheson et al. 2023), and the star-forming main sequence. A larger sample would enable a comparative analysis using partial correlation coefficients (e.g., Bait et al. 2017; Bluck et al. 2019) or even a machine-learning analysis (e.g., Bluck et al. 2022; Piotrowska et al. 2022).

Intriguingly, the relation between Balmer decrement and SFR may be tighter than the relation with M_\star (except the set of outliers with high Balmer decrement and very low SFR, $0.1\text{--}0.3 M_\odot \text{ yr}^{-1}$). A primary correlation with SFR would also be consistent – at least in a qualitative sense – with the picture of bursty SFHs from numerical simulations. Starbursts in low-mass galaxies are fuelled by short-lived reservoirs of dense gas. The burst

phase ends as a consequence of the gas being exhausted and/or expelled, therefore low-SFR galaxies would correspond to gas-poor systems observed in a ‘lull’ of their star formation.

The Balmer decrement intrinsically scaling with SFR would also be consistent with other scaling relations observed in the local Universe. Specifically, the dust content scales with the amount of cold gas, via the dust-to-gas ratio. On the other hand, the SFR correlates with the amount of cold gas via the Kennicutt-Schmidt relation. Therefore, a correlation between Balmer decrement and SFR is not unexpected. In fact, in local galaxies the Balmer decrement correlates with the surface density of molecular gas (Barrera-Ballesteros et al. 2018; Piotrowska et al. 2020).

Other works (Maheson et al. 2023) have argued that – after controlling for inclination – the correlation between SFR and Balmer decrement is less important than the correlation of Balmer decrement with M_\star and other physical quantities (ISM metallicity and gas velocity dispersion). However, they are unable to compare the Balmer decrement to the SFR on timescales of 10 Myr – simply because the classic $H\alpha$ -based estimator uses the Balmer decrement itself in its definition. Instead, they use the 4000 break as a proxy for the current SFR. However, the 4000 break is sensitive to SFR on longer timescales of 100 Myr, so their different results could also be due to different timescales being probed. In any case, their much more detailed analysis is impossible with our sample size of only 51 galaxies, but requires samples 10–100 times larger that do not exist yet for the redshift range we are interested in.

A possible caveat is represented by the effect of different morphologies and inclination. We do not make any morphology cut, and assume that our sample probes all morphologies and inclinations equally. Larger samples may help clarify the role of morphology and inclination in our findings.

5. Summary and Conclusions

In this work, we presented a comparative analysis of the Balmer decrement for galaxies with $M_\star = 10^7\text{--}10^9 M_\odot$ between cosmic noon and the end of reionisation ($4 < z < 7$). We used deep (28 hours), low spectral resolution observations of JWST/NIRSpec MSA, obtained as part of JADES. We use medium-resolution observations to apply a correction for [N II] contamination of $H\alpha$. We further explore the dependence on SFR, averaged over the last 10 Myr, as measured from the stellar continuum – without using information from the emission lines.

We confirm earlier findings of a correlation between Balmer decrement (i.e. dust attenuation) with M_\star , already in place at such early epochs.

At the low-mass end ($M_\star < 3 \times 10^7 M_\odot$), there is little evidence of any dust attenuation, in agreement with theoretical expectations (Popping et al. 2017). This result is consistent with the expectation from these systems being metal poor, young (hence with less time for dust formation) and with bursty SFHs (which may be more effective in depleting and expelling dust). In this mass range, the median Balmer decrement is only 2.88 ± 0.08 , extremely close to 2.86 (the Case B value commonly assumed for star-forming regions at lower redshifts). This suggests that low-mass galaxies at these redshifts might have higher T_e and/or n_e compared to their local counterparts, which would result into a slightly lower intrinsic Balmer decrement.

We find tentative evidence of a correlation between the Balmer decrement and SFR. If confirmed, this may trace the underlying correlation between SFR and cold gas mass, via the dust-to-gas ratio.

Future studies based on larger samples may clarify which of these correlations are intrinsic and direct, and which ones are an indirect byproduct of secondary correlations. Larger samples will also be able to uncover correlations with other galaxy parameters, such as metallicity and velocity dispersion (Maheson et al. 2023).
