KEYWORDS. ATP, ICD, Liquid-Jet Photoelectron Spectroscopy, Mg-ATP Interactions, Phosphate Chain

#### Abstract

Site-specific information on how adenosine triphosphate in the aqueous phase $\left(\operatorname{ATP}_{(\mathrm{aq})}\right)$ interacts with magnesium $\left(\mathrm{Mg}^{2+}{ }_{\text {aqq }}\right)$ is a prerequisite to understanding its complex biochemistry. To gather such information, we apply liquid-jet photoelectron spectroscopy (LJ-PES) assisted by electronic-structure calculations to study ATP $_{(\mathrm{aq})}$ solutions with and without dissolved $\mathrm{Mg}^{2+}$. Valence photoemission data reveal spectral changes in the phosphate and adenine features of ATP $(\mathrm{aq})$ due to interactions with the divalent cation. Chemical shifts in $\operatorname{Mg} 2 \mathrm{p}, \mathrm{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2 s core-level spectra as a function of the $\mathrm{Mg}^{2+} /$ ATP concentration ratio are correlated to the formation of [MgATP] ${ }^{2-}(\mathrm{aq})$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$ complexes, demonstrating the element-sensitivity of the technique to $\mathrm{Mg}^{2+}$-phosphate interactions. In addition, we report and compare P 2s data from ATP $_{(\mathrm{aq})}$ and adenosine mono- and di-phosphate $\left(\mathrm{AMP}_{(\mathrm{aq})}\right.$ and $\mathrm{ADP}_{(\mathrm{aq})}$, respectively) solutions, probing the electronic structure of the phosphate chain and the local environment of individual phosphate units in ATP $_{(a q)}$. Finally, we have recorded intermolecular Coulombic decay (ICD) spectra initiated by ionization of Mg 1 s electrons to probe ligand exchange in the $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ coordination environment, demonstrating the unique capabilities of ICD for revealing structural information. Our results provide an overview of the electronic structure of $\operatorname{ATP}_{(\mathrm{aq})}$ and $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ moieties relevant to phosphorylation and dephosphorylation reactions that are central to bioenergetics in living organisms.

## INTRODUCTION

The adenosine triphosphate nucleotide in aqueous solution $\left(\operatorname{ATP}_{(\mathrm{aq})}\right)$ is a complex molecule that enables energy exchange and signal transduction in living organisms.[1-6] It consists of a nucleoside (adenosine, which is formed by adenine and ribose) bound to a chain of three phosphate groups.[7] The biological function of $\operatorname{ATP}_{(\mathrm{aq})}$ stems from dephosphorylation - i.e., liberation of phosphate units - and phosphorylation - i.e., addition of phosphate units - reactions in the aqueous environment of the cell. [8] In the former case, energy is released via hydrolysis to produce adenosine diphosphate ( $\mathrm{ADP}_{(\mathrm{aq})}$ ). In the latter case, phosphorylation of ADP ${ }_{(a q)}$ takes place to restore ATP $_{(a q)}$ in the cell. Overall, metabolic pathways involving ATP $_{(\mathrm{aq})}$ and ADP $_{(\mathrm{aq})}$ are regulated by chemical bond breaking and bond formation at the phosphate chain.[9] While the aforementioned reactions take place either catalyzed by enzymes or non-enzy-
matically, the processes are largely determined by the presence of divalent metal cations - such as $\mathrm{Mg}^{2+}(\mathrm{aq})$, the divalent cation with the highest ATP $_{(\mathrm{aq})}$ binding affinity $[10,11]$ - and hydration effects inherent to the aqueous environment of the cell.[12-15] In that way, aqueous-phase metal-ligand coordination at the phosphate chain is involved in dephosphorylation (hydrolysis) or phosphorylation at specific phosphate units via charge redistribution and conformational changes.[14, 16] On the other hand, nucleic base-metal-ion interactions have been hypothesized, more than half a century ago,[17] to play a role in the overall reaction. A large amount of association equilibria data has been determined in support of such effects.[18] However, the characterization of associated structures by advanced spectroscopic methods is lacking.

The molecular structure of $\operatorname{ATP}_{(a q)}$ is illustrated in Figure 1(a), highlighting the adenine, ribose, and phosphate units. The latter are designated as $\alpha, \beta$, and $\gamma$ (where $\alpha$ refers to the phosphate directly bound to the nucleoside, $\beta$ refers
to the bridging phosphate unit, and $\gamma$ refers to the terminal phosphate) and are shown in their deprotonated form
(ATP4-(aq)), as predominantly found at physiological pH conditions.[19] We also include the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ ion -
a) Open form

Ribose

Adenine
b) Closed form

Figure 1. (a) Molecular structure of $\operatorname{ATP}_{(\mathrm{aq})}$ in the deprotonated form ( ATP $^{4}{ }_{(\mathrm{aq})}$ ) predominantly found at physiological pH .[19] Adenine, ribose, and $\alpha$-, $\beta$-, and $\gamma$-phosphate units are labeled; one of many motifs for $\mathrm{Mg}^{2+}$ binding is shown (see text). Binding of $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ to one versus two phosphate units is illustrated by the different interaction strengths (indicated by different lengths of red and blue dashed lines). (b) [MgATP] ${ }^{2-}$ (aq) complex tentative closedform structure in which the divalent cation interacts both with an O atom from the phosphate chain and an N atom from the adenine unit in $\operatorname{ATP}_{(a q)}$, with the latter interaction being mediated by a water molecule.[11] $\mathrm{Mg}^{2+}$ ATP $_{(a q)}$ (probed in valence PE spectra) and $\mathrm{Mg}^{2+}$-water (probed in ICD spectra) interactions are highlighted by red and blue dashed lines, respectively. P- and Mg-specific chemical shifts (probed in core-level PE spectra) are highlighted by a double arrow. Similar structures associated with the $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$ complex are shown in Figure S 1 in the Supporting Information. This figure was produced using the ACD / ChemSketch software.[20] In both cases, the phosphate unit/s interacting with $\mathrm{Mg}^{2+}($ aq $)$ were chosen arbitrarily.
or more specifically, $\left[\mathrm{Mg}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}{ }_{(\text {aq })}$, the octahedral complex configuration adopted by the free ion in aqueous solution [21] - interacting with one or more phosphate units to form various $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ complexes,[10, 16] such as $\left[\operatorname{Mg}(A T P)_{2}\right]^{6-}{ }_{(\mathrm{aq}),}[16, \quad 22-25] \quad \mathrm{Mg}_{2}$ ATP $_{(\mathrm{aq}),}[26] \quad$ and $\left[\mathrm{Mg}_{2}(\mathrm{ATP})_{2}\right]^{4-}{ }_{\text {(aq). }}[16,27]$ In addition to the open form of Figure 1(a), we present in Figure 1(b) a proposed closed form. Here, the metal ion interacts not only with 0 atoms from the phosphate units (Figure 1(a)), but also, presumably through a water molecule, with an N atom from the adenine unit (Figure 1(b)).[6, 11, 28, 29] The 'closed form' / 'open form' ratio in aqueous solution has been reported to be 1:10.[11, 28, 30]

Despite a single phosphate unit seemingly being involved in phosphorylation and dephosphorylation reactions,[31] $\mathrm{Mg}^{2+}{ }_{\text {aq }}$ complexation to multiple sites in the phosphate chain is required for the overall reaction to proceed.[32-35] In the absence of enzymes, $\alpha$-, $\beta$-, and $\gamma$-phosphate are expected to be equally involved in $\mathrm{Mg}^{2+}(\mathrm{aq})$ association to $\operatorname{ATP}_{(a q) \cdot}[36,37]$ In enzyme-bound ATP $_{(a q)}$, the $\beta$ - and $\gamma$-phosphate units are most likely to interact with $\mathrm{Mg}^{2+}{ }_{(\text {aq) }}$.[14] The binding constants associated with specific $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ ion
pairing motifs alter the Gibbs free energy of hydrolysis,[38] as they determine the concentration of each of the species involved in the reaction.

In addition, the relatively small size of the $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ ion facilitates coordination to multiple phosphate units within ATP ${ }_{(\mathrm{aq})}$, leading to phosphate-phosphate interactions via the negatively charged 0 sites.[39] These bonding interactions result in charge-distribution changes at the $\mathrm{P}-0-\mathrm{P}$ bond[31] and differences in electron binding energies (BEs) of the $\alpha-, \beta-$, and $\gamma$-phosphates in $\operatorname{ATP}_{(\mathrm{aq})}$ and $\mathrm{Mg}^{2+}$ ATP $_{(\mathrm{aq})}$. Such intramolecular (and intermolecular) charge redistributions, in addition to solvation effects, are reflected in the phosphorylation and dephosphorylation reaction mechanisms.[31, 32, 35, 40]

With that in mind, this study seeks to probe $\mathrm{Mg}^{2+}$ ATP $_{(\mathrm{aq})}$ interactions at physiological pH using liquid-jet photoelectron spectroscopy (LJ-PES).[41, 42] We aim to investigate whether LJ-PES - which has been proven to have the unique ability to probe chemical shifts in inorganic and organic solutes in aqueous environments[43-47] - is sensitive enough to reveal spectral changes due to $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ ion pairing and/or complexation. $\mathrm{Mg}^{2+}$-phosphate interactions have
been previously explored using aqueous-phase X-ray emission,[48] infrared,[30] Raman,[49] and nuclear magnetic resonance (NMR)[50] spectroscopies. The $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ coordination chemistry has been recently investigated in the gas phase using mass spectrometry (in particular, phosphate $-\mathrm{Mg}^{2+}$-adenine interactions)[29] and in acetate solutions[51] using NMR spectroscopy. Previous LJ-PES work focused on the ribose or adenine units in ATP ${ }_{(\mathrm{aq})}$ [52-54] or on inorganic phosphate[55] aqueous solutions.

Here, we report on the electronic-structure changes upon the addition of $\mathrm{Mg}^{2+}$ to $\mathrm{ATP}_{(\mathrm{aq})}$ solutions and the formation of different $\mathrm{Mg}^{2+}-$ ATP $_{(\mathrm{aq})}$ complexes from valence and $\operatorname{Mg} 2 p, \operatorname{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2s core-level photoelectron (PE) spectra. The valence spectral region provides information on orbital hybridization due to chemical bonding and ionpairing interactions, while core-level data reveals site-specific chemical shifts.[43, 56, 57] We also present P 2s spectra from $\operatorname{ATP}_{(a q)}, \operatorname{ADP}_{(a q)}$, and AMP $_{(\mathrm{aq})}$ solutions and investigate relative changes in the BEs of $\alpha-, \beta$-, and $\gamma$-phosphate with the aid of theoretical calculations. In addition to recording PE spectra upon direct photoionization, we explore the potential of a particular structure-sensitive non-local autoionization probe. Specifically, we report on intermolecular Coulombic decay (ICD)[58-62] of $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ ions in the presence of $\mathrm{ATP}_{(\mathrm{aq})}$ in their coordination environment (i.e., in the first solvation shell). More precisely, we measure ICD upon photoionization of Mg 1 s core-level electrons. Here, the respective core hole is refilled by electrons from the Mg 2 s (or Mg 2p) core levels, and the released excess energy is used to ionize the surrounding molecules in the first solvation shell. The emitted secondary electron is then detected as an ICD signal. The ICD spectral region is thus exclusively sensitive to intermolecular interactions, allowing us to directly probe ligand exchange at the $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ coordination environment.

Overall, the work presented here provides an elementspecific overview of the coordination chemistry of ATP $_{(\text {(aq) }}$ in the presence of $\mathrm{Mg}^{2+}(\mathrm{aq})$ and constitutes, to our knowledge, the first report of aqueous-phase PES - including both direct photoionization and non-local autoionization - probing site-specific $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ interactions at the phosphate chain and the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ coordination sphere.

## METHODS

Experiments. $0.5 \mathrm{M} \mathrm{ATP}_{(\mathrm{aq})}, \operatorname{ADP}_{(\mathrm{aq})}$, and $\operatorname{AMP}_{(\mathrm{aq})}$ solutions were prepared by dissolving the required amount of adenosine 5 '-triphosphate disodium salt hydrate, adenosine $5^{\prime}$-diphosphate acid, and adenosine $5^{\prime}$-monophosphate disodium salt (Carbosynth, 95\%) in Millipore water, respectively. ATP $_{(\mathrm{aq})}$ and $\mathrm{ADP}_{(\mathrm{aq})}$ samples containing $\mathrm{Mg}^{2+}$ were prepared by addition of $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}$ (ACROS ORGANICS, $99+\%$ ) to $0.5 \mathrm{M} \mathrm{ATP}_{(\mathrm{aq})}$ or $\mathrm{ADP}_{(\mathrm{aq})}$ solutions in order to reach $0.25: 1,0.5: 1,0.75: 1,1: 1$, and $1.5: 1 \mathrm{Mg}^{2+} /$ ATP concentration ratios. For each sample, the solution pH was adjusted to 8.2 by the addition of the required amount of Tris [tris(hydroxymethyl)aminomethane, Sigma Aldrich, $\geq 99.8 \%$ ], to ensure that the ATP $_{(\mathrm{aq})}$ phosphate chain was fully deprotonated (ATP ${ }^{4-}$ (aq), see Figure 1).[19, 22, 63] This alternative approach to the traditional Tris/TrisHCl buffer pH adjustment methodology allows us to reduce the number of chem-
ical species in the solution that can interfere with the observation of the PE signals of interest. The specific concentration of $\operatorname{Tris}_{(\mathrm{aq})}$ in each sample is listed in Table S1 in the Supporting Information (SI).

LJ-PES experiments were performed at the P04 beamline at PETRA III[64] (DESY, Hamburg, Germany) using the EASI setup.[65] Photoelectrons emitted from the sample were detected using a differentially pumped hemispherical electron analyzer at $130^{\circ}$ with respect to the light propagation axis (circular polarization). The samples were delivered into the vacuum chamber of the EASI setup in the form of liquid microjets[66] using a glass capillary of $28 \mu \mathrm{~m}$ inner diameter and flow rates in the range of 0.55-0.80 mL/min. The sample temperature was kept at $10^{\circ} \mathrm{C}$ by means of a cooling system interfaced with the liquid-jet holder. In addition, a small metallic tube was placed into the main polyether ether ketone (PEEK) liquid delivery line to electrically connect and ground the liquid jet to EASI. The liquid jet's (horizontal) flow axis was perpendicular to both the light propagation (floor plane) and the electron detection (at an angle of $130^{\circ}$ with respect to the photon beam) axes. PE spectra from $\mathrm{ATP}_{(\mathrm{aq})}$ with dissolved $\mathrm{Mg}^{2+}$ were recorded using a photon energy of 250 eV , spanning over the valence, $\operatorname{Mg} 2 \mathrm{p}, \mathrm{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2s spectral regions. P 2 s PE spectra from $\mathrm{AMP}_{(\mathrm{aq})}, \mathrm{ADP}_{(\mathrm{aq})}$, and $\mathrm{ATP}_{(\mathrm{aq})}$ were recorded using a photon energy of 330 eV . ICD experiments were performed at 1314 eV . The overall instrumental energy resolution was, approximately, 210 meV at $250 \mathrm{eV}, 220 \mathrm{meV}$ at 330 eV , and 570 meV at 1314 eV photon energy.

The BE scale in the data presented here was calibrated based on the liquid water $1 \mathrm{~b}_{1} \mathrm{BE}$ of 11.33 eV ,[67] as commonly adopted in LJ-PES experiments.[68] While we have recently reported a more robust methodology,[67] the data acquisition of the results presented here precede those experiments. Furthermore, absolute BEs are not the principal quantity of interest in this work, but rather relative spacing of peaks identifiable to different species in solution.

Computations. $\alpha$-, $\beta$-, and $\gamma$-phosphate P 2s BEs of ATP ${ }^{4-}$ ${ }_{(\text {aq) }}\left(\right.$ as $\left.\mathrm{NaATP}^{3-}{ }_{(\mathrm{aq})}\right),[\mathrm{MgATP}]^{2-}(\mathrm{aq}), \mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, and $[\mathrm{MgADP}]^{-}$ (aq), as well as $\mathrm{Mg}^{2+}(\mathrm{aq})$, were calculated using the maximumoverlap method[69] as implemented in the Q-Chem 6.0 software[70] (the sample input for these calculations can be found in the SI). An excellent computational cost/performance ratio was previously demonstrated with this approach.[71] Due to the system size, we pragmatically employed the Hartree-Fock (HF) method with a core-enhanced aug-cc-pCVTZ basis set on P atoms and aug-cc-pVTZ basis set on other atoms. To model Mg 2s and 2p BEs, a coreenhanced aug-cc-pCVTZ basis set was used for Mg atoms and aug-cc-pVTZ for other atoms. The aqueous solution was modeled by the cluster-continuum approach. For our quantum system, we explicitly included 26 water molecules around the triphosphate chain (to cover each terminal 0 with at least three hydrogen bonds from water molecules) of ATP $^{4-}(\mathrm{aq}),[\operatorname{MgATP}]^{2-}{ }^{-(\mathrm{aq})}, \mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, and [MgADP] ${ }^{-(\mathrm{aq})}$ to screen the high charge density while the rest of the solvent was described by the polarizable-continuum model (PCM).[72, 73] We used the non-equilibrium variant of PCM with integral-equation formalism (IEF), Bondi radii, and recommended scaling factor $\alpha=1.2$.[74] For pure $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$
solutions, the cation was solvated by six explicit water molecules in an octahedral geometry, while the rest of the solvent was modeled by PCM. The calculated P 2s BEs (using HF) were corrected for the correlation as follows. We used pyrophosphate $\left(\mathrm{HP}_{2} \mathrm{O}_{7}{ }^{2-}\right)$ hydrated by five explicit water molecules as a smaller model of the phosphate chain in our ATP $^{4-}{ }_{(\mathrm{aq})}$, $[\mathrm{MgATP}]^{2-}{ }^{-(\mathrm{aq})}, \mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, and $[\mathrm{MgADP}]^{-}{ }^{(\mathrm{aq})}$ systems. We computed the P 2s BEs using the HF and MP2 methods to approximately determine the error connected to the missing correlation in the HF method. The correction was estimated to be +0.33 eV . The calculations of BEs were done on single structures optimized on the $\mathrm{HF} / 6-31+\mathrm{G}^{*}$ level of theory with PCM (IEF, Bondi radii, $\alpha=1.2$ ) using Gaussian 09, revision D.01[75] (the Cartesian coordinates can be found in the SI).

## RESULTS AND DISCUSSION

Element-specific overview of $\mathbf{M g}^{2+}$ ATP $_{(\text {aq })}$ interactions. This section presents valence and core-level PE spectra from ATP $_{(\mathrm{aq})}$ samples with dissolved $\mathrm{Mg}^{2+}$, providing an overview of the electronic structure of ATP $_{(\mathrm{aq})}$ and the interactions between the metal cation and different units in the ATP $_{(\mathrm{aq})}$ molecule.

PE spectra from $0.5 \mathrm{M} \mathrm{ATP}_{(\mathrm{aq})}$ solutions with $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ at different $\mathrm{Mg}^{2+} /$ ATP concentration ratios recorded at a photon energy of 250 eV are presented in Figure 2. For each sample, the data spans over the valence, Mg 2 p ,

Figure 2. Valence as well as $\operatorname{Mg} 2 \mathrm{p}, \mathrm{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2 s core-level PE spectra from $\mathrm{ATP}_{(\mathrm{aq})}$ samples containing $\mathrm{Mg}^{2+}(\mathrm{aq})$ as a function of the $\mathrm{Mg}^{2+} /$ ATP concentration ratio. The BE scale was calibrated based on the liquid-water solvent valence $1 \mathrm{~b}_{1}$ peak position, and spectral intensities are displayed to yield its same height. A vertical offset was applied to each spectrum to facilitate a better comparison between the different data sets. The broad signals close to 160 eV and $\sim 55 \mathrm{eV}$ likely originate from energy-loss peaks.[76]
$\operatorname{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2 s spectral regions in a single scan. Similar data recorded from $0.5 \mathrm{M} \mathrm{ATP}_{(\mathrm{aq})}$ without $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ is shown for comparison. The as-measured spectra are en-ergy-calibrated§ against the liquid water $1 b_{1}$ peak at $11.33 \mathrm{eV},[67]$ and intensities are displayed to yield the same liquid water $1 b_{1}$ peak heights. The differences in baseline height are due to slight jet instabilities inherent to the measurements. Spectral features from the $\mathrm{Na}^{+}{ }_{(\text {aq })}$ counter ion in the ATP salt used to prepare the solutions are labeled according to Reference[77]. The intensity of these features is
observed to decrease as the $\mathrm{Mg}^{2+}{ }_{(a q)}$ concentration increases. The reason is not understood but might be due to changing propensity of the solute under study at the surface. Contributions from the $\mathrm{NO}_{3^{-}}{ }^{-}$(aq) counter ion from the Mg salt used in the experiments are expected in the 9-9.5 eV BE range.[41] Contributions from Tris added to adjust the pH are labeled based on Reference [47] and valence PE data

Figure 3. Highlights of the valence [panel (a)], Mg 2p [panel (b)], Mg 2s [panel (c)], P 2p [panel (d)], and P 2s [panel (e)] spectral regions from the data presented in Figure 2. In panel (a), PE signatures of ionization of water's valence electrons are labelled as (liquid- and gas-phase) 1b1, 3a1, and 1b2, according to Reference[76]. The arrow highlights PE signatures due to $\mathrm{Mg}^{2+}$-phosphate interactions, as explained in the text. The Mg 2s, P 2 p , and P 2 s data are shown with a vertical offset for a better comparison, and chemical shifts are highlighted by the dashed lines. The P 2p and P 2s data were normalized in intensity, considering that the ATP ${ }_{(a q)}$ concentration remains constant across those data sets (as opposed to the $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ concentration in the Mg 2 p and Mg 2 s spectra, whose variation is reflected in the peak intensities). Linear baselines were subtracted from the $P 2 s$ data to remove the secondary electron background (see Figure S5 in the SI for details).
recorded from Tris ${ }_{(\mathrm{aq})}$ solutions (see Figure S2 in the SI). A highlight of each spectral region is shown in Figure 3 [panels (a)-(e)].

Figure 3(a) focuses on the valence region, which is dominated by PE signatures of ionization of water valence electrons,[76] labeled as (liquid- and gas-phase) $1 b_{1}, 3 a_{1}, 1 b_{2}$, and $2 a_{1}$ (the latter only included in Figure 2). Observed energy shifts and intensity variations of the $1 \mathrm{~b}_{1(\mathrm{~g})}$ peak can be assigned to a weak charging of the liquid-jet surface upon addition of solute[65]. Based on a valence LJ-PES study of AMP $_{(a q)}$ published previously[47] and valence PE spectra from $\operatorname{ADP}_{(\mathrm{aq})}$ and $\mathrm{ATP}_{(\mathrm{aq})}$ (see Figure S3 in the SI for details), the phosphate, ribose, and adenine PE signatures are present in the 8-10 eV BE range, with an additional adenine feature also present at 7-8 eV, as highlighted in the figure inset in Figure 3(a).

The adenine feature at $7-8 \mathrm{eV}$ BE in Figure 3(a) is observed to shift as the $\mathrm{Mg}^{2+} /$ ATP concentration ratio increases. Similar shifts are observed in valence PE spectra recorded from $\mathrm{ADP}_{(\mathrm{aq})}$ solutions as a function of the $\mathrm{Mg}^{2+}$ /ADP concentration ratio (see Figure S 4 in the SI ). Such a spectral shift might be a signature of the previously and aforementioned speculated water-mediated $\mathrm{Mg}^{2+}$-adenine interactions in [MgATP] ${ }^{2-}{ }_{(\text {(qq) }}[17,18]$, possibly associated with some closed-structure form, as depicted in Figure 1(b). Furthermore, gas-phase mass spectrometry experiments have shown the presence of phosphate- $\mathrm{Mg}^{2+}$-adenine interactions in both $\mathrm{Mg}^{2+}$-ATP and $\mathrm{Mg}^{2+}$-ADP complexes, although no water is involved in the complexes.[29] One could argue that for the closed-form structure, the metal-ionbound water molecule donates a hydrogen bond to the N atom of adenine, causing the observed increase in its BE, leading to a cation-stabilized electron in the highest occupied molecular orbital (HOMO) in the adenine moiety.

Signals at higher BEs associated with adenine and ribose orbitals are expected in the 10-20 eV BE range.[78] Furthermore, the emergence of an additional feature is evident close to 20 eV BE at the highest $\mathrm{Mg}^{2+} /$ ATP concentration ratio [see the arrow in Figure 3(a)]. This spectral change could potentially result from the presence of $\mathrm{Mg}^{2+}$-phosphate interactions in any of the $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ moieties presented in Figure 1 and Figure S1, in which 0 atoms from the phosphate chain are directly exposed to the positive charge from the divalent cation. Previous LJ-PES experiments have been shown to be sensitive to $\mathrm{Na}^{+}$-phosphate electrostatic interactions,[55] and we expect the presence of $\mathrm{Mg}^{2+}$ (aq) to have a more pronounced effect. To understand the identity of the orbitals involved in this ionization feature, the inner-valence region was explored using the same methodology used to calculate P 2s BEs as reported in the computations section. Our results indicate that the 20 eV BE feature originates from ionization of electrons from mixed, delocalized molecular orbitals appearing when $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ ions are closely bound to the phosphate chain, with significant contributions from $\mathrm{O}, \mathrm{C}$, and P atoms. We note that O 2 s signatures from phosphate compounds are expected in the $24-25.7 \mathrm{eV}$ BE range[79] and are likely hidden underneath the water 2a1 peak.

For samples containing $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$, the Mg 2 p and Mg 2 s PE features occur near 55 eV and 95 eV and are highlighted in Figures 3(b) and 3(c), respectively. With increasing $\mathrm{Mg}^{2+} /$ ATP concentration ratio, the respective intensities increase, and the peak centers shift to higher BEs; these shifts are indicated by dashed lines. We observe similar trends in the $P 2$ p and $P 2 s$ spectral regions, near 140 and 196 eV BEs, as highlighted in Figures 3(d) and 3(e).

A quantitative analysis of the evolution of the observed chemical shifts is presented in Figure 4(a). Note that we can include a data point at zero $\mathrm{Mg}^{2+}$ concentration only for the P 2p and P 2s analyses. Although these BEs, from aqueous solutions containing only $\mathrm{Mg}^{2+}$, have been reported previously,[61] connecting those values with the present data is not straightforward. This is due to the inherent experimental error in determining accurate absolute BEs when calibrating to peak positions measured from neat liquid water, and thus neglecting solute-induced effects on the water electronic structure; see again footnote §. Such effects have been recently quantified for a few representative aqueous solutions, based on the simultaneous detection of the lowenergy cut-off of the respective PE spectrum.[67] However, this method could not be applied for the work presented here, and was not applied in Reference [61] either, so the two works may have an error in absolute BE of up to 200 meV that prohibits accurate cross-comparison. While uncertainties in the absolute BEs shown in Figure 4(a) are up to 200 meV , and, as the data shown in Figure 3, were all taken at the same time, the relative shifts should be meaningful. For the Mg 2p and Mg 2s data in Figure 4(a), we have thus assumed that for the lowest $\mathrm{Mg}^{2+}$ /ATP concentration ratio of 0.25 , the chemical shift is negligibly small (well justified for a non-surface-active molecule,[80] corresponding to zero energy shift). The small minimum in the Mg 2s data at the 0.50 ratio implies some deviation from the main trend of increasing chemical shift, which is in agreement with our calculations as we further detail below. Despite these experimental constraints, the results of Figure 4(a) show that Mg and P core-level LJ-PES is indeed sensitive to $\mathrm{Mg}^{2+}$ - phosphate interactions in $\operatorname{ATP}_{(\mathrm{aq})}$.

Figure 4. (a) Chemical shifts extracted from the $\mathrm{Mg} 2 \mathrm{p}, \mathrm{Mg} 2 \mathrm{~s}$, $P 2 p$, and $P$ 2s core-level data presented in Figure 3 [panels (b)(e)] as a function of the $\mathrm{Mg}^{2+} /$ ATP concentration ratio. (b) Molar concentration of the predominant species - ATP4-(aq), [MgATP] ${ }^{2-}(\mathrm{aq})$, and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$ as a function of the $\mathrm{Mg}^{2+} /$ ATP concentration ratio at a solution pH of 8.2 calculated within this work using equilibrium constants from Reference[22]. Details on the procedure can be found in the SI.

Figure 4(a) thus suggests that the BEs of all four core levels exhibit a clear positive chemical shift, up to 300500 meV for the highest $\mathrm{Mg}^{2+} /$ ATP concentration ratios. There is no indication from the present data of any orbital-character-specific sensitivity in the case of $P$ core levels due to $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ interactions. On the other hand, such an effect appears to be revealed for Mg core levels, where chemical shifts in the Mg 2p BEs tend to be larger than for the Mg 2 s counterparts (with the exception of the 0.25 concentration ratio); this may point to the more directional bonding of the outermost $2 p$ orbital.

We next discuss why both P and Mg core-level BEs shift in the same positive direction. Phosphate P core-level BEs are stabilized by the interaction with $\mathrm{Mg}^{2+}(\mathrm{aq})$, as expected based on simple electrostatic arguments. For $\mathrm{Mg}^{2+}{ }_{(a q)}$, the
chemical shifts are either non-monotonous (2s) or of increasing BE (2p), starting already at small $\mathrm{Mg}^{2+}(\mathrm{aq})$ concentrations.

To investigate this behavior, we performed calculations of Mg 2 s and 2 p BEs. The results are presented in Table 1. Our computations suggest a decrease in BEs when moving from pure $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ to $[\mathrm{MgATP}]^{2-}{ }_{(\mathrm{aq})}$ and an increase in BE when moving to $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{(\mathrm{aq})}$. This would be in agreement with the minimum in the Mg 2 s data in Figure 4 a . But in the absence of reference measurements of Mg 2 s and 2 p spectra from $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ solutions without ATP, there is not enough experimental evidence for the theoretically predicted behavior at low $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ concentration. The predicted effect on chemical shifts is approximately the same for Mg 2 s and Mg 2 p . Therefore, the experimentally observed orbital-character-sensitivity for Mg core levels remains to be explained. Furthermore, note that the calculated difference in Mg core-level BEs for [MgATP $]^{2-}(\mathrm{aq})$ and $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{(\mathrm{aq})}$ is somewhat higher (approximately 800 meV ) compared to the experiment (approximately 300-500 meV). We attribute this discrepancy to the level of computational theory. Importantly, the trends are well reproduced.

|  | Mg 2s | Mg 2p |
| :---: | :---: | :---: |
| $\mathrm{Mg}^{2+}$ (aq) | 96.01 | 55.24 |
| [MgATP] ${ }^{2-(a q)}$ | 95.21 | 54.42 |
| [ $\left.\mathrm{Mg}_{2} \mathrm{ATP}\right]_{(\mathrm{aq})}$ | 96.08 | 55.30 |

We have also estimated the solution composition of the $\mathrm{Mg}^{2+} / \mathrm{ATP}_{(\mathrm{aq})}$ samples studied here using the binding constants of different $\mathrm{Mg}^{2+}-$ ATP $_{(\mathrm{aq})}$ complexes reported in Reference[22] (see the SI for details, including Table S2). While these values refer to lower ionic-strength conditions compared to the samples studied in this work, our primary focus is to produce a first-order approximation speciation plot to guide our qualitative description of the data. We have estimated that ATP $^{4-}{ }_{(a q)}$ and [MgATP] ${ }^{2-}($ aq $)$ (see Figure 1) are the dominant species at $\mathrm{Mg}^{2+} /$ ATP concentration ratios between $0.25: 1$ and $0.75: 1$, with an increasing proportion of [MgATP] ${ }^{2-}{ }_{(\text {aq })}$ as the concentration of $\mathrm{Mg}^{2+}$ increases. At a $1: 1$ $\mathrm{Mg}^{2+} /$ ATP ratio, there is no longer free $\operatorname{ATP}_{(\mathrm{aq})}\left(\right.$ ATP $\left.^{4-(\mathrm{aq})}\right)$ in solution, and [MgATP $]^{2-}(\mathrm{aq})$ is the prevailing species. At a $1.5: 1 \mathrm{Mg}^{2+} /$ ATP ratio, the $[\mathrm{MgATP}]^{2-}$ (aq) concentration decreases as the formation of $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{(\mathrm{aq})}$ becomes relevant (see Figure S1 in the SI). The amount of free $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ was estimated to be negligible at all the $\mathrm{Mg}^{2+} /$ ATP concentration ratios studied here. The results are summarized in Figure $4(\mathrm{~b})$. We consider this to be a minimal set of species expected in significant amounts in the prepared solutions influenced by the speciation analysis of Reference[22]. For instance, to simplify, we have omitted $\left[\operatorname{Mg}(A T P)_{2}\right]^{6-}$ (aq), although this species may contribute to the signal at the lower $\mathrm{Mg}^{2+}$ concentrations[23].

As listed in Table S1 in the SI, it was necessary to increase the Tris ${ }_{(\mathrm{aq})}$ concentration in our samples with the $\mathrm{Mg}^{2+} /$ ATP ratio to maintain a constant solution pH of 8.2. One potential concern might be that $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ binding to Tris (aq) would impact speciation with $\operatorname{ATP}_{(a q)}$. However, $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ complexation to $\operatorname{Tris}_{(\mathrm{aq})}$ is known to be weak compared to other divalent cations, such as $\mathrm{Cu}^{2+}{ }_{(\mathrm{aq})}$,[81] and the binding constant of Tris $\left(\right.$ aq) with $\mathrm{Cu}^{2+}{ }_{(\mathrm{aq})}$ is 2-4 orders of magnitude lower than those for [MgATP] ${ }^{2-}(\mathrm{aq})$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$ (as listed in the SI). Hence, we expect the valence (and Mg core-level) spectral changes observed as a function of the $\mathrm{Mg}^{2+} /$ ATP concentration ratio to be predominantly accounted for the formation of [MgATP ${ }^{2-}{ }^{-}$(aq). and $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{\text {(aq) }}$. Consequently, the valence spectral changes and core-level chemical shifts observed in Figures 2 and 3 can be attributed to the presence of [MgATP] ${ }^{2-}$ (aq) and $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{(\mathrm{aq})}$ in increasing proportion at each $\mathrm{Mg}^{2+} /$ ATP ratio.

Notably, at the sample concentrations employed here, any $\mathrm{Mg}^{2+}$-phosphate interactions observed in our data can also correspond to phosphate- $\mathrm{Mg}^{2+}$-phosphate intramolecular bridges between ATP $_{(\mathrm{aq})}$ molecules, which are expected to occur at concentrations above $10^{-3} \mathrm{M}$.[82, 83]. Nevertheless, the presence of deprotonated sites on the phosphate chain (as in the samples studied here, where ATP $_{(\text {aq })}$ is expected to be fully deprotonated) reduces the formation of such bridges due to repulsion interactions between the negatively charged 0 atoms.[83] Furthermore, our ICD measurements to be discussed below show no evidence for the bridged structure.
$\alpha$-, $\beta$-, and $\gamma$-phosphate-specific interactions in ATP $_{(\mathrm{aq})}$ and $\mathbf{M g}^{2+}-$ ATP $_{(\mathrm{aq})}$. Here, we focus on the question of whether it is possible to discriminate $\alpha$-, $\beta$-, and $\gamma$-phosphate units in the $\operatorname{ATP}_{(\text {aq) }}$ phosphate chain on the basis of PE spectra. As a starting point, we performed computations to calculate the P 2 s BEs of each phosphate unit in fully deprotonated ATP $_{(\mathrm{aq})}\left(\right.$ ATP $\left.^{4}{ }_{(\mathrm{aq})}\right)$, as found at the solution pH of the samples studied here. We obtained nearly identical $\alpha$ - and $\beta$-phosphate P 2s BEs $(196.93 \mathrm{eV}$ and 196.97 eV , respectively), and an $\sim 850-900 \mathrm{meV}$ lower $\gamma$-phosphate P 2s BE (196.08 eV). In agreement with a previous report on P 2p PES from solid-phase calcium tripolyphosphate,[84] our results show that the bridging phosphate groups ( $\alpha$ and $\beta$ units) have higher BEs than the terminal phosphate ( $\gamma$ phosphate). In ATP ${ }^{4-}$ (aq), P core-level electrons in the $\gamma$-phosphate are uniquely subjected to repulsive interactions from two negatively charged 0 sites, while $\alpha$ and $\beta$ units contain a single deprotonated site [see Figure 1(a)]. Such differences in the local chemical environment lead to lower $\gamma$ phosphate P 2 s BE values compared to the $\alpha$ and $\beta$ units. (We note that the present and following discussions do not extend to P 2p BEs since the expected doublet peak-structure would prevent a similarly accurate distinction of the small energetic differences associated with the specific phosphate groups.)

With this information in mind, we attempted to deconvolve P 2 s PE spectra recorded from ATP $_{(\mathrm{aq})}$ samples into individual $\alpha-$, $\beta$-, and $\gamma$-phosphate contributions with the aid
of spectra from $\mathrm{AMP}_{(\mathrm{aq})}$ and $\mathrm{ADP}_{(\mathrm{aq})}$. When discussing the respective electron BEs, it is useful to refer to each phosphate group as adenosine-phosphate bridging unit, terminal unit, and phosphate-phosphate bridging unit, rather than $\alpha, \gamma$, and $\beta$, respectively; this characterization most directly reflects the origin of the different BEs, as described below.

Figure 5 shows P 2s PE spectra from $0.5 \mathrm{M} \mathrm{AMP}_{(\mathrm{aq})}$ (magenta curve), ADP $_{\text {(aq) }}$ (cyan curve), and ATP $_{\text {(aq) }}$ (black curve) solutions at pH 8.2 recorded using a photon energy of 330 eV . A linear baseline was subtracted from each spectrum, and the BE scale was calibrated with respect to the liquid water $1 b_{1}$ feature[67] in valence data recorded under similar conditions. P 2s peak areas extracted from Voigt profile fits were used to re-scale the signal intensities of the $\mathrm{ADP}_{(\mathrm{aq})}$ and $\mathrm{ATP}_{(\mathrm{aq})}$ spectra to twice $\left(\mathrm{ADP}_{(\mathrm{aq})}\right)$ and three times $\left(\mathrm{ATP}_{(\mathrm{aq})}\right)$ with respect to the $\mathrm{AMP}_{(\mathrm{aq})}$ spectrum, based on the number of phosphate units in each case. Further details regarding the data treatment are presented in Figure S6 in the SI.

Figure 5. P 2 s PE spectra recorded from $\operatorname{AMP}_{(\mathrm{aq})}, \operatorname{ADP}_{(\mathrm{aq})}$, and ATP $_{(a q)}$ solutions without dissolved $\mathrm{Mg}^{2+}$. The AMP $_{(\text {(aq })}$ data is representative of a terminal phosphate (peak 1), while bridging phosphate units in $\operatorname{ATP}_{(\mathrm{aq})}$ (peaks 2 and 3) were identified by subtracting the $\operatorname{AMP}_{(a q)}$ data from the $\operatorname{ADP}_{(\mathrm{aq})}$ spectrum (cyan dashed line) and the $\mathrm{ADP}_{(\mathrm{aq})}$ data from the $\operatorname{ATP}_{(a q)}$ spectrum (black dashed line).

A BE of 195.3 eV (peak 1 in Figure 5) was determined for $\mathrm{AMP}_{(\mathrm{aq})}$, corresponding to its single (terminal) phosphate group. Given that the $\operatorname{ADP}_{(\text {aq) }}$ phosphate chain contains two phosphate units, a second phosphate BE (peak 2) was determined by subtracting the $\mathrm{AMP}_{(\mathrm{aq})}$ spectrum from the $\mathrm{ADP}_{(\mathrm{aq})}$ data. The difference spectrum is shown using a cyan dashed line. A similar approach was implemented to determine the BE of a third phosphate unit (peak 3) by producing the ATP $_{(\mathrm{aq})}-$ ADP $_{(\mathrm{aq})}$ difference spectrum, shown using a black dashed line in Figure 5. Voigt profile fits to the difference spectra revealed BEs of 196.2 eV and 196.3 eV for peak 2 and 3, respectively (see Figure S6 in the SI).

As mentioned in the experimental section, we consider the methodology applied here to provide only relative BE values rather than absolute values. Hence, we determined BE energy differences of 900 meV between peaks 1 and 2, and 100 meV between peaks 2 and 3 , in agreement with our computations. Based on these results, we assign peak 1 as a PE signature of the terminal phosphate $(\gamma)$ in $\operatorname{ATP}_{(a q)}$, and peaks 2 and 3 as PE signatures of bridging phosphate units. In doing so, we are assuming that the terminal phosphate P 2 s BE value is the same in $\mathrm{AMP}_{(\mathrm{aq})}, \operatorname{ADP}_{(\mathrm{aq})}$, and ATP $_{(\mathrm{aq})}$. The other two phosphate groups, the adenosine-phosphate bridging $(\alpha)$ moiety and the phosphate-phosphate bridging $(\beta)$ unit, correspond each to different chemical environments, associated with different $P$ 2s BEs.

To assign the BEs extracted from peaks 2 and 3 to such moieties, and to evaluate our assumption more generally, we calculated the P 2s BEs of the individual phosphate units in $\operatorname{ADP}_{(\mathrm{aq})}\left([\mathrm{MgADP}]^{-(\mathrm{aq})}\right)$. Our results confirm that the terminal phosphate in $\operatorname{ADP}_{(\mathrm{aq})}$ has a lower BE (196.04 eV) compared to the bridging phosphate attached to the nucleoside ( 196.80 eV ). With that in mind, we can assign peaks 2 and 3 as $\beta$ - and $\alpha$-phosphate in $\operatorname{ATP}_{(a q)}$, respectively. Our calculations also show that our assumption of the BE values of the terminal phosphate units in $\operatorname{ADP}_{(\mathrm{aq})}$ and $\operatorname{ATP}_{(\mathrm{aq})}$ being of the same magnitude is valid.

In addition, we investigated the effect of $\mathrm{Mg}^{2+}$-phosphate interactions on the $P$ core-level BEs of each individual phosphate group in $\operatorname{ATP}_{(\mathrm{aq})}$ by calculating the P 2s BEs of $\alpha-, \beta$-, and $\gamma$ - phosphate of $\left[\mathrm{MgATP}^{2-}{ }^{2-}(\mathrm{aq})\right.$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$. For [MgATP] ${ }^{2-}$ (aq), we considered two different binding motifs the cation simultaneously bound to the three phosphate units and the cation bound only to the $\beta$ - and $\gamma$-phosphate groups. The results are summarized in Table 2. Overall, we observe an increase in the $\mathrm{P} 2 \mathrm{~s}^{\prime} \mathrm{BEs}$ due to $\mathrm{Mg}^{2+}$-phosphate interactions, in agreement with the experimental results from the previous section. For all phosphate units in [MgATP ${ }^{2-}{ }_{(a q)}$, changes in the number of phosphate groups interacting with $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ lead to BE differences of $\sim 100 \mathrm{meV}$ between the two binding motifs cases. On the other hand, binding to a second $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ ion, as in $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, results in the largest increment in the P 2 s BEs, as expected due to the additional positive charge from the metal cation. In addition, the presence of $\mathrm{Mg}^{2+}$-phosphate interactions in [MgATP] ${ }^{2-}$ (aq) and in $\operatorname{Mg}_{2}$ ATP $_{(\text {aq })}$ causes the $\alpha$ - and $\beta$-phosphate P 2s BEs to adopt different values, as opposed to in $\mathrm{ATP}_{(\mathrm{aq})}$ in the absence of the divalent cation.

|  | $\alpha$ | $\beta$ | $\gamma$ |
| :---: | :---: | :---: | :---: |
| [ATP] ${ }^{4-}$ (aq) | 196.93 | 196.97 | 196.08 |

| :--- | :---: | :---: | :---: |
| $\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]_{\text {(aq) }}$ | 198.27 | 197.83 | 196.82 |

Intermolecular-specific probe of the $\mathbf{M g}^{2+}$ (aq) coordination environment in the presence of ATP $_{(a q)}$. The analysis of the $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ concentration-dependent valence and core-level spectral changes presented in the previous sections provides site-specific information on the $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ bonding interactions. The ICD spectra presented in this section are particularly sensitive to interactions between $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ and its coordination environment, revealing additional insight into the number and identity of its chelating units.

We show that the ICD signal intensity associated with the hydration shell of a charged atomic ion is proportional to the number of hydrating water molecules and, as a result, the ion-water ICD signal decreases upon replacement of a water molecule by a solute component. In this way, we are sensitive to the exchange of water molecules by ATP $_{(\mathrm{aq})}$ due to the formation of $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$; this is illustrated in Figure 6 a , where one water molecule is replaced by one phosphate group in the first solvation shell of $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$. The associated ICD spectrum further reveals the character of the most involved water orbital,[61] as we discuss later.

The ICD process explored here, and illustrated in Figure $6(\mathrm{~b})$, takes place after the initial photoionization of Mg 1 s core-level electrons producing primary photoelectrons $\mathrm{e}^{-}$ph. The Mg 1 s core hole left behind is refilled by electrons from the Mg 2s (or Mg 2p) core levels, and the released excess energy is used to ionize the surrounding molecules - i.e., the water molecules and the chelating phosphate units in the first coordination shell - producing ICD electrons $\mathrm{e}^{-}$IcD.

Figure 7(a) shows ICD spectra recorded from 0.5 M $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2(\mathrm{aq})}$ solutions without ATP ${ }_{(\mathrm{aq})}$ (black line) and with 1:1 and 1.5:1 $\mathrm{Mg}^{2+} /$ ATP concentration ratios (orange and red lines, respectively). For the $0.5 \mathrm{M} \mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2 \text { (aq) }}$ solutions (no ATP added), the cation exists in its octahedral configuration $\left(\left[\mathrm{Mg}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}{ }_{(\mathrm{aq})}\right)$ (compare Figure 6(a)), regardless of the presence of the counter ion $\left(\mathrm{NO}_{3}{ }^{-}(\mathrm{aq})\right) \cdot[21,22]$ The data were recorded at a constant photon energy of 1314 eV , which was selected so as to exceed the Mg 1s BE (based on Reference[61]). The secondary-electron background was removed by fitting and subsequently subtracting cubic baselines from the different spectral regions. The Mg 2s peak areas extracted from Voigt fits to each data set were used to normalize the signal intensity in all the spectra by scaling the PE signal ordinate based on the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ concentration, assuming similar cross sections. In that way, we normalized the data in Figure 7(a) so as to

Figure 6. (a) Ejection of the initial 1s photoelectron, 1s e-, from $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ and an ICD electron, $\mathrm{e}^{-\mathrm{ICD}}$, associated with the subsequent valence ionization of a hydration-shell water molecule. The sketch also illustrates the direct interaction of $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ with a phosphate unit of $\mathrm{ATP}_{(\mathrm{aq})}$ which reduces the number of water molecules in the first solvation shell. (b) Energy level diagram depicting the ICD process. The open circle denotes the 1 s core hole upon ionization of $\mathrm{Mg}^{2+}$; $\mathrm{e}^{-}{ }^{-}{ }^{-1}$ are the ejected $1 \mathrm{~s}, 2 \mathrm{~s}, 2 \mathrm{p}$ photoelectrons. BE and KE denote electron binding and electron kinetic energies of the measured electrons, respectively. The non-local ICD processes, where the relaxation of the metal core hole involves the first solvation shell, lead to the ionization of all water valence (VB) orbitals (and potentially also of phosphate). This produces the ICD electrons $\mathrm{e}^{-}$ICD,2s and $\mathrm{e}^{-}{ }^{-1 C D, 2 p}$.
display the same peak area for the samples where the $\mathrm{Mg}^{2+}{ }_{(\text {aq) }}$ concentration is 0.5 M (black and orange curves) and an area 1.5 times larger for the sample containing $0.75 \mathrm{M} \mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ (red curve). In the $\mathrm{Mg}^{2+} / \mathrm{ATP}_{(\mathrm{aq})}$ data, the energy scale was calibrated with respect to the Na 2 p PE peak, which we observe to remain fixed in BE (at 68.3 eV ) across all samples in Figure 2. In the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$-only data, the energy calibration was performed based on the Mg 2 s BE value ( 94.3 eV ) reported in Reference[61]. Further details regarding the data treatment can be found in Figure S7 of the SI.

Our first observation is that the Mg 2 p and Mg 2 s ICD signals occur at slightly but distinctly different KEs in the $\mathrm{Mg}^{2+} / \mathrm{ATP}_{(\mathrm{aq})}$ spectra with respect to the $\mathrm{Mg}^{2+}(\mathrm{aq})$-only $\left(\left[\mathrm{Mg}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}{ }_{\text {aq }}\right)$ data. This directly reflects the formation of [MgATP] ${ }^{2-(\text { aq }) ~(i n ~ t h e ~} 1: 1 \mathrm{Mg}^{2+} /$ ATP ratio case) and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$ (in the $1.5: 1 \mathrm{Mg}^{2+} /$ ATP ratio case) as discussed in connection with Figure 4(b). The observed spectral changes imply that interactions with ATP $_{(\mathrm{aq})}$ affect the transfer of excess energy from $\mathrm{Mg}^{2+}($ aq $)$ to its coordinating environment during the ICD process, likely due to charge redistribution between the metal ion and the phosphate

Figure 7. (a) ICD spectra from $\mathrm{Mg}^{2+}(\mathrm{aq})$ without ATP $_{(\mathrm{aq})}$ and in the presence of ATP $_{(\mathrm{aq})}$ at $1: 1$ and $1.5: 1 \mathrm{Mg}^{2+} /$ ATP concentration ratios. The signal intensity is shown normalized according to the $\mathrm{Mg}^{2+}(\mathrm{aq})$ concentration. The spectral range of the 2 s and 2 p ICD channels covers the direct Mg 2 s ionization. (b) Close-up of the Mg 2p ICD spectral region from the 1.5:1 $\mathrm{Mg}^{2+}$ /ATP concentration ratio data presented in panel (a). Spectra are displayed such that the main peaks are at the same KE, and their heights are the same. Gaussian curves (red dashed lines) in the $\mathrm{Mg}^{2+}$ only data highlight the individual ionization features from the water orbitals $1 b_{2}, 3 a_{1}$, $1 \mathrm{~b}_{1}$ involved in the ICD process. The $\mathrm{Mg}^{2+} /$ ATP minus the $\mathrm{Mg}^{2+}$-only difference spectrum shown at the bottom (dark green) reveals the ICD signal associated with the $\mathrm{Mg}^{2+}$ phosphate interaction (labelled ATP).
units in the nucleotide. We note that the $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$-only sample did not contain Tris (aq), in contrast to the $\mathrm{Mg}^{2+} /$ ATP solutions, but $\mathrm{Mg}^{2+}{ }^{-} \mathrm{Tris}_{(\mathrm{aq})}$ complexation should be relatively weak, as discussed previously.

Our second observation is that the intensity of the Mg 2p ICD feature decreases in the $1: 1 \mathrm{Mg}^{2+} /$ ATP data compared to the $\mathrm{Mg}^{2+}(\mathrm{aq})$-only data, both of which are associated with equal $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ concentrations. This reveals the aforementioned formation of [MgATP ${ }^{2-}{ }^{2-}$ (aq) and the associated reduction in the number of the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$-water ICD channels available. Accordingly, we observe an $\sim 15 \%$ reduction in signal intensity. This corresponds to one water molecule out of six being replaced in $\left[\mathrm{Mg}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}{ }_{\text {aq }}$ upon complexation to

ATP ${ }_{(\mathrm{aq})}$ (assuming negligible $\mathrm{Mg}^{2+}$-Tris $(\mathrm{aq})$ complexation); compare Figure 6(a). We note that this interpretation implicitly assumes that ICD signals involving phosphate are significantly weaker compared to those involving water.

As expected, based on the $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ concentration in each sample, the intensity of the Mg 2p ICD signal in the 1.5:1 $\mathrm{Mg}^{2+}$ /ATP data is $\sim 1.5$ times higher with respect to the $1: 1$ $\mathrm{Mg}^{2+} /$ ATP case. However, if we compare the $1.5: 1 \mathrm{Mg}^{2+} / \mathrm{ATP}$ spectra with the $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$-only data, we observe that the ICD signal intensity in the $1.5: 1 \mathrm{Mg}^{2+} /$ ATP case is only 1.3 times higher than in the $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$-only case. This shows that the presence of ATP ${ }_{(\mathrm{aq})}$ causes the signal to change non-linearly with respect to the concentration of the metal cation. In other words, and following our argument from the previous paragraph, we observe an $\sim 15 \%$ reduction in signal due to the formation of $[\mathrm{MgATP}]^{2-}{ }_{(\mathrm{aq})}$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$.

Another spectral change becomes apparent when overlapping the main peaks (at a common KE and normalized area) of the Mg 2p ICD spectra from both samples, as shown in Figure 7 (b) and detailed in the respective figure caption. We recall that the ICD signals are the convolution of ionization peaks associated with all the orbitals involved in the charge-transfer process occurring within the coordination shell. The observed broader Mg 2p ICD feature in the $\mathrm{Mg}^{2+} /$ ATP spectrum with respect to the $\mathrm{Mg}^{2+}$ (aq)-only spectrum thus suggests that the ICD process in the latter involves additional orbitals, other than the water orbitals.[61] In order to test this interpretation, we subtracted the $\mathrm{Mg}^{2+}($ aq) $)$ only data from the $1.5: 1 \mathrm{Mg}^{2+} /$ ATP data. The difference spectrum is shown in dark green at the bottom of Figure 7(b), highlighting an ICD component associated with ATP (labelled ATP) occurring near 1241 eV KE. Note the occurrence of another feature near 1238 eV , the assignment of which is not clear at the moment. Gaussian fits of the individual water orbitals ( $1 \mathrm{~b}_{2}, 3 \mathrm{a}_{1}$, and $1 \mathrm{~b}_{1}$ ) to the $\mathrm{Mg}^{2+}(\mathrm{aq})$-only spectrum are shown in dashed lines and are in semi-quantitative agreement with Reference [61]. The ATP contribution from $\mathrm{ATP}_{(\mathrm{aq})}$ interacting with $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$, i.e., due to the formation of $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, is indeed consistent with the lowest phosphate BE being approximately 2 eV lower than that of water $1 \mathrm{~b}_{1}$.[47] As reported previously, $\mathrm{Mg}^{2+}(\mathrm{aq})$-water ICD signals show a high specificity for water electrons from the $3 a_{1}$ orbitals.[61] This is also the case for the data presented here, highlighting the sensitivity of the technique to orbital spatial orientation.

Overall, the sensitivity of the ICD signal intensity to the charge of the solvated ion involved in the solute-water en-ergy-transfer process allows us to uniquely probe charge distribution changes upon replacing water molecules in the coordination sphere of $\left[\mathrm{Mg}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ (aq) by phosphate from $\mathrm{ATP}_{(\mathrm{aq})}$ to form different $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ complexes. We note that the ICD spectra do not uncover the water-mediated adenine $-\mathrm{Mg}^{2+}$ interaction suggested in the literature since the respective water molecule is one of the constituents in the first hydration shell, with differences in electronic structure with respect to the other water molecules being too small to be detected here.

## CONCLUSIONS

We have probed interactions between adenine and phosphate units in $\operatorname{ATP}_{(\mathrm{aq})}$ with $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$, as well as the electronic structure of the phosphate chain in ATP $_{(\mathrm{aq})}$, using LJ-PES plus theoretical calculations and correlating our observations to the formation of [MgATP] ${ }^{2-}(\mathrm{aq})$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$.
Valence PE spectra from solutions with different $\mathrm{Mg}^{2+} /$ ATP concentration ratios reveal the adenine PE feature in ATP ${ }_{(a q)}$ to shift in BE as the $\mathrm{Mg}^{2+}{ }_{\text {(aq) }}$ concentration increases, providing direct evidence of $\mathrm{Mg}^{2+}$-adenine and $\mathrm{Mg}^{2+}$ - phosphate interactions in [MgATP] ${ }^{2-}{ }_{(\mathrm{aq})}$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$.
The Mg 2p, Mg 2s, P 2p, and P 2s PE data demonstrate the element-sensitivity of core-level PES to further support the presence of $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ interactions in aqueous solution. We report chemical shifts to higher BEs as the $\mathrm{Mg}^{2+}{ }_{(\text {aq) }}$ concentration increases, with stronger effects for the Mg core levels compared to the P core levels, reflecting the indirect character of $\mathrm{Mg}-\mathrm{P}$ interactions, which occur via O atoms.
We performed a combined analysis of P 2 s PE spectra from $\operatorname{ATP}_{(\mathrm{aq})}, \operatorname{ADP}_{(\mathrm{aq})}$, and $\mathrm{AMP}_{(\mathrm{aq})}$, and computed BEs to isolate spectral fingerprints of $\alpha-, \beta$-, and $\gamma$-phosphate in $\operatorname{ATP}_{(a q)}$. Our results reveal that the BEs of the bridging groups in the phosphate chain are higher than that of the terminal phosphate. We also calculated the P 2s phosphate-specific BEs of [MgATP] ${ }^{2-}{ }_{(\mathrm{aq})}$ and $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq})}$, to characterize the effect of different $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$-binding motifs.
Finally, we presented ICD spectra from ATP $_{(\mathrm{aq})}$ solutions containing $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ at two different concentration ratios, allowing us to probe the interactions between the metal cation and its coordination environment with exceptional sensitivity. From a comparison with $\mathrm{Mg}^{2+}$-water ICD features in the absence of ATP $_{(a q)}$, we detect changes in signal intensity and spectral shape due to the replacement of first-hydra-tion-shell water molecules by phosphate from ATP $\left(\right.$ aq) ${ }^{\text {. }}$
In summary, the work presented here provides a thorough element-specific overview of $\mathrm{Mg}^{2+}$ ATP interactions in aqueous solution on the molecular level. Specifically, the information on the electronic structure, charge distribution, and coordination environment in $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ complexes offers insight into the molecular aspects underlying phosphorylation and dephosphorylation reactions at physiological pH . In addition, our findings provide insight into the formation of the widely discussed water-mediated $\mathrm{Mg}^{2+}$-adenine interactions and while our data is consistent with a closed (ring) $\mathrm{Mg}^{2+}-$ ATP $_{(\text {aq })}$ moiety, we cannot rule out the $\mathrm{Mg}^{2+}$ ion separately interacting either with adenine or phosphate in the open-form structure.
While we provide a qualitative spectral assignment of $\mathrm{Mg}^{2+}-$ ATP $_{(\text {(aq) }}$ interactions, such information cannot be used, at present, to extend the speciation results reported by Storer et al.[22] - which are based on information from pH titration experiments - or to derive thermodynamic information. This is complicated by the very small P 2s BE differences between the $\alpha, \beta$, and $\gamma$ units. Nevertheless, the combined information extracted from the spectral assignments, chemical shifts, and ICD phenomena provides a foundation for potential temperature-dependent PES experiments that
recover the $\mathrm{Mg}^{2+}$-phosphate-dependent $\mathrm{Mg}^{2+}-\mathrm{ATP}_{(\mathrm{aq})}$ association equilibria energies and entropy data.
Overall, we have explored the current capabilities of state-of-the-art LJ-PES, including direct PE emission and non-local relaxation processes upon core-level ionization, in characterizing the electronic-structure interactions between ATP and $\mathrm{Mg}^{2+}$ in aqueous solution. Future studies will extend the structure-sensitivity of ICD to include the respective P - and N -induced relaxation processes, particularly aiming at providing evidence for the closed-ring structure. Moreover, and in a wider context, we believe that the present results are of relevance to the elucidation of the mechanisms and reaction intermediaries in phosphorylation and dephosphorylation of $\operatorname{ATP}_{(\mathrm{aq})}$ - including the study of the role of $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}\left(\right.$ or $\left.\mathrm{Ca}^{2+}{ }_{(\mathrm{aq})}\right)$ divalent cations as well as the importance of solvation and the role played by specific water molecules.

## Author Contributions

$\ddagger$ These authors contributed equally.

## Notes

§ In the present study, no low-energy cut-off measurements from an electrically biased liquid jet have been performed. This is the reason why we cannot apply the more robust method for a determination of absolute electron binding energies, as recently reported in Reference[67].

## ACKNOWLEDGMENT

The authors would like to thank Robert Seidel, Christi Schroeder, Anne B. Stephansen, Claudia Kolbeck, Marvin Pohl, Iain Wilkinson, and Gerard Meijer for their support along different stages of the project and during initial experiments at BESSY II. C.L and D.M. were supported by the Director, Office of Basic Energy Science, Chemical Sciences Division of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231 and by the Alexander von Humboldt Foundation. L.T. and P.S. acknowledge the support of the Czech Science Foundation, project number 21-26601X (EXPRO project). S.B. acknowledges NSF CHE-0617060 for early phases of this work and NSF CHE1665532 for travel support in finalizing the work. B.W. acknowledges funding from the European Research Council
(ERC) under the European Union's Horizon 2020 research and investigation programme (grant agreement No. 883759). F.T. and B.W. acknowledge support from the MaxWater initiative of the Max-Planck-Gesellschaft. We acknowledge DESY (Hamburg, Germany), a member of the Helmholtz Association HGF, for the provision of experimental facilities. This research was carried out initially at BESSY II (project number 2009_2_90613 at beamline U41-PGM) and subsequently at PETRA III, and we thank Moritz Hoesch as well as the whole beamline staff, the PETRA III chemistry-laboratory and crane operators for assistance in using the P04 soft X-ray beamline.

## ABBREVIATIONS

ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; BE, binding energy; HOMO, highest occupied molecular orbital; HF, Hartree-Fock; ICD, intermolecular Coulombic decay; KE, kinetic energy; LJ-PES, liquidjet photoelectron spectroscopy; NMR, nuclear magnetic resonance; PCM, polarizable continuum model; PE, photoelectron; PEEK, polyether ether ketone; PES, photoelectron spectroscopy; Tris, (tris(hydroxymethyl)aminomethane).

## Possible 'open form' and 'closed form' configuration of $\mathbf{M g}_{2} \mathbf{A T P}{ }_{(a q)}$

a) Open form

b) Closed form

Figure S1. Possible molecular structures adopted by $\mathrm{Mg}_{2} \mathrm{ATP}_{(\mathrm{aq}}$. (a) Open form. (b) Closed form. This figure was produced using the ACD / ChemSketch software [1].

## Predicted composition of the $\operatorname{ATP}(\mathrm{aq})$ samples with dissolved $\mathbf{M g}^{\mathbf{2 +}}$ as a function of the $\mathbf{M g}^{2+} / \mathrm{ATP}$ concentration ratio

The composition of the $\mathrm{ATP}_{(\mathrm{aq})}$ samples with dissolved $\mathrm{Mg}^{2+}$ was calculated as follows. First, we assumed the species in solution to be $\mathrm{ATP}^{4-}$, $\mathrm{HATP}^{3-}, \mathrm{H}_{2} \mathrm{ATP}^{2-}$, $\mathrm{MgATP}^{2-}, \mathrm{Mg}_{2} \mathrm{ATP}, \mathrm{MgHATP}$, $\mathrm{MgH}_{2} \mathrm{ATP}, \mathrm{Mg}^{2+}, \mathrm{Na}^{+}, \mathrm{H}^{+}$, and $\mathrm{OH}^{-}$, with a solution pH of 8.2 to match the experimental conditions. Thus,

$$
\begin{equation*}
\left[\mathrm{H}^{+}\right]=10^{-8.2} \tag{1}
\end{equation*}
$$

We used equilibrium constants from Storer and Cornish-Bowden [2] - namely, Equations (1), (2), (4), (5), (6), and (7) from Table 2. Notably, the values correspond to solutions of lower ionic strength than those studied here. Nevertheless, they still serve to allow for a qualitative estimate of our system.

$$
\begin{align*}
& \frac{\left[\mathrm{H}_{2} \mathrm{ATP}^{2-}\right]}{\left[\mathrm{H}^{+}\right] \cdot\left[\mathrm{HATP}^{3-}\right]}=8.5 \cdot 10^{3}  \tag{2}\\
& \frac{\left[\mathrm{HATP}^{3-}\right]}{\left[\mathrm{H}^{+}\right] \cdot\left[\mathrm{ATP}^{4-}\right]}=1.09 \cdot 10^{7} \tag{3}
\end{align*}
$$

$$
\begin{align*}
& \frac{\left[\mathrm{MgH}_{2} \mathrm{ATP}\right]}{\left[\mathrm{Mg}^{2+}\right] \cdot\left[\mathrm{H}_{2} \mathrm{ATP}^{2-}\right]}=2.0 \cdot 10^{1}  \tag{4}\\
& \frac{\left[\mathrm{MgHATP}^{-}\right]}{\left[\mathrm{Mg}^{2+}\right] \cdot\left[\mathrm{HATP}^{3-}\right]}=5.42 \cdot 10^{2}  \tag{5}\\
& \frac{\left[\mathrm{MgATP}^{2-}\right]}{\left[\mathrm{Mg}^{2+}\right] \cdot\left[\mathrm{ATP}^{4-}\right]}=3.48 \cdot 10^{4}  \tag{6}\\
& \frac{\left[\mathrm{Mg}_{2} \mathrm{ATP}^{2}\right]}{\left[\mathrm{Mg}^{2+}\right] \cdot\left[\mathrm{MgATP}^{2-}\right]}=4.0 \cdot 10^{1} \tag{7}
\end{align*}
$$

In addition, we used equations for mass balance, where $c_{0}\left(\mathrm{Na}_{2} \mathrm{H}_{2} \mathrm{ATP}\right)$ is the initial concentration of the ATP compound and $c_{0}\left(\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}\right)$ is the initial concentration of the Mg salt.

$$
\begin{gather*}
c_{0}\left(\mathrm{Na}_{2} \mathrm{H}_{2} \mathrm{ATP}\right)=\left[\mathrm{ATP}^{4-}\right]+\left[\mathrm{HATP}^{3-}\right]+\left[\mathrm{H}_{2} \mathrm{ATP}^{2-}\right]+\left[\mathrm{MgATP}^{2-}\right]+\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]  \tag{8}\\
+\left[\mathrm{MgHATP}^{-}\right]+\left[\mathrm{MgH}_{2} \mathrm{ATP}\right] \\
c_{0}\left(\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}\right)=\left[\mathrm{Mg}^{2+}\right]+\left[\mathrm{MgATP}^{2-}\right]+2 \cdot\left[\mathrm{Mg}_{2} \mathrm{ATP}\right]+\left[\mathrm{MgHATP}^{-}\right]  \tag{9}\\
+\left[\mathrm{MgH}_{2} \mathrm{ATP}\right] \\
{\left[\mathrm{Na}^{+}\right]=2 \cdot c_{0}\left(\mathrm{Na}_{2} \mathrm{H}_{2} \mathrm{ATP}\right)} \tag{10}
\end{gather*}
$$

Finally, we considered the self-ionization of water at $25^{\circ} \mathrm{C}$.

$$
\begin{equation*}
\left[\mathrm{H}^{+}\right] \cdot\left[\mathrm{OH}^{-}\right]=10^{-14} \tag{11}
\end{equation*}
$$

This represents a system of 11 equations with 11 unknowns, which was solved for different $\mathrm{Mg}^{2+} / \mathrm{ATP}$ concentration ratios using the Maple 2016 software [3]. The results are reported in Table S2.

Table S2. Calculated concentration of species as a function of $\mathrm{Mg}^{2+} /$ ATP concentration ratio at a solution pH of 8.2. The values were determined as described in the text, using equilibrium constants from Reference [2]. The total concentration of $\operatorname{ATP}_{(\mathrm{aq})}$ was kept at $0.5 \mathrm{~mol} \mathrm{dm}^{-3}$ while the total concentration of $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ was varied in the range $0.125-0.75 \mathrm{~mol} \mathrm{dm}^{-3}$. All values are in $\mathrm{mol} \mathrm{dm}^{-3}$.

|  | 0.25:1 ratio | 0.5:1 ratio | 0.75:1 ratio | 1:1 ratio | 1.5:1 ratio |

## Photoelectron spectra from Tris(aq) ${ }_{(a l u t i o n s ~ w i t h ~ a n d ~ w i t h o u t ~ d i s s o l v e d ~}^{\mathbf{M g}^{\mathbf{2}}}$

Figure S2. (a) Photoelectron spectra recorded from $3.2 \mathrm{M} \mathrm{Tris}_{(\mathrm{aq})}$ without $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ (blue line) and with 0.5 M $\mathrm{MgCl}_{2 \text { (aq) }}$ (red line) using a photon energy of 250 eV . The sample pH was adjusted to 8.2 by addition of concentrated HCl in both cases. The binding energy (BE) scale was calibrated based on the liquid-water solvent valence $1 b_{1}$ peak position, and spectral intensities are displayed to yield its same height. (b) Highlight of the valence spectral region from panel (a). Photoelectron signatures of water and $\mathrm{Cl}_{(\mathrm{aq})}$ are labelled according to References [4] and [5], respectively.

## Valence photoelectron spectra of $\operatorname{ATP}_{(a q)}, \operatorname{ADP}_{(a q)}$, and $\operatorname{AMP}_{(a q)}$

Figure S3. Valence photoelectron signals from $\mathrm{AMP}_{(\mathrm{aq})}, \mathrm{ADP}_{(\mathrm{aq})}$, and $\mathrm{ATP}_{(\mathrm{aq})}$ solutions without disolved $\mathrm{Mg}^{2+}$ isolated by subtracting the solvent water contributions, facilitating the identification of the phosphate feature and its changes in signal intensity across the nucleotide series. The figure was extracted from Reference [6]. The experimental conditions used are described in Reference [7].

## Valence photoelectron spectra of ADP $_{(\text {aq })}$ with $\mathbf{M g}^{\mathbf{2 +}}{ }_{(\text {aq })}$

Figure S4. Valence and core-level ( $\mathrm{Mg} 2 \mathrm{p}, \mathrm{Mg} 2 \mathrm{~s}, \mathrm{P} 2 \mathrm{p}$, and P 2 s ) photoelectron spectra from $0.5 \mathrm{M} \mathrm{ADP}_{(\mathrm{aq})}$ samples containing $\mathrm{Mg}^{2+}{ }_{(\mathrm{aq})}$ as a function of the $\mathrm{Mg}^{2+} / \mathrm{ADP}$ concentration ratio recorded using a photon energy of 250 eV . The sample pH was 8.2 , adjusted by addition of Tris. The BE scale was calibrated based on the liquid-water solvent valence $1 b_{1}$ peak position, and spectral intensities are displayed to yield its same height. The figure inset highlights chemical shifts for the adenine unit, hinting to the presence of phosphate $-\mathrm{Mg}^{2+}-$ adenine interactions, as reported in Reference [8]. The arrow highlights PE signatures due to $\mathrm{Mg}^{2+}$-phosphate interactions, as explained in the main text in connection with Figure 3(a).

Linear baselines to the $P$ 2s data presented in Figure 3(e) in the main text

Figure S5. Linear baselines subtracted to the data presented in Figure 3(e) in the main text. The data are shown with a vertical offset for a better comparison.

## Data treatment to determine $\alpha-, \beta$-, and $\gamma$-phosphate $\mathbf{P} 2 s$ binding energies in $\mathbf{A T P}_{(\text {aq })}$

Figure S6. (a) Linear baselines fit to and subtracted from the $\mathrm{P} 2 \mathrm{~s} \mathrm{AMP}_{(\mathrm{aq})}, \operatorname{ADP}_{(\mathrm{aq})}$, and ATP $_{(\mathrm{aq})}$ spectra. (b) Voigt fits to the background-subtracted data performed to extract peak areas to re-scale each spectrum based on the number of phosphate units in each sample, as explained in the main text. (c) Voigt fits to the $\mathrm{AMP}_{(\mathrm{aq})}$ and the $\mathrm{ADP}_{(\mathrm{aq})}-\mathrm{AMP}_{(\mathrm{aq})}$ and $\mathrm{ATP}_{(\mathrm{aq})}-\mathrm{ADP}_{(\mathrm{aq})}$ difference spectra. The data are shown with a vertical offset for a better comparison. Peaks 1, 2, and 3 correspond to $\gamma-, \beta-$, and $\alpha$-phosphate, as described in the main text.

## Intermolecular Coulombic decay (ICD) spectra of ATP $_{(\text {(aq) }}$ solutions with dissolved $\mathbf{M g}^{\mathbf{2 +}}$

Figure S7. ICD spectra from a $0.5 \mathrm{M} \mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2(\text { aq) }}$ solution [panel (a)] and samples additionally containing ATP $_{(\mathrm{aq})}$ at 1:1 and $1.5: 1 \mathrm{Mg}^{2+} / \mathrm{ATP}$ concentration ratios [panels (b) and (c), respectively]. Cubic baselines were fit to and subtracted from different spectral regions - highlighted by green and blue dashed lines - to obtain the background-free data shown at the bottom of each plot and in Figure 6 in the main text (the use of a single baseline per spectrum did not allow the background to be removed completely, particularly in the vicinity of the Mg 2 p peak). Voigt profile fits to the Mg 2 s feature used to extract peak areas to normalize the signal intensity according to the $\mathrm{Mg}^{2+}{ }_{(\text {aq })}$ concentration are shown in magenta.
