Abstract

The digital divide describes disparities in access to and usage of digital tooling between social and economic groups. Emerging generative artificial intelligence tools, which strongly affect productivity, could magnify the impact of these divides. However, the affordability, multi-modality, and multilingual capabilities of these tools could also make them more accessible to diverse users in comparison with previous forms of digital tooling. In this study, we characterize spatial differences in U.S. residents' knowledge of a new generative AI tool, ChatGPT, through an analysis of state- and county-level search query data. In the first six months after the tool's release, we observe the highest rates of users searching for ChatGPT in West Coast states and persistently low rates of search in Appalachian and Gulf states. Counties with the highest rates of search are relatively more urbanized and have proportionally more educated, more economically advantaged, and more Asian residents in comparison with other counties or with the U.S. average. In multilevel models adjusting for socioeconomic and demographic factors as well as industry makeup, education is the strongest positive predictor of rates of search for generative AI tooling. Although generative AI technologies may be novel, early differences in uptake appear to be following familiar paths of digital marginalization.

Keywords: digital divide, artificial intelligence, large language models, digital inclusion

1 Introduction

Generative Artificial Intelligence (AI) is a general-purpose technology, an innovation that will affect many sectors of the economy [1]. Previous general-purpose technologies took decades to centuries to achieve widespread adoption [2, 3]. By contrast, many of the newest generative AI models have been made available within months of development, to anyone, anywhere in the world, at low to no cost, so long as they have access to a device with a stable internet connection. Hypothetically, then, a plurality of people should benefit from access to these new tools. But adoption could also be subject to the “digital divide”, differences between those who do and do not benefit from digital tooling that follow historical patterns of social marginalization [4]. As DiMaggio et al. [5] emphasize, the digital divide frequently exists not only at the level of access to devices and bandwidth, but also at a second level—whether access is converted into actual use [6]—and, at a third level, whether use leads to beneficial versus damaging outcomes [7]. While access to generative AI will necessarily be constrained by first-level divides, effects at the second and third levels remain unclear.

Early differences in access to and use of new generative AI tooling could have important and long-lasting social implications. Researchers have spent decades working to develop “artificial intelligence”, or computer systems that can match or outperform humans in cognitive capacities like reasoning and sensemaking [8, 9], but even technical experts have been surprised by the speed of recent advances in generative AI systems [10]. Generative AI refers broadly to models that can create new content without explicit programming beyond initial guidelines (prompts) [11]. These include generative large language models, neural networks that process sequential data including but not limited to natural language [12], which have gone from scoring in the bottom 10% on the legal bar exam to the top 10% within a year [13].¹ Generative image diffusion models, neural networks trained to emulate the inverse of a process where an image decays into noise, can now not only generate but also edit images and even video [15]. Recent advances are made possible by emergent properties of scale: As compute power, model parameters, and training data sizes increase, models exhibit qualitatively different abilities from their capabilities at smaller scales, and from the capabilities that their objective functions entailed.²

These powerful technical capabilities translate into real-world benefits. Access to generative AI can have large effects on productivity [17–19], creativity [20–23], and performance [24]. In an experimental study of computer programmers, for example, use of the large language model-based tool ChatGPT increased lines of code written by 56%, benefitting the least-skilled workers the most [17]. A real-world deployment with call center agents similarly found that use of a generative AI-based conversational agent increased overall productivity and reduced productivity gaps between novices

¹Reevaluations suggest that GPT-4’s score may be closer to the 68th percentile [14]—still an impressive improvement in performance over the previous near-random scores of smaller models.

²Wei et al. [16] show that Transformer language models trained with a next- or missing-word objective function, for example, begin to succeed at modified arithmetic, unscrambling words, and other simple tasks at just over 10 billion parameters ($2 * 10^{22}$ training FLOPs); to solve questions based on diverse domain knowledge as size approaches 100 billion parameters ($3 - 5 * 10^{23}$ training FLOPs); and to exhibit a jump in truthfulness at 280 billion parameters ($5 * 10^{23}$ training FLOPs, Gopher model only).

and experts [18]. Although the tools are still new, impaired access already has consequences. Italy’s nationwide ban on ChatGPT was associated with a short-term but large drop in code production before methods for bypassing the restrictions enabled a rebound [25]. However, several studies offer important caveats: first, a set of field experiments showed that access to a high-performing large language model led to significant improvements in creative ideation—again with the largest improvements for low performers—its use reduced the uniqueness of ideas overall (a finding also observed in [26] and [23]) and actually impaired performance in business problem solving [21]; second, an experiment on the impacts of ChatGPT access with the UK working-age population did not find reductions in performance inequality between education or age groups, though it did continue to find evidence of performance improvements overall [27]. Although the value these tools create for their users is likely to increase economic growth in general, differences in adoption could also magnify the already considerable harms of digital divides.

There is thus a pressing need to evaluate the extent to which digital divides are evident in emerging patterns of generative AI usage. This study characterizes emerging spatial and social patterns in knowledge of generative AI tooling across the United States. We focus on a single generative AI tool, ChatGPT, a simple chat interface atop a powerful large language model that saw unprecedented rapid uptake after its initial public release on November 30, 2021 [28], leveraging a large-scale search log database to characterize the fraction of searches for ChatGPT by county over the first six months since the tool’s release. Our analysis surfaces three observations. First, interest in chatGPT, as proxied by searches, is spatially clustered, with the highest rates of search in West Coast states and persistently low rates of search in Appalachia and Gulf states. Second, counties with the highest rates of search for ChatGPT are proportionally more urbanized, more educated, and have more technology and creative sector jobs in comparison with the U.S. overall. Finally, in fully adjusted hierarchical models, education emerges as the strongest predictor of interest—a finding that is consistent with past literature on the second-level digital divide. Although generative AI tools may be new, user interest follows the well-worn patterns of established digital divides.

2 Methods

2.1 Data

Our dataset comprises deidentified search interactions from Microsoft’s Bing search engine. We analyze billions of searches collected between December 1, 2022 and May 31, 2023 in the United States, including both desktop and mobile query search. All data were deidentified, aggregated to zip code and then to the county level, and securely stored, and analyzed only after aggregation to preserve user privacy and in accordance with Bing’s privacy policy. The study was reviewed and approved by the Microsoft Research Institutional Review Board (protocol ID 10590) prior to research activities.

To construct our analytic dataset, we first calculated the counts of searches for ChatGPT as well as total search counts and user counts by county. Each search interaction includes the search query string as well as a randomly generated client ID, a

timestamp, and the associated ZIP code and state. We added an indicator of whether the query referred to ChatGPT by a case-insensitive search for the terms “chatgpt” or the similarly common “chat gpt”, and then aggregated total counts and unique user counts by zip code. The ZIP code linkage is provided via a proprietary location inference engine that, though still subject to error, uses contextual and historical information to improve upon accuracy over standard reverse IP lookup databases. We linked ZIP codes with counties using the HUD-USPS ZIP Code crosswalk files [29]. For any ZIP code linked with multiple counties, we allocate queries to counties proportionally to the ratio of all addresses in the ZIP-county overlap to the total number of all addresses in the ZIPcode. Finally, we suppress data from county-query cells with fewer than 50 unique users to preserve anonymity. We also aggregate counts of overall and ChatGPT queries by state and month; at these levels of aggregation, all cells meet the threshold for inclusion. We use Bing because of its broad coverage across the United States as well as our ability to examine finer spatial geographies than those available using comparable, publicly available datasets, following Suh et al. [30]. However, as a robustness check, we also run all analyses using the finest available geographies (metropolitan areas) from publicly available Google Trends query data [31].

Finally, we obtain county-level socioeconomic, demographic, and industry makeup from the 5-year American Community Survey for 2016-2020 using the National Historical Geographic Information System [32]. We use these data to construct socioeconomic variables including: percent college educated, calculated as the fraction of the population over 25 with a college education or higher; percent rural, or the fraction of the population living in a rural area; median household income in the past 12 months; and the unemployment rate, or the fraction of the civilian labor force 16 years and over that is unemployed. To characterize demographic makeup, we first calculate Hispanic or Latino as a fraction of the total population; for the other three demographic groups (White, Black, and Asian) we calculate the percent identifying with that group only as a fraction of the total population. Finally, we calculate industry makeup as the percent of all people in the adult employed civilian population who are employed in technology, arts, finance, or service sector jobs.

2.2 Analyses

We first map logged rates of search for ChatGPT by state. At this level of aggregation, we are also able to evaluate trends over time, examining rates over each month of observation. Mapping is conducted using the `sf` [33] and `usmap` [34] packages in R 4.1.1 [35].

We next map county-level rates, testing for spatial autocorrelation using the Moran’s I statistic [36]. That is, given n counties, we calculate

$$I = \frac{n}{W} \frac{\sum_{i=1}^n \sum_{j=1}^n (x_i - \bar{x})(x_j - \bar{x})}{\sum_{i=1}^n (x_i - \bar{x})^2} \quad (1)$$

where x_i is the rate of search for ChatGPT in county i , x_j is the corresponding value for county j , and $\bar{x}$ is the overall mean across counties. We set $w_{i,j}$ as the spatial weight between two counties i and j , using queen’s contiguity weights where $w_{i,j} = 1$

if counties i and j share a border and zero otherwise.³ W is the aggregate of the spatial weights, $W = \sum_{i=1}^n \sum_{j=1}^n w_{i,j}$. The Moran's I statistic is normalized so that values fall between -1 and 1, with positive values indicating that neighboring features tend to be both smaller or both larger than the mean (clustering) and negative values indicating that features higher than the mean tend to be located next to features with low scores (dispersal). We can use this statistic to test, using a one-sided test at the 5% level, whether there is more spatial clustering of observed values relative to what would be expected if values were distributed randomly.

Given evidence of global spatial clustering, we examine local clustering patterns. We calculate the Getis-Ord G^* statistic [37] as follows:

$$G_i^* = \frac{\sum_j^n w_{i,j} x_j - \bar{x} \sum_j^n w_{i,j}}{S \sqrt{\frac{n \sum_{j=1}^n w_{i,j}^2 - (\sum_{j=1}^n w_{i,j})^2}{n-1}}} \quad (2)$$

That is, for county of interest i , $w_{i,j}$ is the spatial weight for county i and county j ⁴, n is again the total number of counties, $\bar{x}$ is the overall average, x_j is the outcome value for county j , and

$$S = \sqrt{\frac{\sum_{j=1}^n x_j^2}{n} - \bar{x}^2} \quad (3)$$

The result is a z-score, which can be used to test the null hypothesis that neighboring counties have rates no more similar to one another than would be expected by random change. In contrast with the Moran's I, however, which is a global score across all counties, we are able to calculate the G^* statistic for each county individually. We can thus map results using a two-sided 5% cutoff, identifying hotspots as counties where the G^* statistic > 1.96 and coldspots as those counties where the G^* statistic < -1.96 . We conduct both our global and local clustering analyses in R using the `spdep` package [38].

Next, we examine raw associations between rates of search for ChatGPT and county-level socioeconomic, demographic, and industry makeup. Because county-level correlates have skewed and non-normal distributions, we examine logged rates of search for ChatGPT in comparison with counties' percentile ranks for each variable. We further calculate medians and interquartile ranges (IQRs) of search rates in each percentile rank bin. We calculate these estimates, weighted by population, in R using the `HMisc` package [39].

Finally, we fit a series of negative binomial models to predict the rate of searches for ChatGPT. We use a multilevel specification, allowing a random effect by state to account for the spatial autocorrelation in our data. Likelihood ratio tests confirm a significant improvement in fit from the use of a multilevel specification, as well as significant improvements from the use of negative binomial rather than simpler poisson models to account for overdispersion; we also observe large reductions in AIC and BIC values for the multilevel negative binomial specification in comparison with simpler approaches.

³We exclude counties with no neighbors or with no neighbors with unsuppressed data from our calculation.

⁴We set $w_{i,j} = 1$ if county j is a contiguous neighbor of county i or if $j = i$ and 0 otherwise.

Our final models have the following form

$$\begin{aligned}\log(\text{SearchesChatGPT}_{ij}) &= X_{ij}\beta + u_j + \text{offset}(\log(\text{SearchesOverall}_{ij})) \\ \text{SearchesChatGPT}_{ij} &\sim \text{NegativeBinomial}(\mu_{ij}, \theta)\end{aligned}\tag{4}$$

Where we model the count of searches, $\text{SearchesChatGPT}_{ij}$ for county i in state j , as a function of county-level covariations X_{ij} and a state-level random effect u_j , with the total count of searches at the county level, $\text{SearchesOverall}_{ij}$, included as an offset. We fit models with the sets of socioeconomic, demographic, and industry makeup variables separately; we then fit a full specification including all covariates. We standardize and scale covariates both to stabilize the model fit and to facilitate comparison across coefficients. After observing large changes in the full model in comparison with the separate specifications—consistent with confounding—we iteratively remove individual regressors to evaluate the change across other covariates associated with each variable’s exclusion. Finally, we assess the fit of the final model by mapping the predicted and residual values and again using the Moran’s I statistic to test for residual spatial autocorrelation. Models are fitted using the `glmmTMB` package [40], with residuals assessed using the `DHARMA` package [41], again using R.

To test the robustness of our results to the limitations of our search data set with respect to coverage and data suppression, we also re-run all of our analyses with the Google trends data set. Although these data are the gold standard for research using internet search data given their disproportionate coverage relative to all search queries [42], the finest available level of disaggregation is at the metro level. This limits our ability to examine fine-grained differences between percentile groups with respect to economic and demographic correlates; nevertheless, we are able to reproduce our main analyses at this level as a means of testing the robustness of our results to limitations of the choice of dataset.

3 Results

Over the six months of observation, we observe a median rate of approximately 6.2 searches for ChatGPT per 10,000 total searches (IQR 4.5 - 7.7). Figure 1 shows rates of search for ChatGPT by state. Rates of search are highest in Washington and California and lowest in states in the Gulf (Louisiana, Alabama, Mississippi) and Appalachia (West Virginia, Kentucky and Tennessee), as well as New Mexico and South Dakota.

These spatial differences emerge early and persist throughout the observation period. Figure 2 shows state-level search rates disaggregated by month. The west-coast states rank in the top 10% of all state-period observations beginning in February, and remain among the highest-ranked regions through May. Although rates of search for ChatGPT do increase in Gulf and Appalachian states over this period, these states persistently rank in the bottom 10 states with respect to interest over each month of the six-month period of observation.⁵

⁵The remaining two places in the top five with respect to search rates are the District of Columbia and Utah.

Fig. 1 Rates of Search for ChatGPT by State. Colors indicate the fraction of all searches that included reference to ChatGPT in each state-period observation across the first six months since the initial public release of the generative artificial intelligence tool.

Examining rates of search at the county level, we observe a moderate but statistically significant level of spatial clustering (Moran's $I = 0.26$, $p < 0.001$). This suggests that counties with higher rates of search for ChatGPT are likely to be geographically clustered. The estimate is robust to the exclusion of values from outlier counties: examining winsorized rather than raw values, we see a similar result (Moran's $I = 0.27$, $p < 0.001$).

Figure 3 shows clusters of neighboring counties with more elevated rates of search (hotspots) or lower rates of search (coldspots) than would be expected if rates were distributed randomly; we note that the hotspots coincide with major metropolitan areas in the West (Seattle, Portland, San Francisco and Silicon Valley, Los Angeles); in the Mountain West (Salt Lake City and Denver); on the East coast (Boston, New York City to Philadelphia, and Washington D.C); and in Texas (Houston, Austin, and Dallas); as well as Atlanta and Minneapolis. Coldspots are predominantly observed in more rural areas including the northern reaches of Wisconsin and Michigan, and in West Virginia, South Carolina, and Georgia. We also observe notable urban coldspots surrounding Memphis, TN, Baton Rouge, LA, and Jackson, MS. No coldspots are observed in the three West Coast states.

Fig. 2 Average monthly rates of searches for ChatGPT by state. West coast states with the highest rates of search are highlighted in green; states with persistently low rates of search are highlighted in purple (Louisiana, Alabama, Mississippi) and blue (Tennessee, West Virginia, Kentucky).

We next examine the associations between rates of search for chatGPT and socioeconomic, demographic, and industry makeup respectively. In Figure 4, we see a strong positive association between the fraction college-educated or median incomes and logged rates of search. In particular, in counties in the top 10% with respect to the fraction of residents who are college-educated, population-weighted median rates of search are approximately 7.7 per 10k searches (IQR 6.8 - 10.4) versus 2.8 (IQR 2.4-3.3) for the bottom 10% of counties. By contrast, more rural counties have relatively lower rates of search (3.0, IQR 2.4-3.9 for the bottom 10%) in comparison with less rural counties (7.1, IQR 6.0 - 8.7 for the top 10%).

Figure 5 offers evidence of an inverse association with the fraction of the population that is non-Hispanic White, with counties with the highest rates of search characterized by proportionally large Hispanic or Latino and Asian populations. The association with the fraction Asian is particularly strong: counties in the top percentiles with respect to fraction Asian have rates of search greater than 10 per 10k searches (IQR 7.8 - 14.8) versus 2.6 (2.2 - 3.3), 5.8 (3.7 - 5.9), and 5.6 (4.1 - 7.3) for the top percentiles of White, Black, and Hispanic or Latino populations, respectively. These associations should be interpreted with caution, as they are likely confounded by the strong associations of region or urbanicity and ChatGPT search rates.

Finally, Figure 6 examines the association of search rates for ChatGPT with the fraction of jobs in different sectors. As might be expected, there is a strong and increasing association between the percentile of fraction tech sector jobs in a given county and its rates of search for ChatGPT. Counties in the lowest ten percentiles of arts sector jobs also have lower rates of search (3.0, IQR 2.5 - 3.7) in comparison to other

Fig. 3 Detection of hot- and coldspots with the Getis-Ord G^* Statistic. Red indicates the presence of a statistically significant hotspot (Getis-Ord $G^* > 1.96$) and blue indicates the presence of a statistically significant coldspot (Getis-Ord $G^* < -1.96$).

counties (6.3, 4.6 - 7.8), though the trend flattens across the upper quantiles. With respect to finance sector jobs, we observe an increasing trend, though the gradient is not as steep as that observed for the tech sector. No similar gradient is observed for service sector jobs.

Table 1 shows rate ratios from adjusted models with state-level random effects. We first examine the adjusted associations between socioeconomic factors and rates of search for ChatGPT (columns 1 and 2). We continue to see negative associations of fraction rural and rates of search for ChatGPT after adjusting for median income (Column 1); however, after including education as a covariate, the fraction rural is no longer statistically significant and median income is actually inversely associated with rates of search for ChatGPT (Column 2).

We next examine adjusted associations with demographic makeup. Table 1 column 3 shows a strong positive association with the fraction Asian—a county that has 1SD higher fraction Asian would have approximately 1.3 times the rate of search for ChatGPT of a comparable county in the same state with the same Black and Hispanic fractions (implying a reduction in fraction White, which is excluded). This association remains positive and significant, though it is attenuated, after the inclusion of education as a covariate (Column 4). Notably, there is a significant and negative association with the fraction Black in single-level models as well as in robustness checks

Fig. 4 Searches for ChatGPT in relation to socioeconomic makeup. Blue points indicate raw observations; black points are medians and 75% inter-quartile ranges. Observations and estimates are weighted by county population.

Fig. 5 Searches for ChatGPT in relation to demographic makeup. Blue points indicate raw observations; black points are medians and 75% inter-quartile ranges. Observations and estimates are weighted by county population.

with Google Trends data (Table A1), but this association is no longer significant in the main specifications after the inclusion of state-level random effects.

Columns 5 and 6 offer evidence that education confounds the association of industry makeup and search rates. In column 5, we observe a significant and positive effect of fraction jobs in the tech sector, a smaller but still significant and positive association with arts sector jobs, and a small but significant inverse association with the share of jobs in the service industry. However, after adjusting for fraction college educated,

Fig. 6 Searches for ChatGPT in relation to industry makeup. Blue points indicate raw observations; black points are medians and 75% inter-quartile ranges. Observations and estimates are weighted by county population.

associations are attenuated or even inverted (Column 6). Using the Google Trends data, the fraction of jobs in the technology sector has a large and significant positive association with rates of search, but the association is attenuated with the inclusion of education (Table A1 Columns 5-6).

Finally, fully adjusted models follow a similar pattern. When education is excluded, we see positive associations with median income, fraction asian, and arts share, and negative associations with fraction rural and fraction Hispanic. After accounting for education, we continue to see positive associations with fraction Asian and fraction Hispanic, but associations with median income, tech share, and finance share are negative and other associations are no longer significant. Notably, the association with education is both significant and large: holding other factors constant, a county with 1 SD higher fraction college educated would have approximately 1.4 times more searches for ChatGPT as a fraction of total searches. This result is also robust to the use of Google Trends rather than Bing Search data (Table A1 Column 8).

Residual tests show that observations deviate significantly from the distribution expected given the model, but we see no significant evidence of over- or underdispersion or of outliers. Spatial autocorrelation in the residuals is attenuated relative to that observed for the raw values (Moran's $I = 0.18$) though still statistically significant ($p < 0.001$).

4 Discussion

This study characterizes the digital divide with respect to knowledge of generative AI in the United States. Examining county- and state-level rates of search for a popular new technology, ChatGPT, we make three observations. First, we observe a strong geographic divide, with the highest rates of search on the West coast and lower rates of search along the Gulf Coast through Appalachia. Second, we show how spatial

	Model 1	Model 2	Model 3	Model 4	Model 5	Model 6	Model 7	Model 8
College Educated		1.39*** 0.02		1.31*** 0.01		1.44*** 0.02		1.43*** 0.02

Table 1 Results are exponentiated coefficients and standard errors from multilevel negative binomial models. Models predict the count of searches for ChatGPT, with the total count of searches by county included as an offset. N = 2,397 counties across 51 states. *** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$

differences are consistent with socioeconomic divides. In particular, we observe that counties with the highest rates of search for ChatGPT are relatively more urbanized, higher income, more educated, more Asian, and have more technology jobs relative to other counties. Finally, education emerges as the strongest predictor of interest in fully adjusted models.

These findings offer evidence of a new, emerging set of disparities in generative AI access and use that follows very similar patterns to the more general digital divide in access and use of internet tooling [4, 6, 43]. It is important to note, however, that the strong observed associations with area-level racial makeup, urbanicity, income, and industry makeup are confounded by education, which emerges as the strongest positive predictor of rates of search for ChatGPT. This finding is consistent with prior research, which finds that education is among the strongest predictors of differences in internet use [44–47] and, in one case [45] documents a similar attenuation of other associations after accounting for education. Our study is novel, however, in documenting this association for emerging generative AI tooling as well as in highlighting the spatial as well as socioeconomic patterning in observed differences.

Our study is subject to several limitations. First, our data are from a major search provider. While this affords us the benefit of scale, with a large enough sample size that we can examine finer-grained geographic patterns (counties) relative to those available using other data sources, the data may be subject to selection bias due to the set of people who choose to use the particular search provider from which we obtain our data. Moreover, to protect the privacy of search users, data are suppressed for a relatively large fraction of counties. To assess the sensitivity of our results to these challenges, we revisit all analysis with data from the google trends database, a search database with the highest rates of coverage nationally [42], using data at the smallest available spatial unit—metropolitan areas—without data suppression. We obtain similar results to those described in our primary analyses.

Second, we recognize that search is a crude proxy for actual usage, and one that may be subject to confounding over time if users use search only for initial discovery and then gradually select out of the data set. We mitigate this challenge by examining a completely novel tool (ChatGPT), and by limiting our analyses to only the first six months after it became publicly available—a period for which searches are among the best available early indicators of interest. Moreover, we note that the confounding problem would lead us to underestimate disparities as users in the highest-interest areas selected out of the dataset while more people in other areas continued to rely on search for initial discovery; similarly, because we examine differences in *rates* of search over time, our results describe only differences in use (second-level divides) and are likely exacerbated by fundamental differences in internet access (the first-level divide). The differences we observe should thus be treated as a lower bound on actual disparities. As users increasingly access these tools directly rather than relying on internet search discovery, there is a need for further research that examines actual rates of usage either using the relevant (proprietary) usage datasets or individual-level surveys.

Third, we examine spatially aggregated outcomes that may be subject to the modifiable areal unit problem in which aggregate patterns may not correspond directly with individual-level relationships [48]. However, our findings are consistent with early individual-level studies. For example, in a Pew Research poll conducted in March of 2023—four months after the initial release of ChatGPT—adults with postgraduate degrees were almost twice as likely to have heard about ChatGPT in comparison with adults with high school degrees or less, and Asian adults had notably higher awareness of the tool in comparison with Black, Hispanic, or White adults [49].

Finally, our findings are not causally identified and focus exclusively on a Global North context. To our knowledge, however, this study is the first national-scale characterization of geographic differences in uptake of tooling with large potential impacts on productivity and performance [17–19, 21–24]. The stylized facts presented here support further research to better characterize and isolate relevant processes of social and spatial diffusion producing these aggregate patterns. Moreover, regardless of the underlying processes, the stark differences we observe across places should be of serious concern to policymakers given the evidence of strong economic advantages for places where novel technologies are adopted early [50].

This study offers an important early warning of an emerging digital divide in generative AI, the likely next general-purpose technology [1]. While these findings are not surprising given their consistency with prior digital divides [43], generative AI has unique characteristics that *should* make possible a leapfrogging rather than lagging of the most disadvantaged places with respect to its use. For example, multi-lingual capabilities make these tools more widely accessible to non-english speakers in comparison with existing digital tooling [51], though early research shows that these elements must be incorporated early in design with active effort required to mitigate differences in cost and quality between high- and low-resource languages [52]. Similarly, the multimodality of advanced models shows promise to support general-purpose interfaces that make traditional tooling accessible by voice, text, or other diverse forms of interaction [53]. While these characteristics have the potential to enable broadly accessible tooling, our research suggests that more active intervention may be necessary. Mitigating divides in computer and internet access continues to require mass campaigns, with workshops and free resources at public libraries and active interventions across schools [54]; a similar effort may be called for in the context of the new generative AI divide.

Acknowledgments. The authors are grateful for comments and suggestions from Jina Suh, Jake Hofman, Dan Goldstein, Sonia Jaffe, Daricia Wilkinson, and Siddharth Suri. This work was also improved by feedback from Scott Page and Seth Spielman.

Appendix A Comparison with Google Trends

Fig. A1 Map of state-level searches for ChatGPT using the Google Trends index. The inset shows that the Google Trends Index is highly correlated with the rates of search calculated from Bing search data (Pearson's Correlation = 0.86)

Fig. A2 Searches for ChatGPT in relation to socioeconomic makeup. Blue points indicate values of the google search trends index; black points are medians and 75% inter-quartile ranges of metro-level ACS data, manually linked to the closest designated market area. Observations and estimates are weighted by metro area population.

Fig. A3 Searches for ChatGPT in relation to demographic makeup. Blue points indicate values of the google search trends index; black points are medians and 75% inter-quartile ranges of metro-level ACS data, manually linked to the closest designated market area. Observations and estimates are weighted by metro area population.
