Abstract

arXiv:2404.17008v1 [q-fin.RM] 25 Apr 2024

A novel procedure is presented for finding the true but latent endpoints within the repayment histories of individual loans. The monthly observations beyond these true endpoints are false, largely due to operational failures that delay account closure, thereby corrupting some loans in the dataset with 'false' observations. Detecting these false observations is difficult at scale since each affected loan history might have a different sequence of zero (or very small) month-end balances that persist towards the end. Identifying these trails of diminutive balances would require an exact definition of a "small balance", which can be found using our so-called *TruEnd*-procedure. We demonstrate this procedure and isolate the ideal small-balance definition using residential mortgages from a large South African bank. Evidently, corrupted loans are remarkably prevalent and have excess histories that are surprisingly long, which ruin the timing of certain risk events and compromise any subsequent time-to-event model such as survival analysis. Excess histories can be discarded using the ideal small-balance definition, which demonstrably improves the accuracy of both the predicted timing and severity of risk events, without materially impacting the monetary value of the portfolio. The resulting estimates of credit losses are lower and less biased, which augurs well for raising accurate credit impairments under the IFRS 9 accounting standard. Our work therefore addresses a pernicious data error, which highlights the pivotal role of data preparation in producing credible forecasts of credit risk.

1 Introduction

Hailing from the biostatistical literature, survival analysis is a powerful class of techniques for modelling any time-to-event data across many disciplines; see Singer and Willett (1993), Kleinbaum and Klein (2012), Kartsonaki (2016), and Schober and Vetter (2018). Survival analysis examines the length of time until reaching some well-defined endpoint, should the event occur. By implication, survival models do not only predict the probability of an event occurring, but also its timing. In quantitative finance, Narain (1992) originally demonstrated that a loan's probability of default (or PD) is a function of time. Banasik et al. (1999) extended this work by developing Cox proportional hazards (PH) regression models using UK loans data, which compared favourably to cross-sectional logistic regression (LR) models. Another notable extension is Stepanova and Thomas (2002), who investigated Harrel's correlation method for finding time-dependent covariates, whereafter they compared various types of model diagnostics within the credit domain, e.g., Cox-Snell and Schoenfeld residuals. The authors also demonstrated a (more dynamic) time-sensitive binning procedure for Cox PH-models, which improves upon the otherwise static weight of evidence (WOE) transform; itself commonly used within LR-models, as explained in Thomas (2009, §1.5). In predicting the PD, other authors demonstrated that including time-dependent variables (especially macroeconomic variables such as interest/policy rates) into a Cox PH-model can improve the model fit and/or its predictive power, typically beyond that of a comparable LR-model; see Bellotti and Crook (2009), Crook and Bellotti (2010), Bellotti and Crook (2013), and Bellotti and Crook (2014). Lastly, Dirick et al. (2017) compared various types of default survival models, including Cox PH with/without spline functions, mixture cure models, and accelerated failure time models. Though certainly not exhaustive, this growing body of literature augurs well for the increasing use of survival analysis in predicting both the prevalence and timing of default.

The advent of the IFRS 9 accounting standard from IASB (2014) has generated greater impetus for more dynamic modelling such as survival analysis. In particular, IFRS 9 requires that a financial asset's value be comprehensively and regularly adjusted, based on the asset's expected credit loss (ECL) over its lifetime; see Novotny-Farkas (2016) and Skoglund (2017). This ECL-estimation depends not only on the PD as risk parameter, but also on the Loss Given Default (LGD), i.e., the fraction of the loan balance that was eventually lost, as measured at the point of default. However, this LGD-parameter is notoriously difficult to model due to the bimodality and asymmetry of the realised LGD-density, as discussed in Schuermann (2004), Calabrese and Zenga (2010), and Baesens et al. (2016, pp. 271-314). These statistical complications arise naturally since the reality of resolving a defaulted loan can be complex, highly uncertain, lengthy, sensitive to the macroeconomic cycle, and even vary by jurisdiction; see Schuermann (2004), Finlay (2010, pp. 11-13), Gürtler and Hibbeln (2013), and Botha (2021, pp. 23-26). Ultimately, it takes time to resolve a so-called *default spell* (or episode) that may end in write-off, whereupon all cash flows are discounted back to the default point in calculating the associated non-zero credit loss. Some default spells may resolve into a so-called *cured* outcome (with a zero-valued loss), while more recent spells are likely to be right-censored since collectors are still pursuing the resolution of these spells. This framing suggests that survival analysis is a natural choice for modelling the LGD-parameter, particularly in predicting the time to either write-off or cure. In fact, a few studies have already explored some aspects hereof, though this topic is certainly still evolving; see Witzany et al. (2012), Zhang and Thomas (2012), Wood and Powell (2017), Joubert et al. (2018), and Larney et al. (2023).

Despite methodological soundness, the inappropriate parametrisation of a survival model will inadvertently invite so-called *model risk*. In particular, De Jongh et al. (2017) define model risk as the adverse exposure resulting from a model that: 1) is conceptually flawed; 2) provides inaccurate output or predictions; 3) is used inappropriately;

or 4) has a flawed implementation. As such, a survival model that is trained on inaccurate or flawed data will render predictions that can disagree with reality quite substantially, thereby ruining subsequent decision-making as well as compromising the ECL-estimates for a bank's loss provision. Proper data preparation is itself paramount to producing any reliable statistical model, which can include many exercises such as data cleaning, feature engineering, data fusion, outlier detection, and missing value treatments, as discussed in James et al. (2013). Moreover, the UK regulator has recently published five broad principles in managing model risk across banks, given the growing prevalence of using model outputs within decision-making; see PRA (2023a) and PRA (2023b). When using data during modelling, Principles 3.2 and 4.3 from PRA (2023b) call for verifying whether this data represents reality, as well as for assuring the quality and reliability of the same data. The South African regulator decrees similarly in Guidance Note 9 from SARB (2022) that data should be both complete and truly relevant when using it for developing credit risk models. By pronouncing so pervasively on model risk, these regulators have only further affirmed the obvious importance of training models from data that is largely error-free.

One such significant data error is the potential for loan accounts with a series of zero-valued (or exceedingly small) month-end balances that trail the end of their observed repayment histories, i.e., *trailing zero-valued balances* (TZB). These TZB-cases arise due to historical issues when migrating data between disparate computer systems, as well as operational failures in managing loan accounts that ultimately compromise their timely closure. The actual closure dates of some loan accounts can therefore precede the last dates observed from data, thereby resulting in excess monthly records (or 'false' history) between these two dates; see Fig. 1. This excess credit history renders the observed endpoint as ambiguous and inconsistent that, as explained in Schober and Vetter (2018), will bias any subsequent survival estimates of the 'true' time-to-write-off; itself latent and unobservable. Moreover, the realised LGD-value becomes upwardly biased since the resolution period over which cash flows are discounted is too long. While a larger LGD-value may prudently reflect operational failures within the bank, the resulting bias disagrees with the true credit risk profile of the affected loan. As such, the subsequent ECL-estimate is higher than strictly necessary, and this premium poses as an opportunity cost for ignoring these erroneous TZB-cases.

Fig. 1. Illustrating the 'healthy' non-TZB period (green-shaded) and the 'unhealthy' TZB-period (red-shaded) over the lifetime of an affected loan. The exact cut-off point between either period type is uncertain, as represented by the magnifying glass.

The obvious remedy is to remove the TZB-affected part from a loan's history, i.e., move the observed but false endpoint earlier, at least to the first instance of a zero-valued (or suitably small) balance. The excess history beyond this true but latent endpoint can then be discarded, not unlike a surgeon excising a malignant tumour. However, manually finding this latent endpoint for each affected loan would quickly become challenging, especially given the typically large credit datasets in retail lending; often containing hundreds of thousands of loans over multiple decades. Moreover, these diminutive balances that trail the ends of credit histories can vary across accounts and can therefore defy definition of the endpoint itself. Isolating such a trail will naturally depend on the exact definition of a "small or immaterial balance", beyond which the remaining history is deemed as practically zero-valued and therefore best deleted. This small-balance definition will itself inform the overall prevalence of TZB-cases, and quite significantly so, as we will demonstrate later. Such definitions that are too small will incorrectly sequester only a portion of account lifetimes into supposed TZB-histories, which may very well be too short; thereby leaving behind 'cancerous' stumps of data while failing to solve the problem. Conversely, small-balance definitions that are too large will excessively elongate TZB-histories and inflate their prevalence; ultimately cutting away into otherwise credible data (not unlike an overzealous surgeon), thereby compromising the subsequent modelling. Therefore, the question becomes this: how small exactly is a "small balance" in finding the true endpoint, though without discarding 'healthy' history?

The aforementioned question clearly suggests an optimisation framework for finding the starting point of the 'cancerous' TZB-period, such that this true endpoint is neither too early (thereby cutting away credible history), nor too late (thereby retaining false history). Optimisation itself, as explained in Boyd and Vandenberghe (2004), is the process of finding the best solution to a quantitative problem while meeting certain constraints. In our context, the number of such possible solutions is infinite since the size of a small-balance definition can theoretically assume any non-negative currency amount. Evaluating any solution therefore requires an appropriate *objective function* f that can simultaneously reward or penalise various aspects of such a solution in finding the 'true' endpoint. Accordingly, we contribute such an f and a broader optimisation framework that systematically evaluates the costs/benefits of any small-balance definition in isolating the latent TZB-period. For a given loan portfolio, our so-called *TruEnd-procedure* therefore finds the *best* small-balance definition or 'policy', denoted as b^* . Any latent TZB-periods within a given portfolio can then be identified and duly discarded using this b^* -policy, thereby correcting this data error. Doing so would intuitively improve the predicted timing of risk events (such as write-off or settlement) when using this corrected data in training survival models. Accordingly, we believe our work demonstrates the sound pursuit of innovation in modelling towards alleviating model risk and improving the accuracy of ECL-estimates under IFRS 9.

In section 2, we present the TruEnd-procedure and motivate its design using a real-world case study. We calibrate and demonstrate this procedure in subsection 3.1 using residential mortgage data from the South African credit market. This demonstration culminates in selecting the best b^* -policy from the ensuing optimisation results, having applied the TruEnd-procedure on a few subsamples of data in showing the overall robustness of optima. In subsection 3.2, we investigate the impact of imposing this particular b^* -policy on the same data, thereby discarding the resulting TZB-periods across all duly affected accounts. In this impact study, two survival models are compared in predicting the time-to-write-off, respectively derived from the original untreated data vs a TruEnd-treated variant thereof without TZB-periods. The TruEnd-procedure is implemented and demonstrated using the R-programming language; see our source code in Botha and Bester (2024).

2 A method for finding trailing zero-valued balances (TZB)

Consider a portfolio of *N* loans, indexed using i = 1, ..., N, where each loan account *i* is observed over time *t* up to its observed (but possibly false) lifetime T_i , which is measured in calendar months. By definition, loan *i* has a TZB-period of minimum length $l \ge 1$ month when the month-end balances during such a period are persistently zero or close to zero. Let $B_i \ge 0$ denote the account's currency balance (denominated in ZAR), which is a random variable that is sequentially measured at month-end times $t = 1, ..., T_i$ for loan *i*. This yields the column vector $B_i = [B_{i1}, B_{i2}, ..., B_{iT_i}]^T$, also represented as the time series $\{B_{it}\}_{t=1}^{T_i}$. Given an affected account *i*, its TZB-period has a starting point $t_z(i) \ge 1$ whereafter most of the remaining observed balances $\{B_{it}\}_{t\ge t_z(i)}$ are noticeably lower when compared to the preceding balances $\{B_{it}\}_{t< t_z(i)}$ prior to the TZB-period.

In finding this $t_z(i)$ -point for an affected account *i*, one can examine the elements of B_i ; itself effectively becoming a control variable within a broader optimisation context. More formally, let $b \ge 0$ be a constant (or threshold) respective to the domain of B_i . Then, a TZB-account is identified whenever it has a period $t = t_z(i), \ldots, T_i$ such that $B_{it} \le b$ at every point *t* during this period. The "true end" of such a TZB-account therefore occurs at time $t_z(i) - 1$ whereat the last small balance can credibly occur, which is also $\le b$ by definition. As such, let S_T be the subset of all TZB-accounts within a portfolio, which is defined for a particular *b*-value and the so-called *control matrix* $B = [B_1, \ldots, B_N]$ as

$$\mathcal{S}_T\left(\boldsymbol{B},b\right) = \left\{i \mid \exists t' \in [1,T_i] : B_{it} \le b \quad \text{for } t = t', \dots, T_i \quad \text{s.t} \quad T_i - t' \ge l\right\}.$$
(1)

Accordingly, the $t_z(i)$ -point is the earliest moment (t' + 1) of such a TZB-period, barring the last small balance that can credibly occur at t' (hence the '+1'-term), and is given by the procedure

$$T_{z}(\boldsymbol{B}_{i},b): \quad t_{z}(i) = (t'+1): B_{it} \le b \quad \text{for } t = t', \dots, T_{i} \quad \text{s.t} \quad T_{i} - t' \ge l \quad \forall i \in \mathcal{S}_{T}(\boldsymbol{B},b) .$$
(2)

For illustration purposes, let Z_{it} (B_{it} , b) $\in \{0, 1\}$ be a Boolean-valued decision function that indicates an element's membership to a TZB-period at t, defined for any loan i as

$$Z_{it}(B_{it},b) = \begin{cases} 1 & \text{if } B_{it} \le b & \text{for } t = T_z(\boldsymbol{b}_i, b), \dots, T_i \\ 0 & \text{otherwise} \end{cases}$$
(3)

Table 1: Finding the TZB-start point t_z for a single real-world account *i* by evaluating $T_z(B_i, b)$ from Eq. 2 against b = 500 using B_i as control. Membership to a TZB-period is indicated over time *t* using $Z_t(B_{it}, b)$ from Eq. 3. The green-shaded row is the account's true end at time $t_z(i) - 1$, while the orange-shaded rows constitute the TZB-period, marked for deletion. Given $t_z = 62$, the measures $M_1(t_z)$ and $M_2(t_z, 6)$ from Eqs. (4)–(5) are estimated accordingly.

As an illustration, consider the credit history of a single real-world mortgage account *i* in Table 1, using the threshold *b* respective to the domain of B_i . Evidently, the loan balance decreased substantially to $B_{it} = 156.47$

at the time of early settlement t = 61, at which point the credit history should have logically stopped but did not. Using b = 500, the TZB-indicator $Z_{it}(B_{it}, b)$ flags the start of the TZB-period at $t_z = 62$, thereby implying that the account's "true end" is at t = 61. Moreover, consider the mean balance across the preceding 6-month non-TZB period $t = 56, \ldots, 61$ and compare against that of the supposed TZB-period thereafter. The substantial difference in the respective means (6,053.66 vs. 161.36) corroborates an otherwise clear split in the credit balances, as manifested when implicitly choosing t_z by explicitly choosing b.

A manual evaluation of individual $t_z(i)$ -points across many affected loans $i \in S_T(B, b)$ will quickly become cumbersome without some automation. However, we can formalise the use of the arithmetic mean as a tool for evaluating any particular $t_z(i)$ -value of loan i; and indeed, for evaluating a chosen b-value as the portfolio-wide TZB-threshold. This idea exploits the mean's known weakness to outliers, particularly those B_{it} -values close to zero within a supposed TZB-period. As such, consider the measure

$$M_1(t_z) = \mathbb{E}_t \left[\boldsymbol{B}_i \right] \approx \frac{1}{T_i - t_z} \sum_t B_{it} \quad \text{for } t = t_z, \dots, T_i \quad \text{s.t.} \quad T_i - t_z \ge l \,, \tag{4}$$

where M_1 is evaluated across the account's TZB-period given some t_z -value; i.e., M_1 is the affected account's mean TZB-balance. Now consider the counterweight measure

$$M_2(t_z,\tau) = \mathbb{E}_t \left[\boldsymbol{B}_i \right] \approx \frac{1}{\tau} \sum_t B_{it} \quad \text{for } t = (t_z - \tau - 1), \dots, (t_z - 1), \qquad (5)$$

where M_2 is estimated across the period (of specifiable length $\tau \ge 1$) that immediately precedes the TZB-period; i.e., M_2 is the affected account's non-TZB mean balance. For non-TZB accounts, M_1 is undefined while M_2 simply becomes the mean balance of the last τ periods, i.e., t_z becomes T_i . In the interest of expediency, we simply set the length $\tau = 6$ months when calculating M_2 ; though this aspect can certainly be investigated in future work. More importantly, and since both measures M_1 and M_2 work in concert when varying t_z , the influence of either measure on the other can be tracked as follows. Given a $t_z(i)$ -value for a TZB-account *i*, let $\phi_i(t_z(i))$ denote the degree to which $M_1(t_z(i))$ is 'contaminated' by $M_2(t_z(i), \tau)$, defined simply as

$$\phi_i(t_z(i)) = \frac{M_1(t_z(i))}{M_1(t_z(i)) + M_2(t_z(i), \tau)} \quad \forall i \in \mathcal{S}_T(\boldsymbol{B}, b) .$$
(6)

In principle, the $M_1(t_z(i))$ -value should be relatively closer to zero than its sibling $M_2(t_z(i), \tau)$ -value, as demonstrated in Table 1 with $t_z(i) = 62$. Exceedingly greater $t_z(i)$ -values will produce lower $M_2(t_z(i), \tau)$ -values given the increasing influence of overly small B_{it} -values that should rightfully be discarded; thereby failing to isolate the 'true' starting point of TZB-history. On the other hand, excessively smaller $t_z(i)$ -values will wrongfully discard larger elements within B_i that denote otherwise credible history, thereby causing larger $M_1(t_z(i))$ -values. As an illustration, consider Fig. 2 that compares three hypothetical scenarios for M_1 and M_2 when choosing specific $t_z(i)$ -values, having used the same real-world account *i* from Table 1. In the ideal scenario, i.e., $t_z(i) = 62$, the preceding non-TZB period is perfectly separated from the subsequent TZB-period in that the latter contains noticeably smaller balances while the former does not. The "too early" scenario, i.e., $t_z(i) = 56$, shows the increasing 'contamination' in M_1 from including the obviously larger B_{it} -values within the TZB-period, specifically those six extra elements at $t = 56, \ldots, 61$ in Table 1. Accordingly, the M_1 -value increases substantially from its previous value under the ideal scenario. Conversely, the "too late" scenario, i.e., $t_z(i) = 66$, demonstrates the debilitating effect on the M_2 -value (itself decreasing substantially) when including minuscule B_{it} -values within the non-TZB period.

Functions - $M_1 -$ $M_2 -$ $f = M_2 - M_1$

Fig. 2. Illustrating three independent scenarios for M_1 and M_2 from Eqs. (4)–(5) in choosing the TZB-period's starting point $t_z(i)$: too early, ideal, and too late. The function $f = M_2(t_z(i), \tau) - M_1(t_z(i))$ illustrates the combined effect across all scenarios, shown in green.

Put differently, a delayed t_z -point will yield smaller $M_2(t_z, \tau)$ -values whereas a premature t_z -point will produce larger $M_1(t_z)$ -values. Both factors suggest that the ideal $t_z(i)$ -point for a TZB-account *i* can be found by maximising M_2 and minimising M_1 with respect to $t_z(i)$, which is itself controlled by varying *b* in $T_z(\mathbf{B}_i, b)$ from Eq. 2. Doing so implies maximising the loan-level objective function

$$l_i(t_z(i)) = w \cdot M_2(t_z(i), \tau) - M_1(t_z(i)) \quad \text{for } w \in [0, 1] \quad \text{and} \quad \forall \, i \in \mathcal{S}_T(B, b) \;.$$
(7)

The specifiable weight w in Eq. 7 is simply a mathematical expedient, which is motivated as follows. In isolating the TZB-account's "true end", any reasonable $t_z(i)$ -value also implies that the associated $M_2(t_z(i), \tau)$ -value will most likely be orders of magnitude larger than its sibling $M_1(t_z(i))$ -value. In turn, this discrepancy in domain sizes imply that the value of M_2 will remain relatively unchanged when subtracting that of M_1 , thereby rendering the latter as meaningless and ruining any subsequent optimisation. Accordingly, we introduce the specifiable weight w in Eq. 7 by which M_2 should be scaled towards matching the domain of M_1 , even if only approximately.

Finding a single portfolio-level threshold *b* implies evaluating Eq. 7 across many TZB-accounts. For a particular (\boldsymbol{B}, b)-tuple (or 'configuration'), the final portfolio-level objective function therefore becomes

$$f(\boldsymbol{B}, b) = \frac{1}{\bar{s}} \sum_{i} l_i (T_z(\boldsymbol{B}_i, b)) \quad \text{for } \forall i \in \mathcal{S}_T(\boldsymbol{B}, b) .$$
(8)

Since the size and composition of $S_T(B, b)$ will change in tandem with each (B, b)-configuration, the eventual optimisation will undoubtedly be affected by sampling variability. In mitigating this effect, the summation in Eq. 8 is therefore weighted by the sample standard deviation \bar{s} of the loan-level $l_i(T_z(B_i, b))$ -values within $S_T(B, b)$, which is the so-called TZB-set. More formally, let n_s denote the size (or cardinality) of $S_T(B, b)$, whereafter we estimate the mean \bar{l} of these $l_i(T_z(B_i, b))$ -values as

$$\bar{l} = \frac{1}{n_s} \sum_i l_i (T_z(\boldsymbol{B}_i, b)) \quad \text{for } \forall i \in \mathcal{S}_T(\boldsymbol{B}, b) .$$
(9)

Using \overline{l} , we then estimate the standard deviation \overline{s} as

$$\bar{s} = \sqrt{\frac{1}{n_s - 1} \sum_{i} \left(l_i \left(T_z(\boldsymbol{B}_i, b) \right) - \bar{l} \right)^2} \quad \text{for } \forall i \in \mathcal{S}_T(\boldsymbol{B}, b) .$$
(10)

Finally, the objective function f from Eq. 8 is iteratively calculated across a range of candidate thresholds $b \in S_b$ within the search space S_b , having used B as a particular control variable. Similar to the LROD-procedure from Botha et al. (2021) and Botha et al. (2022), the optimisation problem is effectively partitioned into smaller (B, b)-based 'sub-problems', where B can be any quantity used as a control and screened using b as a domain-specific threshold. Each resulting f(B, b)-value is stored centrally, thereby forming a curve across all pre-chosen b-values for each B, as demonstrated hypothetically in Fig. 3. The objective is then solved by searching for the 'best' threshold b^* such that $f(B, b^*) \ge f(B, b)$ across all candidate b-values within the search space S_b . This b^* -value is then used in finding the start times of TZB-periods $T_z(B_i, b^*)$ of each applicable account i within the underlying TZB-set $S_T(B, b^*)$, whereafter all monthly records are discarded for those times $T_z(B_i, b^*), \ldots, T_i$, given that these accounts actually ended at $T_z(B_i, b^*) - 1$. The TruEnd-procedure is therefore summarised into the following general steps:

- 1. Enumerate the search space S_b with thresholds b_1, b_2, \ldots respective to the domain of a control **B**;
- 2. Calculate $f(\boldsymbol{B}, b)$ for every (\boldsymbol{B}, b) -configuration within S_b , and collate into the collection $\{f(\boldsymbol{B}, b)\}$;
- 3. Search the collection $\{f(B, b)\}$ for the global maximum, i.e., the optimal threshold b^* is given for each **B** by

$$b^* = \underset{b \in \mathcal{S}_b}{\arg\max} \left\{ f(\boldsymbol{B}, b) \right\}; \tag{11}$$

4. Discard all records across times $t = T_z(\mathbf{B}_i, b^*), \dots, T_i$ for all applicable accounts $i \in S_T(\mathbf{B}, b^*)$.

3 Illustrating the TruEnd-procedure using residential mortgage data

The TruEnd-procedure is illustrated and tested using a rich portfolio of residential mortgages, provided by a large South African bank. This longitudinal dataset has monthly loan performance observations over time $t = 1, ..., T_i$ for account i = 1, ..., N with N = 653, 331 20-year mortgage accounts. These amortising mortgages were observed from January 2007 up to December 2022, during which new mortgages were continuously originated, thereby yielding 49,880,588 raw monthly observations of loan repayment performance. This data includes net cash flows (receipts), expected instalments, arrears balances, month-end balances, variable interest rates, original loan principals, re-advance amounts and times, write-off amounts and times, and early settlement amounts and times.

Fig. 3. Illustrating the TruEnd-procedure in finding the optimal threshold b^* that maximises the objective function f from Eq. 8. Given a control variable **B** (e.g., balance), the elements within this times series that are smaller than b^* can then be discarded, moving backwards.

Having prepared and cleaned this data extensively, we present the optimisation results in subsection 3.1 across a few subsamples of this data on which the TruEnd-procedure is applied. Then, we select the optimal threshold from these results and perform an impact study in subsection 3.2, wherein the dataset is compared before and after excluding the TZB-periods, as isolated using this optimal threshold.

3.1. Optimisation results using the datasets D_s and D_f

In applying the TruEnd-procedure on a loan portfolio of size N, a value must first be assigned to the weight $w \in [0, 1]$ in Eq. 7 for down-scaling the non-TZB mean M_2 , lest the effect of the (much smaller) TZB-mean M_1 becomes negligible. Consider that the contamination degree ϕ from Eq. 6 already represents the percentage-valued contribution of M_1 to the sum $M_1 + M_2$; an intuitive basis from which we can derive a *w*-value at the portfolio-level. For each candidate threshold *b*, we calculate the means of both M_1 and M_2 across all applicable accounts, denoted respectively as \overline{M}_1 and \overline{M}_2 . More formally, the *portfolio-level* contamination degree $\overline{\phi}(\boldsymbol{B}, b)$ is estimated for each $b \in S_b$ respective to a given control \boldsymbol{B} as

$$\bar{\phi}(\boldsymbol{B}, b) = \frac{\bar{M}_1(\boldsymbol{B}, b)}{\bar{M}_1(\boldsymbol{B}, b) + \bar{M}_2(\boldsymbol{B}, b)},$$
(12)

where its components are simply estimated as

$$\bar{M}_{1}(\boldsymbol{B}, b) = \frac{1}{n_{s}} \sum_{i \in S_{T}(\boldsymbol{B}, b)} M_{1}(T_{z}(\boldsymbol{B}_{i}, b)), \text{ and}$$

$$\bar{M}_{2}(\boldsymbol{B}, b) = \frac{1}{N} \left(\sum_{i \in S_{T}(\boldsymbol{B}, b)} M_{2}(T_{z}(\boldsymbol{B}_{i}, b), \tau) + \sum_{j \notin S_{T}(\boldsymbol{B}, b)} M_{2}(T_{j}, \tau) \right) \text{ for } \tau = 6 \text{ months}.$$

$$\int_{0.05\%} M_{1}(\boldsymbol{D}_{1}(\boldsymbol{A}_{1})) = \frac{1}{N} \left(\sum_{i \in S_{T}(\boldsymbol{B}, b)} M_{2}(T_{z}(\boldsymbol{B}_{i}, b), \tau) + \sum_{j \notin S_{T}(\boldsymbol{B}, b)} M_{2}(T_{j}, \tau) \right)$$

Fig. 4. Portfolio-level contamination degree $\bar{\phi}(B, b)$ from Eq. 12 across candidate thresholds *b* respective to account balances **B** as control. The midpoint is overlaid, which informs the *w*-value within the TruEnd-procedure.

Threshold (ZAR) b

We graph the contamination degree $\bar{\phi}(\boldsymbol{B}, b)$ in Fig. 4 across several candidate thresholds $b \in S_b$, where the search space is enumerated using expert judgement as

$$S_b = \{0; 10; 25; 50; 75; 100; 150; 200; 250; 300; 400; 500; 750; 1, 000; 1, 250; 1, 500; 1, 750; 2, 000; 2, 500; 3, 000; 4, 000; 5, 000; 7, 500; 10, 000\}.$$
 (13)

Evidently, the $\bar{\phi}(\boldsymbol{B}, b)$ -quantity appears to be a monotonically increasing function of *b*, and even somewhat linear. This result is intuitively sensible since $\bar{M}_1(\boldsymbol{B}, b)$ should increase in tandem with *b*, especially when denoting balances smaller than *b* as "practically zero-valued" towards identifying TZB-periods later. Then, we define the so-called *midpoint* across all contamination degrees as the average $\bar{\phi}(\boldsymbol{B}, b)$ -value between the lowest and highest of such degrees; i.e., $50\% \cdot \sum \bar{\phi}(\boldsymbol{B}, b)$ for the first and last *b*-values within S_b from Eq. 13. The resulting midpoint of 0.065% is then used as the *w*-value in Eq. 7, thereby calibrating the TruEnd-procedure towards this particular mortgage portfolio. This rather simplistic method for finding a *w*-value produces reasonable and intuitive optimisation results, as will be shown later. However, future research can most certainly improve upon this aspect of calibrating the TruEnd-procedure, as well as examine the impact of the chosen τ -value.

Given the extremely large sample sizes, we deliberately subsample the full dataset \mathcal{D}_f into a smaller set \mathcal{D}_s using clustered random sampling. This \mathcal{D}_s -set contains the entire repayment histories of only 10,000 mortgage accounts that were randomly selected, which effectively constitutes only 1.5% of all accounts within \mathcal{D}_f . The TruEnd-procedure can then be applied on both of these sets $\{\mathcal{D}_f; \mathcal{D}_s\}$, whereupon the resulting optima can be compared with respect to the influence of sample size. Such an analysis can help inspire confidence in the overall robustness of optima, or highlight instability related to overly small sample sizes. As a first step, we repeat the analysis shown in Fig. 4 by using the smaller \mathcal{D}_s with Eq. 12 in estimating the portfolio contamination degrees $\bar{\phi}(B, b)$. The resulting differences in the $\bar{\phi}(B, b)$ -values are almost indiscernible across all *b*-thresholds when using \mathcal{D}_s instead of \mathcal{D}_f . That said, the midpoint changed every so slightly from 0.065% (\mathcal{D}_f) to 0.064% (\mathcal{D}_s). These minute differences in $\bar{\phi}(B, b)$ -values already suggest some robustness against 'small' sample sizes; however, this result is highly dependent on the exact size of \mathcal{D}_s and random sampling.

We present the so-called TruEnd-results in Fig. 5 across the same search space $b \in S_b$ from Eq. 13 and for the same control variable **B** (balances), having iteratively estimated $f(\mathbf{B}, b)$ from Eq. 8 on both of the datasets $\{\mathcal{D}_s, \mathcal{D}_f\}$. The results are strikingly similar in that both datasets produce an f-curve with the same shape, as well as yield the same optimal b^* -value of ZAR 300 that can serve as a "small-balance definition" (or policy). The optimal region¹ that contains this b^* -value is slightly larger for the smaller set \mathcal{D}_s than for \mathcal{D}_f , though this discrepancy is attributable to sampling variability; itself corroborated when comparing the slightly perturbed shape of the f-curve in Fig. 5a to the smoother shape in Fig. 5b. Moreover, the b-values within this optimal region, i.e., $b \in [200, 500]$, do not differ significantly from one another on their face value; as corroborated by the relatively small differences in their $f(\mathbf{B}, b)$ -values. By implication, any of these b-values can serve quite intuitively as small-balance definitions in practice, despite b^* being the 'best' such value. Conversely, more extreme b-values such as b < 100 or $b \ge 2,500$ are correctly disqualified in Fig. 5 given their increasing sub-optimality. These results therefore provide high-level assurance on the soundness and robustness of the TruEnd-procedure and its optima.

In principle, the prevalence of any phenomenon depends on the definition thereof. Likewise, the portfolio-wide prevalence of accounts with a TZB-period will also depend on the exact definition of a "small balance" used in isolating such TZB-periods, i.e., the candidate *b*-values. Given a particular *b*-value, recall the decision function $Z_{it}(B_{it}, b)$ from Eq. 3 that indicates at time *t* whether account *i* is in its TZB-period or not; i.e., the respective value 1 or 0. We aggregate these values for each *i* by taking the maximum over *t*, whereafter these aggregates are denoted as $Z_i(B_i, b)$ given each balance vector B_i . These account-level TZB-indicators form a sample of size *N* from which the so-called *TZB-prevalence rate* can be estimated at the portfolio-level. Expressed as $\sum_i Z_i(B_i, b)/N$, we graph the resulting TZB-prevalence rate in Fig. 6 across the same *b*-values using \mathcal{D}_f . Evidently, TZB-prevalence increases rapidly as *b* increases, though its slope flattens progressively for points beyond the optimal *b**-policy. With a range of approximately 15-28%, overall TZB-prevalence is remarkably sensitive to the choice of *b*, especially when considering that TZB-prevalence rate of 23% for \mathcal{D}_f , which remains practically unchanged at 22.7% for the smaller dataset \mathcal{D}_s . Almost a quarter of the portfolio's accounts are therefore afflicted with this pernicious TZB-error, which would have likely remained undetected if not for applying the TruEnd-procedure.

¹This region is determined simply by calculating the Euclidean distance $d_E(x_i)$ between each point x_i on the *f*-curve and the global maximum x^* . All x_i -points with $d_E(x_i) \le c$ are said to be within the "optimal region", where *c* is a cut-off that equates to a suitably-chosen lower quantile (say 20-30%) of the resulting distribution of d_E -values.

Fig. 5. TruEnd-results f(B, b) across candidate thresholds b, respective to account balances B as control. The encircled point denotes the best policy b^* that maximises f from Eq. 8. The pink triangular points that surround b^* signify an optimal region in f as annotated. The TruEnd-results are respectively derived in (a) and (b) from either the smaller subsampled dataset \mathcal{D}_s or from the full dataset \mathcal{D}_f .

Fig. 6. The TZB-prevalence rate across candidate thresholds *b*, respective to account balances **B** as control within the full dataset \mathcal{D}_f . Given the optimal *b*^{*}-policy from Fig. 5, the associated TZB-prevalence rate is overlaid.

The high TZB-prevalence rates presented thus far are certainly worrisome, given the potential for severely biased predictions from subsequent time-to-event models. However, the degree of such bias will inherently depend

on the materiality (or impact) of TZB-cases, even if quite prevalent within a portfolio. For each candidate threshold *b* in Fig. 7, we therefore investigate the impact of imposing such a *b*-policy, having discarded the resulting TZB-period for each affected account. Starting at 98.7 months for b = 0, the mean account age in Fig. 7a decreases swiftly at first as *b* increases up to the optimal b^* -policy, at which point the loans have a shorter average lifetime of 96.7 months. The mean length of these discarded TZB-periods also increases as *b* grows slightly larger; i.e., from 13.9 to 18.5 months for $b = 0, \ldots, b^*$. The respective downward and upward trends in both means are intrinsically sensible since we fully expect the mean age to decrease when discarding TZB-periods of greater length as *b* increases. However, for larger *b*-values, the rate of change in both of these means slows down noticeably after reaching the optimal b^* -policy, despite the increments between successive *b*-values growing larger. These flatter slopes suggest that the TruEnd-procedure has greater impact for smaller *b*-values given the greater sensitivity to changes at those smaller locales. Moreover, the mean loan age of 100.9 months within the raw dataset decreases quite significantly by about 4.2 months when imposing the optimal b^* -policy and discarding the resulting TZB-periods; themselves having a mean length of 18.5 months and median of 5 months. Accordingly, certain risk events such as write-off or early settlement can occur far earlier than previously thought, which has sobering implications for the degree of 'mistimed' predictions from survival models.

Fig. 7. Sample mean values of various measures across candidate thresholds b, respective to account balances B as control within the full dataset \mathcal{D}_f . Error margins (shaded) are overlaid for each estimate using 95% confidence intervals; some of which are very narrow and barely visible. Given the optimal b^* -policy from Fig. 5, the associated means are annotated. In (a), the means of account ages and TZB-period lengths are shown in the respective sub-panels. In (b), the portfolio-level means $\overline{M}_1(B, b)$ and $\overline{M}_2(B, b)$ from Eq. 12 are shown in the respective sub-panels.

Aside from analysing the age-related impact of applying the TZB-procedure, we also examine its impact in Fig. 7b from the perspective of monetary value. In particular, the portfolio-level mean \overline{M}_1 appears to be a monotonically increasing function of the candidate threshold b, which is unsurprising given the role of b in qualifying balances as TZB-cases. Moreover, the mean balances during these TZB-periods are reassuringly small across most *b*-values, at least up to the optimal b^* -policy; at which point the mean is approximately ZAR 7.45. This empirical result corroborates the intuition that a TZB-period should – by definition – only span those last few balances that are "practically zero-valued". The monetary impact on the portfolio would therefore be minuscule when discarding these isolated TZB-periods, especially for smaller *b*-values. Furthermore, the other portfolio-level mean M_2 also seems to be a monotonically increasing function of b. Such an increasing trend is innately sensible since small-valued outlying TZB-cases are increasingly removed from the window over which \bar{M}_2 is calculated, thereby 'sifting' the mean. However, and unlike \overline{M}_1 , the rate of change in \overline{M}_2 is far greater for smaller values of $b \le b^*$ than for larger values; just like for the means of loan age and TZB-period length in Fig. 7a. Lastly, all of these results in Fig. 7 do not change materially when using the smaller dataset \mathcal{D}_s instead of \mathcal{D}_f , thereby providing at least some assurance on their robustness against sampling variability. Assuming the optimal b^* -policy, we therefore conclude that TZB-cases are not only quite prevalent in affecting 23% of accounts, but can materially prejudice the timing of risk events given the surprisingly long trail of excessive history (≥ 18 months). Excluding these trails will correct the timing though without affecting the overall portfolio size, given the very low mean TZB-balance of $\overline{M}_1(\boldsymbol{B}, b^*) = ZAR 7.45$.

3.2. The impact of applying the TruEnd-procedure vs its absence

Following subsection 3.1, we duly select the optimal policy $b^* = 300$ in serving as the portfolio-wide cut-off for identifying the start times of TZB-periods; i.e., b^* is the 'best' small-balance definition. However, this b^* -policy is selectively applied in that the resulting TZB-periods are discarded only for terminated accounts, i.e., write-offs and settlements. Doing so is deemed prudent in limiting the potential for unwittingly 'overwriting' the observed reality (or data) when discarding records, at least beyond what is necessary. Furthermore, it so happens that these terminated accounts constitute 83% of identified TZB-cases, while the remaining minority cases are still active (or right-censored) by the end of the sampling window. This rather high prevalence of terminated accounts within TZB-cases actually corroborates the original description of the problem; i.e., operational and/or system failures can delay the timely closure of accounts, thereby corrupting their observed endpoints.

Having excluded the identified TZB-periods using this b^* -policy, we examine the impact thereof using a comparative distributional analysis. In particular, the empirical probability distribution of a certain quantity is analysed against that of its 'predecessor'; i.e., the true distribution f_T that rightfully excludes TZB-periods vs the preceding false distribution f_F that still includes TZB-periods. By virtue of shortening some account histories, we fully expect account ages a to be affected, which should reflect in the distributional shapes of f_F and f_T across a. In fact, Fig. 8a shows that $f_F(a) < f_T(a)$ for smaller ages a < 80 months, which reverses to $f_F(a) > f_T(a)$ for larger ages a > 240; a clockwise "distributional till" in the shape of f_T relative to that of f_F . The overall mean age reduces by 3 months to 97.9 when applying this b^* -policy, even though its effect is much more pronounced for terminated accounts – in which case, the mean age reduces by about 18 months. Moreover, we obtain a similar result for the realised loss rates l, as calculated from written-off accounts using the workout-method with observed cash flows; see Gürtler and Hibbeln (2013) and Baesens et al. (2016, §10). Specifically, f_T also exhibits a clockwise distributional tilt relative to f_F across all l, as shown in Fig. 8b. The mean loss rate therefore decreases by 1.2% points to 40.5% when applying this b^* -policy. While seemingly small, this reduction can amount to many millions saved in credit

Fig. 8. A distributional analysis in comparing the histograms and densities of certain quantities in the full dataset \mathcal{D}_f , before and after discarding the isolated TZB-cases using the optimal b^* -policy. Sample means are overlaid, showing a 3-month reduction in the average account age in (**a**); and a 1.2% point reduction in the average realised loss in (**b**).

losses for typical mortgage portfolios, purely as an innocuous data fix before any intensive modelling.

One can also gauge the impact of imposing this b^* -policy by using survival analysis to model another aspect of the LGD risk parameter: the time until write-off T. This non-negative random variable T represents the age of a default spell that either ends with a resolved outcome (write-off) or is left unresolved as right-censored. Then, consider the cumulative lifetime probability distribution $F(t) = \mathbb{P}(T \le t)$ across some time horizon t, which represents the cumulative probability of write-off by time t; see Kleinbaum and Klein (2012, pp. 1-15). Its complement is the write-off survivor function $S(t) = 1 - F(t) = \mathbb{P}(T > t)$, which may be estimated using the well-known non-parametric Kaplan-Meier (KM) estimator $\hat{S}(t)$ from Kaplan and Meier (1958). Regarding competing risks that preclude write-off, the cured outcome is grouped with right-censored observations in the interest of expediency and simplicity. However, by following this "latent risks" approach, the quantity $\hat{F}(t) = 1 - \hat{S}(t)$ can be overestimated, as discussed in Gooley et al. (1999). That said, the effects of such overestimation should at least be consistent within a broader two-component comparative study, especially when both components A and B are equally overestimated in assessing the difference A - B; itself the main objective at present. We therefore deem such overestimation to be negligible in its effect on the ensuing comparative study.

We present the $\hat{F}(t)$ -estimates in Fig. 9 and compare the true distribution $F_T(t)$ that rightfully excludes TZB-periods vs the false distribution $F_F(t)$ that still includes TZB-periods; i.e., applying the TruEnd-procedure vs its absence. The difference between both cumulative distributions seems to grow up to a certain time point t = 84, beyond which the difference gradually subsides again. The slightly larger lifetime write-off probabilities $F_T(t) > F_F(t)$ stem directly from the act of excluding TZB-periods, thereby moving risk events to earlier times during default spells. This result is corroborated in Fig. 10 wherein we provide estimates of the discrete-time hazard rate $\hat{h}(t) = \hat{f}(t)/\hat{S}(t)$, where \hat{f} is the estimated density function of \hat{F} that represents the frequency of failures per unit of time. The write-off hazard $\hat{h}(t)$ therefore denotes the conditional write-off probability of an account during (t - 1, t], having survived at least up to t - 1. Accordingly, estimates of the true hazard distribution $h_T(t)$

that rightfully exclude TZB-periods are compared to those of the false hazard distribution $h_F(t)$ that still include TZB-periods. Again, we observe slightly larger write-off hazards $h_T(t) \ge h_F(t)$ at earlier times $t \le 84$, though these differences grow smaller (and even reverse) at later times. While write-off risk evidently increases when correcting the timing of the underlying risk events, the realised loss rates can decrease by virtue of shorter default spells, as previously shown in Fig. 8. Lastly, default spells longer than 10 years are increasingly rare and of dubious practical value. We have therefore limited the (graphical) survival analyses of both $\hat{F}(t)$ and $\hat{h}(t)$ in Figs. 9–10 to a maximum time in default of 10 years, without necessarily excluding those longer-aged default spells.

Fig. 9. Comparing the cumulative lifetime probability distribution $\hat{F}(t)$ over spell age *t* until write-off, having applied the TruEnd-procedure (F_T) vs its absence (F_F). In (**a**), F(t) is graphed for the early period $t \in [0, 60]$, whereas (**b**) shows the later period $\in [61, 120]$. In summarising the discrepancy between the line graphs A_t and B_t , the *mean absolute error* (MAE) is calculated and overlaid.

4 Conclusion

In credit data, an account's observed repayment history can incorrectly include a lengthy sequence of zero (or very small) month-end balances towards its end, often caused by operational or system failures that delay the account's timely closure. This phenomenon, called *trailing zero-valued balances* (TZB), poses a significant modelling challenge since it distorts the 'true' but unobservable endpoints of affected accounts. As a form of measurement error, these TZB-cases can ruin the timing of certain risk events such as write-off or early settlement. When training LGD-models from affected data, TZB-cases become particularly pernicious to the resulting loss predictions. The excess TZB-history can artificially prolong the period over which cash flows are discounted, thereby inflating the calculated loss percentage even before modelling such 'realised' losses. Moreover, inaccurate timings of risk events in training data can compromise the subsequent predictions of any time-to-event model, including survival analysis. Therefore, the failure to identify and treat these TZB-cases will invite model risk, which can erode trust in all statistical models derived from such inaccurate data.

The remedy is intuitively simple: remove the 'cancerous' TZB-affected part within the history of a loan, thereby moving its endpoint earlier. However, finding the 'true' endpoint for each loan is difficult at scale, especially

Fig. 10. Comparing the hazard function $\hat{h}(t)$ over spell age *t* until write-off, having applied the TruEnd-procedure $(h_{\rm T})$ vs its absence $(h_{\rm F})$; shown across two periods in (**a**) and (**b**). The graph design follows that of Fig. 9.

given the typically large sizes of credit datasets in retail lending. An automated procedure of sorts is clearly needed, though which would then need instruction on identifying these TZB-cases; itself a non-trivial task. Isolating such trails of diminutive balances will depend on the exact definition of a "small or immaterial" balance, which should itself be neither too small nor too large, lest we either retain false history or discard credible history. Determining the 'best' definition b^* amidst many candidates b would require an optimisation approach that embeds the underlying costs/benefits of each b-value. Such an approach would also need to contend with the uncertainty of account balances over time; i.e., the potential for settlement and bouts of loan delinquency, which may even end in write-off. Moreover, the approach would need to find a single small-balance definition that can apply to the entire portfolio (or homogeneous segment therein), thereby exerting appropriate control while achieving consistency and simplicity.

We contribute such a data-driven optimisation approach that can find the best small-balance policy b^* towards identifying and discarding latent TZB-periods within a given loan portfolio. Our so-called *TruEnd-procedure* includes a bespoke objective function f that is statistically evaluated across the histories of all constituent accounts. This f relies on two opposing counter-measures, M_2 and M_1 ; both of which giving the mean balance of an account, albeit calculated over two different periods that respectively predate or succeed the supposed 'true' endpoint. When optimising f using a value iteration technique, the best b^* -policy effectively yields those individual endpoints within affected loan histories that simultaneously maximises M_2 and minimises M_1 on average. Some of the novelty in these measures arises from their deliberate exploitation of the arithmetic mean's known weakness to outliers. Having identified the true endpoints using this b^* -policy, the excess histories thereafter constitute TZB-periods that can be discarded, thereby correcting the timing of account termination.

In demonstrating the TruEnd-procedure, we test a wide range of candidate policies b in defining "small balances", having used a large sample of residential mortgage data from the South African credit market. Not only do we find the best b^* -policy, but our results also reveal a small optimal region of b-values clustered around this b^* -value. The optimisation results f(b) are strikingly similar for those b-values within this region, which suggests that any one of them can practically serve as a policy definition for "small balances".

reacts ever more drastically to larger values of b outside of this region, whilst noting that such larger b-values would increasingly curtail the individual loan histories to their detriment. As b grows larger beyond a certain point, the notion of cutting away more and more of the 'healthy' parts of these histories should rightfully be penalised accordingly. Therefore, the associated and demonstrably severe reaction in f serves as reassurance on the overall and intuitive soundness of the TruEnd-procedure in definitively disqualifying those larger b-values.

Aside from finding the optimal b^* -policy, TZB-affected accounts are remarkably prevalent within this mortgage portfolio, ranging at 15-28% of accounts across all *b*-values. When applying any of these *b*-policies, the isolated (and discarded) TZB-periods have significant durations in that loan histories are now shortened by about 14-19 months on average, depending on the exact *b*-value. Evidently, TZB-cases are both highly prevalent and material in this portfolio, which could not have been detected (or even quantified) if not for applying our TruEnd-procedure. At the optimal b^* -policy of ZAR 300, we find that 23% of accounts are TZB-cases with excess histories that span about 18 months, during which time the mean TZB-balance is practically zero-valued at ZAR 7.45. Having discarded the identified TZB-periods, the timing of account termination is therefore corrected, thereby reducing the mean loss rate of write-offs by 1.2% points; a material result for any LGD-model. Using survival analysis on defaulted loans, we further interrogate this result by modelling and comparing the now-corrected time to write-off versus its uncorrected counterpart. As expected, the write-off hazard generally increases at earlier durations within default spells, chiefly due to risk events now occurring slightly earlier than before. Both the predicted timing and severity of risk events are therefore made more accurate in modelling the recovery process of defaulted loans. By implication, the resulting LGD-model yields lower and less-biased estimates of credit losses for defaulted loans, having better approximated their true profiles of credit risk. Ultimately, we believe this work can safely salvage a dataset that is otherwise corrupted by TZB-cases, which demonstrates the sound pursuit of innovation during data preparation.

Regarding limitations, the TruEnd-procedure currently uses monthly account balances B as the control variable in screening candidate thresholds b, respective to the domain of B. However, these currency-denominated amounts are certainly susceptible to the erosive effects of inflation, especially over longer sampling periods. This inflation susceptibility can detract from finding a single ideal threshold b^* that should apply to all balances across time. Future research can therefore explore alternative controls such as the balance-to-principal ratio of an account over time, whose percentage-valued bounds can circumvent the aforementioned inflation susceptibility. In addition, future researchers can refactor the TruEnd-procedure towards using multiple control variables, e.g., both balance and balance-to-principal. Using multiple controls may afford even greater granularity in the search for optimal thresholds, though the added complexity thereof may become questionable. Similarly, one could also explore the value of a segmentation scheme by which the underlying dataset is first partitioned before running the optimisation step. Instead of yielding a single portfolio-wide threshold b^* , such future work can focus on finding an optimised threshold b_s^* for each homogeneous segment s of accounts.
