Abstract: Regionalization of intensive care for premature babies refers to a triage system of mothers with high-risk pregnancies to hospitals of varied capabilities based on risks faced by infants. Due to the limited capacity of high-level hospitals, which are equipped with advanced expertise to provide critical care, understanding the effect of delivering premature babies at such hospitals on infant mortality for different subgroups of high-risk mothers could facilitate the design of an efficient perinatal regionalization system. Towards answering this question, Baiocchi et al. (2010) proposed to *strengthen* an excess-travel-time-based, continuous instrumental variable (IV) in an IV-based, matched-pair design by switching focus to a smaller cohort amenable to being paired with a larger separation in the IV dose. Three elements changed with the strengthened IV: the study cohort, compliance rate and latent complier subgroup. Here, we introduce a non-bipartite, template matching algorithm that embeds data into a target, pair-randomized encouragement trial which maintains fidelity to the original study cohort while strengthening the IV. We then study randomization-based and IV-dependent, biased-randomization-based inference of partial identification bounds for the sample average treatment effect (SATE) in an IV-based matched pair design, which deviates from the usual effect ratio estimand in that the SATE is agnostic to the IV

and who is matched to whom, although a strengthened IV design could narrow the partial identification bounds. Based on our proposed strengthened-IV design, we found that delivering at a high-level NICU reduced preterm babies' mortality rate compared to a low-level NICU for $81,766 \times 2 = 163,532$ mothers and their preterm babies and the effect appeared to be minimal among non-black, low-risk mothers.

Keywords: Biased randomization; Heterogeneous treatment effect; Instrumental variable; Partial identification bound; Target trial emulation

1 Introduction

1.1 Does delivery at a high-level NICU reduce infant mortality?

Regionalization of intensive care for premature babies refers to a triage system of mothers with high-risk pregnancies to hospitals of varied capabilities based on risks faced by infants. In the analyses of premature births in Pennsylvania, Baiocchi et al. (2010) and Lorch et al. (2012) found that delivering premature babies at a high-level neonatal intensive care unit (NICU), broadly defined as a medical unit equipped with advanced technical expertise and capacity to provide critical care for newborns and premature infants, was associated with lower infant mortality rate for a latent complier subgroup. Yet, due to the limited capacity of high-level NICUs, it is not practical to triage all mothers with high-risk pregnancies to high-level NICUs. Some previous works have further explored the treatment effect heterogeneity of delivering at a high-level versus low-level NICU. For instance, Yang et al. (2014) found that delivering at a high-level NICU significantly reduced deaths for babies of small gestational age but had a negligible effect for almost mature babies. More recently, Chen and Zhang (2023) estimated individual treatment rules subject to different levels of resource constraints and found that mothers' age and race/ethnicity may also be potential effect modifiers. These findings appear to align well with the clinical literature. According to a 2015 National Vital Statistics Reports (Mathews et al., 2015), black infants in the US had a 2.2-fold greater mortality rate than white infants. On the other hand, it has long been established that the risk of miscarriage increases with age; in particular, Hansen (1986) found that pregnant women aged 35 or older experience an increased risk of intrauterine fetal death, pregnancy-induced hypertension, gestational diabetes, and delivery by cesarean. Motivated by these findings, we utilize observational data from the Commonwealth of Pennsylvania to investigate whether delivering preterm babies at

a high-level NICU reduces infant mortality for all mothers in Pennsylvania and certain high-risk subgroups like black mothers and mother who had reached or were past the advanced maternal age of 35.

1.2 Excess travel time as an instrumental variable

To estimate the treatment effect from retrospective observational data, a naïve study design would compare mothers who received care at a high-level NICU with those at a low-level NICU. However, as pointed out in numerous previous works (Baiocchi et al., 2010; Lorch et al., 2012; Yang et al., 2014; Pu and Zhang, 2021; Chen and Zhang, 2023), treatment effect estimates derived from such a naïve comparison would be biased because receipt of neonatal intensive care at a high-level NICU as opposed to a low-level one could be easily confounded by unmeasured variables not captured in administrative databases.

When faced with unmeasured confounding bias, researchers often resort to quasi-experimental devices (see, e.g., Cook et al., 2002; Rosenbaum, 2010). Instrumental variable (IV) methods are among the most popular (Haavelmo, 1943; Angrist and Imbens, 1995; Angrist et al., 1996). Roughly speaking, a valid IV is a variable independent of unmeasured treatment-outcome confounders, possibly within strata defined by observed covariates, and whose sole effect on the outcome is through its effect on the treatment (see Section 4 for a formal definition in the context of a continuous IV). In a seminal paper, Angrist et al. (1996) showed that under an additional “monotonicity” or “no defiers” assumption, a valid IV could be used to nonparametrically identify the treatment effect among a well-defined, albeit latent, subgroup referred to as “compliers.”

In their original study design, Baiocchi et al. (2010) used excess travel time, or the difference in travel times (in minutes) from a mother’s zip code to the nearest high-level and low-level NICUs, as an IV for delivering at a high-level versus low-level NICU. According to this definition, a small excess travel time indicates proximity to a high-level NICU relative to a low-level NICU and corresponds to a strong encouragement to deliver at a high-level NICU. Similar proximity-based IVs have been extensively used in health services research (Newhouse and McClellan, 1998; Baiocchi et al., 2014). Using an IV-based method, Baiocchi et al. (2010) concluded that for every 100 additional mothers encouraged by the IV to deliver at a high-level NICU, 0.9 additional infant deaths could be avoided.

1.3 Compiler average treatment effect; criticism; strengthening a continuous IV

The extensive use of instrumental variables in empirical research is not without criticism. For instance, Deaton (2009) argued that IV estimation methods are analogous to letting the light fall where it may when looking for an object and then proclaiming that whatever the light illuminates is what has been sought after all along. Heckman and Urzua (2010) expressed similar sentiments. The crux of their arguments is concerning the tension between internal and external validities of IV estimates: it is, after all, not clear if the proclaimed treatment effect among compliers could be readily generalized to a target subgroup of interest. The inconvenient fact that the complier subgroup is not identified from the population and could possibly be altered by different incentive structures only makes the generalizability of IV estimates more challenging (Joffe, 2011).

Responding to these criticisms, Imbens (2010) argued that the internal validity of an IV estimate is often superior to that of other estimands for observational data, and that “a credible estimate of the average effect for a subpopulation is preferred to an estimate of the average for the overall population with little credibility” (Imbens, 2010). As discussed by Imbens (2010), two approaches could complement an IV estimate. First, although a valid IV cannot point identify the average treatment effect (ATE), it can partially identify it; see Swanson et al. (2018) for a recent review and references therein. Alternatively, some researchers propose additional identification assumptions that allow the complier average treatment effect to be generalized to the entire population. Some examples include the principal ignorability assumption (Jo and Stuart, 2009; Angrist and Fernandez-Val, 2010; Ding and Lu, 2017) and the homogeneity/no-interaction assumption (Hernán and Robins, 2006; Wang and Tchetgen Tchetgen, 2018), among others.

In their original analysis, Baiocchi et al. (2010) used a study design technique called non-bipartite matching (Lu et al., 2001, 2011; Rigdon et al., 2018; Zhang et al., 2023) to construct matched pairs comprising comparable mothers with different excess travel times. Their key innovation is to consider two study designs: one that utilized all data and created 99,174 pairs (Design I) and the other that “strengthened” the IV by only pairing two similar mothers whose IVs were far apart, yielding 49,587 pairs (Design II).

Three things changed between Design I and Design II. First, the population under investigation changed; for instance, the proportion of white mothers increased from 70% in Design I to 85% in

Design II (Baiocchi et al., 2010, Table 1). Second, the compliance rate changed. Baiocchi et al.’s (2010) key insight is that, by forcing the continuous IV to be further apart within each matched pair, the compliance rate induced by this strengthened IV increased, improving statistical inference of the effect ratio estimand, an analogue of the Wald estimate in a matched-pair design. Third, the latent complier subgroup changed. The original IV in Design I and its strengthened version in Design II targeted a sample average treatment effect over different complier subgroups. Baiocchi et al. (2010, Section 5) argued that the effect ratio estimate obtained from the strengthened design was more “typical” in the sense that a typical mother was more likely to respond to a strong incentive in Design II as opposed to a much weaker incentive in Design I.

1.4 Manipulating a continuous IV with two purposes; caveats

In his perspective piece, Deaton (2009) argued that standard statistical practice would first define a parameter of interest and then construct an estimator targeting the parameter. In the causal inference literature, a causal estimand of interest is often defined first, followed by identification assumptions and estimation procedures operated under these identification assumptions. On the contrary, IV-based procedures implicitly let the chosen IV, which may have little to do with the scientific question at hand, determine the causal estimand.

In this article, we propose a study design framework that builds upon Baiocchi et al.’s (2010) key insight and show that an ideal paradigm—stating a well-defined causal estimand for an identifiable target subgroup and *irrespective of* the IV, followed by identification and estimation using an IV—could be achieved by manipulating a continuous IV in a design-based framework (Rosenbaum, 2002a; Imbens and Rosenbaum, 2005). Our proposed study design starts by building matched pairs that satisfy the following three criteria: (i) the covariates of matched mothers are deemed well balanced according to formal diagnostic tests; (ii) the covariate distribution of the matched sample closely resembles that of a target study population; and (iii) the within-pair difference in the IV is maximized to the extent that the data can afford, with the goal of maximizing the IV-induced compliance rate. We then propose a randomization inference (RI) approach to infer partial identification bounds of the sample average treatment effect and extend the approach to accommodate an IV-dose-dependent, biased randomization scheme. Our framework deviates from previous works that conduct RI-based inference for the structural parameter in a constant, proportional treatment

effect model (Imbens and Rosenbaum, 2005; Small and Rosenbaum, 2008) or the effect ratio estimand (Baiocchi et al., 2010; Zhang et al., 2022). By strengthening the IV and maximizing the compliance rate, a careful design could help derive more informative bounds for the desired effect. In Deaton’s (2009) analogy, researchers clearly state what is desired to be sought after and then adjust the brightness of the light (i.e., strengthen the continuous IV) to illuminate the object.

A valid, continuous IV is at the heart of our proposed design. A binary IV cannot be strengthened; it appears that researchers have to accept the IV as it is and its associated complier subgroup. Fortunately, a lot of commonly used IVs, such as variables related to geography and nature, are often continuous. Alternatively, one may combine multiple binary IVs to construct a many-category IV that is amenable to being strengthened. An important caveat is regarding the validity of the IV: if the putative IV is not valid, then strengthening it could increase the bias if the unmeasured IV-outcome confounder is correlated with the continuous IV (Heng et al., 2023).

2 Algorithm

2.1 Design considerations

Three elements are key to our proposed study design. First, mothers with similar observed covariates but different IV-defined exposures, e.g., excess travel times, need be paired together. One approach would be to dichotomize the continuous exposure and adopt a conventional matching algorithm designed for a binary exposure (Rosenbaum, 2020); however, this practice leads to a potential violation of the stable unit treatment value assumption (SUTVA) (Rubin, 1980, 1986). As an alternative, non-bipartite matching creates matched pairs without dichotomizing the continuous exposure (Lu et al., 2001, 2011; Baiocchi et al., 2010; Zhang et al., 2023). Second, when the data can afford, it is useful to maximize the within-matched-pair difference in the IV dose so that the compliance rate can be maximized. To achieve this, we will resort to a design device called “dose caliper” (see, e.g., Zhang et al., 2023, Section 5). Third, we would like the final matched sample to closely resemble the template, i.e., a random sample from a target subgroup, to enhance the generalizability of the clinical conclusions. This design consideration is referred to as template matching in the literature and has been studied extensively for a binary exposure (Bennett et al., 2020; Zhang, 2023). Yet to our knowledge, statistical matching methods that build representative

matched pairs with a many-category or continuous exposure are currently lacking.

2.2 A non-bipartite matching algorithm that constructs representative samples

To accommodate the three design considerations, we propose a modification of the optimal non-bipartite matching algorithm in Baiocchi et al. (2010). Our key idea is to add e “phantom units,” or “sinks,” that represent units in the template and design a discrepancy matrix in such a way that study participants who do not resemble the template are matched to the sinks and thus eliminated from the final matched sample.

The discrepancy matrix is built using the following steps. Suppose there are n observational units and $e < n$ sinks representing a target subgroup. Define the following $(n+e) \times (n+e)$ distance matrix:

$$\mathcal{M} = \left(\begin{array}{cccc|ccc} \infty & \delta_{1,2} & \cdots & \delta_{1,n} & \Delta_{1,n+1} & \cdots & \Delta_{1,n+e} \\ \delta_{2,1} & \infty & \cdots & \delta_{2,n} & \Delta_{2,n+1} & \cdots & \Delta_{2,n+e} \\ \vdots & & \ddots & \vdots & \vdots & \ddots & \vdots \\ \delta_{n,1} & \delta_{n,2} & \cdots & \infty & \Delta_{n,n+1} & \cdots & \Delta_{n,n+e} \\ \hline \Delta_{n+1,1} & \Delta_{n+1,2} & \cdots & \Delta_{n+1,n} & \infty & \cdots & \infty \\ \vdots & & \ddots & \vdots & \infty & \ddots & \infty \\ \Delta_{n+e,1} & \Delta_{n+e,2} & \cdots & \Delta_{n+e,n} & \infty & \cdots & \infty \end{array} \right),$$

where $\mathcal{M}_{i,j}$ denotes the (i,j) -th entry of \mathcal{M} . Here, $\mathcal{M}_{i,j}$ represents a distance between two observational units for $i, j \in [n]$, between two sinks for $i, j \in \{n+1, n+2, \dots, n+e\}$, and between an observational unit and a sink for the remaining entries.

For $i, j \in [n]$, let $\delta_{i,j}$ be a measure of the distance between the observed covariates x_i and x_j of units i and j , respectively. Intuitively, $\delta_{i,j}$ measures homogeneity between two observational units and can take different specifications. For example, $\delta_{i,j}$ can be the absolute difference in the estimated propensity scores of units i and j or (rank-based) Mahalanobis distance between x_i and x_j (Rosenbaum and Rubin, 1985). To strengthen the continuous IV, we can additionally incorporate the dose caliper into $\delta_{i,j}$ (Zhang et al., 2023). That is, we let $\delta_{i,j} = \tilde{\delta}_{i,j} + C \times \mathbb{I}\{|\tilde{Z}_i - \tilde{Z}_j| \leq \tau\}$, where $\tilde{\delta}_{i,j}$ is a measure of similarity between x_i and x_j , \tilde{Z}_i and \tilde{Z}_j are the continuous IV doses of units i and j , respectively, τ is the dose caliper and C is a large penalty applied when \tilde{Z}_i and \tilde{Z}_j differ

by less than or equal to the caliper size. By setting $C = \infty$ or a large number, the dose caliper can be implemented as a hard or soft constraint, respectively (Zhang et al., 2023). In the NICU study, such a dose caliper would force excess travel times within matched pairs to be far apart by a pre-specified amount τ , thus strengthening the IV and improving the IV-induced compliance rate. Note that we always set $\delta_{i,i} = \infty$ for $i \in [n]$ to prevent observational units from being matched to themselves. By symmetry, $\delta_{i,j} = \delta_{j,i}$.

For $i \in [n]$ and $j \in \{n+1, n+2, \dots, n+e\}$, let $\Delta_{i,j}$ be a measure of the distance between the observed covariates x_i and x_j of observational unit i and sink j , which represents a unit from the template. Intuitively, if unit i is dissimilar to sink j , we would want the algorithm to pair them together in order to eliminate the i -th unit, in which case $\Delta_{i,j}$ would need to be small. Hence, one possible specification is to let $\Delta_{i,j}$ equal an arbitrary large number minus the (rank-based) Mahalanobis distance between x_i and x_j . On top of that, we can further incorporate a “reverse” generalizability caliper defined by a generalizability score such as the “probability of participation,” i.e., the conditional probability of being selected into the template given observed covariates, thereby controlling the degree of resemblance between unit i and sink j (Cole and Stuart, 2010; Stuart et al., 2011). To this end, let $\Delta_{i,j} = \tilde{C} - \tilde{\Delta}_{i,j} + D \times \mathbb{I}\{|\hat{S}_i - \hat{S}_j| \leq \gamma\}$, where \tilde{C} is an arbitrary number added to ensure that $\Delta_{i,j}$ is non-negative; $\tilde{\Delta}_{i,j}$ is rank-based Mahalanobis distance between x_i and x_j ; \hat{S}_i and \hat{S}_j are the estimated probability of participation for units i and j , respectively; γ is the generalizability score caliper; and $D = \infty$ or is a large penalty applied when \hat{S}_i and \hat{S}_j differ by less than or equal to the caliper size γ . If the generalizability scores of unit i and sink j are similar, this implies that unit i closely resembles sink j . By imposing a large penalty D , we prevent them from being matched and thus retain unit i in our final matched sample. By symmetry, $\Delta_{i,j} = \Delta_{j,i}$.

Lastly, $\mathcal{M}_{i,j} = \infty$ for $i, j \in \{n+1, n+2, \dots, n+e\}$. That is, we impose an arbitrarily large penalty for any entry corresponding to two sinks, or to a sink and itself, to prevent them from being matched into pairs. In practice, $\mathcal{M}_{i,j}$ can be set to a large finite number.

An optimal non-bipartite matching algorithm takes as an input the distance matrix \mathcal{M} and $n+e$ units and yields $(n+e)/2$ matched pairs that minimize the sum of the discrepancies. The final matched sample comprises $(n-e)/2$ pairs of observational units and the remaining e pairs consisting of an observational unit and a phantom unit. The algorithm runs in polynomial time and is available in the R package `nbpmatching` (Derigs, 1988; Lu et al., 2011).

2.3 Informal and formal balance diagnostics

An IV-based matched cohort design seeks to embed the retrospective observational data into an “approximate” randomized encouragement experiment. A popular downstream analysis approach is to conduct randomization inference conditional on all the potential outcomes, where the only source of randomness in statistical inference comes from the probabilistic assignment mechanism of the IV doses (Imbens and Rosenbaum, 2005; Baiocchi et al., 2010; Heng et al., 2023). Informal and formal balance diagnostics are often used to justify the *randomization assumption*, which states that the two IV doses within each matched pair are randomly assigned (Silber et al., 2001; Gagnon-Bartsch and Shem-Tov, 2019; Yu, 2020). For instance, Gagnon-Bartsch and Shem-Tov’s (2019) *Classification Permutation Test* (CPT) provides a powerful machine-learning-based test for the randomization assumption. If the randomization assumption is rejected, then some relaxed version of it, such as the biased randomization assumption, may be tested and a minimal degree of residual imbalance due to inexact matching on the observed covariates may be quantified (Chen et al., 2023). If there is strong evidence against the randomization assumption, then one could opt to conduct the primary analysis under a biased randomization scheme. Regardless of whether the randomization or biased randomization assumption is used in the primary analysis, a sensitivity analysis that further examines the impact of unmeasured IV-outcome confounding is recommended.

3 Data and study design

3.1 NICU Data; target trial; details on statistical matching

We considered data on 181,762 preterm babies in the Commonwealth of Pennsylvania between 1995 and 2004. As stipulated by the American Academy of Pediatrics, there are six levels of NICUs of increasing technical expertise and capability: 1, 2, 3A, 3B, 3C and 3D, as well as regional centers 4 (Baiocchi et al., 2010). We followed Baiocchi et al. (2010) and defined a hospital to be high level if it delivered at least 50 preterm babies per year on average and its NICU was of level 3A-3D or 4; we defined a hospital as low level if it delivered fewer than 50 preterm babies annually or its NICU was below level 3A.

Our goal is to embed the retrospective, observational data into a hypothetical randomized encouragement trial in such a way that the instrument is strengthened to the extent that the

data can afford and the final matched sample closely resembles the template. We constructed and compared two matched samples, one constructed using a usual technique (M0) and the other based on the algorithm proposed in Section 2 (M1). For both designs, we matched mothers on birth weight, parity, insurance type (fee for service or others), below poverty, mother’s age, mother’s education, and a single birth indicator, and matched exactly on the year the data was collected. To prepare for the subgroup analyses based on M1, we further matched on a categorical, high-risk variable defined by a combination of a mom’s race, age, and gestational age, motivated by clinical literature discussed in Section 1.1: the high risk category equals 0 if a mother is black, 1 if a mother is at least 35 years old and her gestational age does not exceed 36, 2 if a mother is younger than 35 and her gestational age does not exceed 36, and 3 if a mother’s gestational age exceeds 36.

The first matched sample M0 retained and matched all 181,722 mothers into pairs using a conventional non-bipartite matching algorithm (Lu et al., 2001, 2011). For the second matched sample M1, we first created a template subgroup of mothers by randomly sampling without replacement 10 percent of mothers from the entire dataset spanning 1995 to 2004. We then implemented the statistical matching algorithm introduced in Section 2.2, which includes several design devices such as a generalizability caliper and an IV dose caliper. We implemented the “reverse” generalizability caliper by first estimating the “probability of participation” as the generalizability score (Cole and Stuart, 2010). Specifically, we pooled the corresponding template and the entire observational data, created a binary indicator variable Y_i (1 if participant i belongs to the template and 0 otherwise), and estimated the “probability of participation” by fitting a logistic regression model. Following the notation in Section 2.2, we let $D = 500$, $\tilde{C} = 1 + \max_{i,j} \tilde{\Delta}_{i,j}$, and γ equal to the standard deviation of $|S_i - S_j|$ over all observational units i and template units j . Then, to implement the dose caliper, we let $C = 250$ and used rank-based Mahalanobis distance between two observational units i, j for $\tilde{\delta}_{i,j}$. Finally, we considered a dose caliper τ equal to the standard deviation of the excess travel times from all mothers. Design M1 yielded 81,766 matched pairs of mothers whose within-matched-pair rank-based Mahalanobis distance was minimized subject to the constraints enforced by the above generalizability and IV dose calipers.

3.2 Matched samples

Table 1 contrasts the average excess travel times and covariate balance between mothers encouraged to deliver at high-level and low-level NICUs in the matched samples M0 and M1. In both matches, the absolute SMD of almost every covariate between matched pairs of mothers does not exceed 0.1, or one-tenth of one standard deviation (Silber et al., 2001). We will formally test the randomization and relaxed randomization assumption before conducting inference in Section 7.

Table 1: Degree of encouragement and covariate balance between mothers encouraged to deliver at high-level (near) versus low-level (far) NICUs in two matched comparisons using the 1995 – 2004 data. Matches M0 and M1 are created without and with a dose caliper, respectively. For each variable, we report the mean and the absolute standardized difference. GA: gestational age.

	Match 0 (M0)			Match 1 (M1)		
	90,861 matched pairs			81,766 matched pairs		
	Near Mean	Far Mean	Absolute SMD	Near Mean	Far Mean	Absolute SMD
Instrumental variable						
Excess travel time (min)	6.07	20.97	0.93	2.07	27.10	1.88
Covariates						
Birthweight (g)	2583	2584	0.00	2597	2597	0.00
Gestational age (weeks)	35.12	35.13	0.00	35.21	35.19	0.01
Gestational diabetes (0/1)	0.05	0.05	0.01	0.05	0.05	0.01
Single birth (0/1)	0.83	0.83	0.00	0.85	0.84	0.02
Parity	2.11	2.12	0.01	2.06	2.11	0.03
Mother’s age (years)	28.05	28.04	0.00	28.03	27.80	0.04
Mother’s education (scale)	3.69	3.68	0.00	3.73	3.63	0.08
Black (0/1)	0.16	0.16	0.00	0.16	0.16	0.00
Below poverty (proportion)	0.13	0.13	0.01	0.12	0.12	0.06
Fee for service (0/1)	0.21	0.21	0.00	0.20	0.21	0.05
High risk category						
Black	0.16	0.16	0.00	0.16	0.16	0
Non-Black, age ≥ 35 , GA ≤ 36	0.08	0.08	0.00	0.08	0.08	0
Non-Black, age < 35 , GA ≤ 36	0.40	0.39	0.00	0.40	0.40	0
Non-Black, GA > 36	0.36	0.36	0.00	0.36	0.36	0

A key difference between M0 and M1 is the level of separation in the IV enforced by the study design. The average difference (larger minus smaller within each matched pair) in excess travel times between mothers encouraged to deliver at a low-level versus a high-level NICU for M0 and M1 are $20.97 - 6.07 = 14.90$ and $27.10 - 2.07 = 25.03$ minutes, respectively. This is in line with our study design: a large IV dose caliper enforces the excess travel times for mothers in each matched pair to be further apart, thereby strengthening the IV and improving the IV-induced compliance rate from $65.4\% - 45.6\% = 19.8\%$ in M0 to $71.9\% - 35.5\% = 36.4\%$ in M1. According to the analytical

results in Heng et al. (2023), in order for M0 to attain the same power as M1 when testing Fisher’s sharp null hypothesis, M0 needs to have a sample size that is $(36.4\%/19.8\%)^2 = 3.38$ times that of M1. Design M0’s sample size is only 1.1 times that of M1; therefore, from the perspective of testing Fisher’s sharp null hypothesis, the strengthened design M1 is more advantageous.

Figure 1: Boxplots of the rank-based Mahalanobis distances of two types of matched pairs in M1: (i) two observational units (Obs-Obs) or (ii) an observational unit and a template unit (Obs-Template).

Furthermore, by using the template matching technique and enforcing the generalizability caliper, the matched sample M1 also exhibits good generalizability to the template. For example, M1 largely retains the original composition of black mothers, who comprise 16% of all the mothers in the observational data, and of mothers with fee-for-service health insurance. This contrasts the original strengthened IV design in Baiocchi et al. (2010) which, in transitioning from the unstrengthened to strengthened IV matching design, shifted the study cohort from 15% to 5% of black mothers and from 21% to 25% of mothers with fee-for-service health insurance. Figure 1, which illustrates the distribution of rank-based Mahalanobis distances between matched pairs retained in or eliminated from M1, further demonstrates the effectiveness of our matching algorithm in maintaining good generalizability of the final matched sample to the entire study cohort. For the matched pairs that each consist of two mothers from the observational database and thus comprise M1, the median rank-based Mahalanobis distance is 12 (interquartile range: [5, 31]). For the matched pairs that are eliminated from M1, the median rank-based Mahalanobis distance is 279 (interquartile range: [226, 329]). This is in line with our expectation, as mothers who resembled the template the least in terms of the covariates had large rank-based Mahalanobis distances when matched to the template and were thus eliminated from the final matched sample M1.

4 Notation: potential outcomes and estimands

4.1 Potential outcomes

Our proposed design consists of I matched pairs of two study participants. The j -th participant in the i -th pair is indexed by ij . Each participant ij is associated with a continuous IV $\tilde{Z}_{ij} = \tilde{Z}_{ij}^{\text{obs}}$ e.g., excess travel time in the NICU study. The design embeds the observational data into a hypothetical randomized encouragement experiment as follows. Within each matched pair i , fix the two doses of the continuous IV at $\tilde{Z}_{i1}^{\text{obs}}$ and $\tilde{Z}_{i2}^{\text{obs}}$ and flip a fair coin. If the coin lands heads, assign the IV dose $\tilde{Z}_{i1}^{\text{obs}}$ to $j = 1$ and $\tilde{Z}_{i2}^{\text{obs}}$ to $j = 2$; if the coin lands tails, assign the IV dose $\tilde{Z}_{i1}^{\text{obs}}$ to $j = 2$ and $\tilde{Z}_{i2}^{\text{obs}}$ to $j = 1$. Let $\tilde{\mathbf{Z}} = (\tilde{Z}_{11}, \dots, \tilde{Z}_{I2})$ denote the vector of $I \times 2 = 2I$ IV dose assignments. In a randomized encouragement experiment, it is the encouragement (i.e., the continuous IV \tilde{Z}), not the treatment itself, that is randomized either by nature or an experimenter.

Let $D_{ij}(\tilde{\mathbf{Z}})$ denote the indicator of whether participant ij receives the binary treatment under the IV dose vector $\tilde{\mathbf{Z}}$. We make the SUTVA assumption (Rubin, 1980, 1986) so that $D_{ij}(\tilde{\mathbf{Z}})$ depends on $\tilde{\mathbf{Z}}$ only via \tilde{Z}_{ij} such that $D_{ij}(\tilde{\mathbf{Z}})$ can be simplified to $D_{ij}(\tilde{Z}_{ij})$. We adopt the notation in Zhang et al. (2022) and Heng et al. (2023) and define the following potential outcomes:

$$d_{Cij} \triangleq D_{ij}(\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}) \quad \text{and} \quad d_{Tij} \triangleq D_{ij}(\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}), \quad (1)$$

where $\tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}$ denotes the minimum of two IV doses and $\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}$ the maximum of two IV doses in the i -th matched pair. Importantly, participant ij 's compliance status is determined by two IV doses in matched pair i and the compliance status is fixed once the study design is fixed. Participant ij is said to be a complier with respect to the IV dose pair $(\tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}})$ if $(d_{Tij}, d_{Cij}) = (1, 0)$, an always-taker if $(d_{Tij}, d_{Cij}) = (1, 1)$, a never-taker if $(d_{Tij}, d_{Cij}) = (0, 0)$, and a defier if $(d_{Tij}, d_{Cij}) = (0, 1)$, where d_{Tij} and d_{Cij} are defined as in (1). We make the so-called monotonicity assumption (Angrist et al., 1996) and assume there are no defiers. This is often a mild assumption as it merely states that if unit ij accepts the treatment under dose \tilde{Z} , then it will also accept the treatment under any dose \tilde{Z}' such that $\tilde{Z}' > \tilde{Z}$. Note that even under the monotonicity assumption, researchers can still only observe one of the two potential treatments received, so statistical inference is needed. Under the monotonicity assumption, the compliance

rate in the matched design with respect to a continuous IV is then defined as

$$\iota_C = \frac{1}{2I} \sum_{i=1}^I \sum_{j=1}^2 (d_{Tij} - d_{Cij}), \quad (2)$$

and a strengthened-IV design improves the compliance rate by maximizing the IV dose difference within each matched pair (Baiocchi et al., 2010).

Let $R_{ij}(\tilde{\mathbf{Z}}, \mathbf{D})$ denote the outcome of ij under $\tilde{\mathbf{Z}}$ and $\mathbf{D} = (D_{11}, \dots, D_{I2})$. We assume SUTVA again so that $R_{ij}(\tilde{\mathbf{Z}}, \mathbf{D})$ depends on $\tilde{\mathbf{Z}}$ and \mathbf{D} only via \tilde{Z}_{ij} and D_{ij} . Lastly, we make the exclusion restriction assumption so that the effect of \tilde{Z}_{ij} on R_{ij} is only via D_{ij} ; in other words, $R_{ij}(\tilde{Z}_{ij}, D_{ij})$ can be written as $R_{ij}(D_{ij}(\tilde{Z}_{ij}))$ or $R_{ij}(\tilde{Z}_{ij})$ as a shorthand. Define the following potential outcomes:

$$r_{Cij} \triangleq R_{ij}(\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}) \quad \text{and} \quad r_{Tij} \triangleq R_{ij}(\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}), \quad (3)$$

in parallel to (d_{Tij}, d_{Cij}) in (1). Analogous to (d_{Tij}, d_{Cij}) , (r_{Tij}, r_{Cij}) are defined with respect to the continuous IV dose pair $(\tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}})$. In the NICU study, r_{Cij} describes the potential infant mortality status had the mother lived $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}$ (as opposed to $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}$) minutes farther away from a high-level NICU compared to a low-level NICU and hence encouraged to attend a high-level NICU, while r_{Tij} describes the potential infant mortality status had the mother lived $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}$ (as opposed to $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}$) minutes farther away from a high-level NICU compared to a low-level NICU and hence encouraged to attend a low-level NICU. Importantly, in either case, no mother is forced to attend any hospital. Potential outcomes (r_{Tij}, r_{Cij}) are fixed once the design and hence the two IV doses $(\tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}})$ within each matched pair are fixed.

4.2 Effect ratio estimand; sample average treatment effect

Equipped with these potential outcomes, we now turn to causal estimands. Baiocchi et al. (2010) consider the following effect ratio estimand:

$$\lambda = \frac{\sum_{i=1}^I \sum_{j=1}^2 (r_{Tij} - r_{Cij})}{\sum_{i=1}^I \sum_{j=1}^2 (d_{Tij} - d_{Cij})},$$

which is the ratio of the sample average treatment effect of the IV (possibly after strengthening) on the outcome and that of the IV on the treatment. The effect ratio estimand λ is always well defined provided that the denominator $\sum_{i=1}^j \sum_{j=1}^2 (d_{Tij} - d_{Cij}) \neq 0$, and it coincides with the Wald estimator under an additional monotonicity assumption. In the NICU study, the effect ratio can be interpreted as follows: for every hundred mothers discouraged by the IV from delivering at a high-level NICU, there were $100 \times \lambda$ additional infant deaths (Baiocchi et al., 2010). As researchers switch to a different IV-based matched design, such as one that further separates the two IV doses within each matched pair, the effect ratio estimand will in general be different. In other words, *the effect ratio estimand depends on who is matched to whom, and the design dictates the estimand.*

Lastly, we define the following potential outcomes:

$$r_{d=0,ij} \triangleq R_{ij}(D_{ij} = 0) \quad \text{and} \quad r_{d=1,ij} \triangleq R_{ij}(D_{ij} = 1),$$

which correspond to potential binary infant mortality outcomes had mother ij attended a low-level NICU ($D_{ij} = 1$) or a high-level NICU ($D_{ij} = 0$). Compared to $r_{Tij} - r_{Cij}$ that describes the unit-level intention-to-treat effect (with respect to the designed IV), $r_{d=1,ij} - r_{d=0,ij}$ describes the unit-level treatment effect and arguably is the ultimate estimand of interest in the NICU study. Below, we will focus on the sample average treatment effect of D on R :

$$\kappa = \frac{1}{2I} \sum_{i=1}^I \sum_{j=1}^2 (r_{d=1,ij} - r_{d=0,ij}).$$

Compared to the effect ratio estimand λ , the estimand κ depends on the study cohort but not on the strength of the IV or who is matched to whom in the design phase.

4.3 Partial identification bounds

The estimand κ cannot in general be point identified, as data provides no treatment effect information for non-compliant participants. Partial identification bounds provide an assumption-lean alternative. Define the following index sets: $I_{\text{COM}} = \{(i, j) : (d_{Tij}, d_{Cij}) = (1, 0)\}$, $I_{\text{AT}} = \{(i, j) :$

$(d_{Tij}, d_{Cij}) = (1, 1)\}$, and $I_{NT} = \{(i, j) : (d_{Tij}, d_{Cij}) = (0, 0)\}$. Note that

$$\kappa = \frac{1}{N} \sum_{ij} (r_{d=1,ij} - r_{d=0,ij}) = \frac{1}{N} \left\{ \sum_{(i,j) \in I_{COM}} (r_{d=1,ij} - r_{d=0,ij}) + \sum_{(i,j) \in I_{AT} \cup I_{NT}} (r_{d=1,ij} - r_{d=0,ij}) \right\},$$

where the first term can be further simplified to

$$\sum_{(i,j) \in I_{COM}} (r_{d=1,ij} - r_{d=0,ij}) = \sum_{(i,j) \in I_{COM}} (r_{Tij} - r_{Cij}) = \sum_{ij} (r_{Tij} - r_{Cij}).$$

Let $r_{d=1,ij} - r_{d=0,ij} \in [K_0, K_1]$ for all ij and for some $K_0 \leq K_1 < \infty$. Without loss of generality, assume $K_0 \geq 0$. The second term is then bounded as follows:

$$K_0 \times (N - |I_{COM}|) \leq \sum_{(i,j) \in I_{AT} \cup I_{NT}} (r_{d=1,ij} - r_{d=0,ij}) \leq K_1 \times (N - |I_{COM}|).$$

Because $\sum_{ij} (d_{Tij} - d_{Cij}) = \sum_{(i,j) \in I_{COM}} (d_{Tij} - d_{Cij}) = |I_{COM}|$, we then have

$$K_0 \times \left(N - \sum_{ij} (d_{Tij} - d_{Cij}) \right) \leq \sum_{(i,j) \in I_{AT} \cup I_{NT}} (r_{d=1,ij} - r_{d=0,ij}) \leq K_1 \times \left(N - \sum_{ij} (d_{Tij} - d_{Cij}) \right). \quad (4)$$

Put together, without additional assumptions, the target estimand κ is lower bounded by

$$\text{LB} := \frac{1}{N} \sum_{ij} (r_{Tij} - r_{Cij}) - K_0 \times \frac{1}{N} \sum_{ij} (d_{Tij} - d_{Cij}) + K_0,$$

and upper bounded by

$$\text{UB} := \frac{1}{N} \sum_{ij} (r_{Tij} - r_{Cij}) - K_1 \times \frac{1}{N} \sum_{ij} (d_{Tij} - d_{Cij}) + K_1.$$

Three remarks follow. First, the lower and upper bounds can be achieved when the treatment effect among all the non-compliers attain the minimum and maximum (K_0 and K_1 , respectively). Second, the length of the partial identification interval, $\text{UB} - \text{LB}$, equals $(K_1 - K_0) \times (1 - \iota_C)$, where ι_C is the compliance rate defined in (2). Thus, by maximizing the compliance rate, a strengthened-IV design could help derive a narrower partial identification interval for κ . In an ideal situation where

$\iota_C = 1$, we have $LB = UB$ and the identification of κ is achieved by design. Third, by dividing $N - \sum_{ij}(d_{Tij} - d_{Cij})$ in equation (4), K_0 and K_1 can also be interpreted as the lower and upper bounds of the SATE among non-compliers.

The target parameters LB and UB involve both potential treatments received (d_{Tij}, d_{Cij}) and both potential clinical outcomes (r_{Tij}, r_{Cij}) ; for each study unit ij , either (d_{Tij}, r_{Tij}) or (d_{Cij}, r_{Cij}) is observed, so inference is needed for the LB and UB .

5 Inference for partial identification bounds

5.1 Inference under a randomization assumption

One widely-adopted downstream analysis strategy for matched cohort data is randomization inference treating the matched cohort data as from a finely stratified experiment (Rosenbaum, 2002b, 2010; Fogarty, 2018a,b). We will focus on developing a valid statistical test and confidence statement for the partial identification bounds under the randomization assumption in this section; methods that further take into account within-pair residual bias that persists after matching (Gagnon-Bartsch and Shem-Tov, 2019; Chen et al., 2023) will be discussed next.

Write $\mathcal{F} = \{(\mathbf{x}_{ij}, d_{Tij}, d_{Cij}, r_{Tij}, r_{Cij}) : i = 1, \dots, I, j = 1, 2\}$, where d_{Tij} , d_{Cij} , r_{Tij} and r_{Cij} are defined as in (1) and (3). Write \mathcal{Z} for the set containing the 2^I possible values $\tilde{\mathbf{z}}$ of IV dose assignments $\tilde{\mathbf{Z}}$, so that $\tilde{\mathbf{z}} \in \mathcal{Z}$ if each \tilde{z}_{ij} equals $\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}$ or $\tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}$. Let $\tilde{\mathbf{Z}}_{\vee}^{\text{obs}} = (\tilde{Z}_{11}^{\text{obs}} \vee \tilde{Z}_{12}^{\text{obs}}, \dots, \tilde{Z}_{I1}^{\text{obs}} \vee \tilde{Z}_{I2}^{\text{obs}})$ and $\tilde{\mathbf{Z}}_{\wedge}^{\text{obs}} = (\tilde{Z}_{11}^{\text{obs}} \wedge \tilde{Z}_{12}^{\text{obs}}, \dots, \tilde{Z}_{I1}^{\text{obs}} \wedge \tilde{Z}_{I2}^{\text{obs}})$. In randomization inference with a continuous IV $\tilde{\mathbf{Z}}$, the only probability distribution that enters statistical inference is the conditional probability $\pi_i = P(\tilde{Z}_{i1} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i2} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \mid \mathcal{F}, \tilde{\mathbf{Z}}_{\vee}^{\text{obs}}, \tilde{\mathbf{Z}}_{\wedge}^{\text{obs}})$ that characterizes the underlying IV dose assignment mechanism in each matched pair i . Assuming the IV is valid and the randomization assumption holds, we have $\pi_i = 1/2$ for $i = 1, \dots, I$. Define a shorthand $Z_{ij} = 1$ if $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}$, $Z_{ij} = 0$ if $\tilde{Z}_{ij} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}$ and $\mathbf{Z} = (Z_{11}, Z_{12}, \dots, Z_{I2})$. Under the matched pair design conditional on \mathcal{Z} , $Z_{i1} + Z_{i2} = 1$ for each i . Let $R_{ij} = Z_{ij}r_{Tij} + (1 - Z_{ij})r_{Cij}$ denote the observed outcome and $D_{ij} = Z_{ij}d_{Tij} + (1 - Z_{ij})d_{Cij}$ denote the observed treatment received. We consider the null hypothesis $H_0^L : LB = l$ and an ever-larger experiment with $I \rightarrow \infty$. Proposition 1 derives an asymptotically valid test for H_0^L .

Proposition 1. *Define the test statistic*

$$T(l; K_0) = \frac{1}{I} \sum_{i=1}^I \left\{ \sum_{j=1}^2 Z_{ij} (R_{ij} - K_0 D_{ij}) - \sum_{j=1}^2 (1 - Z_{ij}) (R_{ij} - K_0 D_{ij}) \right\} - (l - K_0)$$

and $S^2(K_0) = \frac{1}{I(I-1)} \sum_{i=1}^I (\hat{\tau}_i - \bar{\tau})^2$, where $\hat{\tau}_i = \sum_{j=1}^2 (2Z_{ij} - 1)(R_{ij} - K_0 D_{ij})$ and $\bar{\tau} = \frac{1}{I} \sum_{i=1}^I \hat{\tau}_i$. Under mild regularity conditions and conditional on $\mathcal{F}, \tilde{\mathbf{Z}}_{\check{V}}^{obs}, \tilde{\mathbf{Z}}_{\check{\wedge}}^{obs}$, the test that rejects $H_0^L : LB = l$ when $|T(l; K_0)| \geq z_{1-\alpha/2} \sqrt{S^2(K_0)}$ is an asymptotically valid level- α test, where $z_{1-\alpha/2}$ is the $(1 - \alpha/2)$ -th quantile of the standard normal distribution.

Remark 1. By replacing K_0 with K_1 in Proposition 1, a valid test can be derived analogously for testing the null hypothesis $H_0^U : UB = u$. A one-sided level- α confidence interval of LB is $\left[T(l; K_0) + l - z_{1-\alpha} \sqrt{S^2(K_0)}, \infty \right)$, where $z_{1-\alpha}$ is the $(1 - \alpha)$ -th quantile of the standard normal distribution. A valid confidence interval of $[LB, UB]$ may then be obtained by combining the two one-sided, level- $\alpha/2$ confidence intervals of LB and UB .

Remark 2. The variance estimator $S^2(K_0)$ in general overestimates the true variance (Imai, 2008). One set of sufficient conditions for it to be an unbiased estimator of the true variance is when the proportional treatment effect model $r_{Tij} - r_{Cij} = \beta(d_{Tij} - d_{Cij})$ holds (Small and Rosenbaum, 2008), the monotonicity assumption holds, and one of the following three conditions holds: (i) all units are compliers; (ii) each pair has one complier and one always-taker or never-taker; (iii) no units are compliers. Such a condition appears restrictive in practice, so the variance estimator $S^2(l)$ would tend to overestimate the true variance and the test based on it would tend to be conservative.

A standard approach to improving the asymptotic precision of randomization-based inference is through regression adjustment (see, e.g., Lin, 2013; Fogarty, 2018a,b; Li and Ding, 2020; Su and Ding, 2021; Lei and Ding, 2021; Zhao and Ding, 2022, among others). Proposition 2 adapts this idea to making inference of the proposed partial identification bounds by proposing a regression-assisted variance estimator for $T(l; K_0)$.

Proposition 2. Let Q denote an $I \times p$ matrix with $p < I$ and $H_Q = Q(Q^T Q)^{-1} Q^T$ be the hat matrix for Q with h_{Qi} on the i -th diagonal. Let $\hat{\tau}_Q$ be an $I \times 1$ column vector with the i -th entry $\hat{\tau}_i / \sqrt{1 - h_{Qi}}$, where $\hat{\tau}_i = \sum_{j=1}^2 (2Z_{ij} - 1)(R_{ij} - K_0 D_{ij})$ as defined in Proposition 1. Let $\boldsymbol{\tau}$ be

an $I \times 1$ column vector with the i -th entry $\tau_i = \frac{1}{2} \sum_{j=1}^2 \{r_{Tij} - r_{Cij} - K_0(d_{Tij} - d_{Cij})\}$. Define $S_Q^2(K_0) = I^{-2} \hat{\tau}_Q^T (I - H_Q) \hat{\tau}_Q$. Under conditions S1-S2 in Supplemental Material A, as $I \rightarrow \infty$,

$$IS_Q^2(K_0) - \text{var}\{\sqrt{IT}(l; K_0) \mid \mathcal{F}, \tilde{\mathbf{Z}}_{\vee}, \tilde{\mathbf{Z}}_{\wedge}\} \xrightarrow{p} \lim_{I \rightarrow \infty} \frac{1}{I} \boldsymbol{\tau}^T (I - H_Q) \boldsymbol{\tau} \geq 0.$$

Remark 3. Proposition 2 indicates that $IS_Q^2(K_0)$ is a conservative estimator for the variance of $\sqrt{IT}(l; K_0)$ in probability, so testing H_0^L based on the statistic $T(l; K_0)/\sqrt{S_Q^2(K_0)}$ and a Gaussian reference distribution are asymptotically valid. When $Q = \mathbf{e}$, a column vector of 1's, $S_Q^2(K_0)$ reduces to the classical variance estimator $S^2(K_0)$ as defined in Proposition 1. In general, for $Q = [\mathbf{e}, \mathbf{V}]$, where \mathbf{V} is a matrix whose i -th row contains centered covariate $(\mathbf{x}_{i1}, \mathbf{x}_{i2})$, $IS_e^2(K_0) - IS_Q^2(K_0) \xrightarrow{p} \beta_V^T \Sigma_V^{-1} \beta_V \geq 0$, where $\Sigma_V = \lim_{I \rightarrow \infty} I^{-1} \mathbf{V}^T \mathbf{V}$ and $\beta_V = \lim_{I \rightarrow \infty} I^{-1} \mathbf{V}^T \boldsymbol{\tau}$. Therefore, $IS_Q^2(K_0)$ is asymptotically no more conservative than $IS^2(K_0)$ if Q contains any covariate information, though the degree of conservativeness reduction depends on how well the covariates predict $\hat{\tau}_i$ (Fogarty, 2018b).

5.2 Inference under a IV-dose-dependent, biased randomization assumption

Although matching helps remove most overt bias, residual bias due to inexact matching and from unmeasured confounders could bias the IV dose assignment within each pair and induce a so-called biased randomization scheme (Rosenbaum, 2002b, 2010; Fogarty, 2020; Fogarty et al., 2021; Chen et al., 2023). Randomization inference under a biased randomization scheme is useful in two scenarios. First, when the minimal degree of bias due to residual confounding from observed covariates can be quantified by formal statistical tests (Chen et al., 2023), primary analyses should adopt a biased randomization scheme. Second, since the observed data contains no information about unmeasured confounding bias, a sensitivity analysis that further relaxes the randomization or biased randomization assumption in the primary analysis is always warranted.

Recall that $\pi_i = P(\tilde{Z}_{i1} = \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i2} = \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \mid \mathcal{F}, \tilde{\mathbf{Z}}_{\vee}^{\text{obs}}, \tilde{\mathbf{Z}}_{\wedge}^{\text{obs}})$. Following Rosenbaum and Rubin (2023), we consider a principal unobserved covariate, $u_{ij} \in [0, 1]$, associated with each participant ij and supported on the unit interval. We consider the following biased IV dose assignment model \mathcal{M}_γ within each matched pair i with an observed IV dose pair $(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}})$

and some $\gamma \geq 0$:

$$\pi_i = \frac{\exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \cdot u_{i1} \right\}}{\exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \cdot u_{i1} \right\} + \exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \cdot u_{i2} \right\}},$$

for $i = 1, \dots, n$, or equivalently,

$$\frac{1}{\exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \right\} + 1} \leq \pi_i \leq \frac{\exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \right\}}{\exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \right\} + 1}.$$

The biased randomization model \mathcal{M}_γ is analogous to that in Rosenbaum (1989) and reduces to the classical Rosenbaum bounds model (Rosenbaum, 1987, 2002b) when $(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}}, \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}) = (1, 0)$. Under \mathcal{M}_γ , the degree of bias in each matched pair depends critically on the IV dose difference. For instance, if a matched pair happens to pair two participants with the same IV dose, that is, $\tilde{Z}_{i1}^{\text{obs}} = \tilde{Z}_{i2}^{\text{obs}}$, then \mathcal{M}_γ would imply $\pi_i = 1/2$, that is, IV dose assignment becomes randomized for this pair. As the IV dose difference increases, \mathcal{M}_γ would stipulate a larger degree of potential bias within each pair. Instead of allowing a dose-dependent maximal bias within each pair, Rosenbaum's classical Γ sensitivity analysis model (Rosenbaum, 1987; Fogarty et al., 2021) places a uniform bound on the maximal biased randomization probability across all pairs, which could be unduly conservative for some matched pairs, e.g., those with $\tilde{Z}_{i1}^{\text{obs}} = \tilde{Z}_{i2}^{\text{obs}}$.

Write $\mathcal{F}' = \{(\mathbf{x}_{ij}, u_{ij}, d_{Tij}, d_{Cij}, r_{Tij}, r_{Cij}) : 0 \leq u_{ij} \leq 1, i = 1, \dots, I, j = 1, 2\}$. Theorem 1 derives an asymptotically valid test for the null hypothesis H_0^L under the biased randomization model \mathcal{M}_γ for some $\gamma \geq 0$.

Theorem 1. *For a fixed $\gamma \geq 0$, define $\Gamma_i = \exp \left\{ \gamma \cdot \left(\tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}} \right) \right\} \geq 1$ to be the IV-dose-dependent odds $\pi_i/(1 - \pi_i)$ under \mathcal{M}_γ in matched pair i . For each matched pair i , define the following scaled treated-minus-control difference in the observed outcome:*

$$\hat{\tau}_{i,\Gamma_i} = \frac{\Gamma_i + 1}{4\Gamma_i} \{(\Gamma_i + 1) \hat{\tau}_i - (\Gamma_i - 1) |\hat{\tau}_i|\}, \quad (5)$$

where $\hat{\tau}_i$ is defined as in Proposition 1. Let $\bar{\tau}_\gamma = \frac{1}{I} \sum_{i=1}^I \hat{\tau}_{i,\Gamma_i}$ be the sample average across all

pairs and $S^2(\gamma; K_0) = \frac{1}{I(I-1)} \sum_{i=1}^I (\hat{\tau}_{i,\Gamma_i} - \bar{\tau}_\gamma)^2$ the usual variance estimator for the sample mean. Under the biased IV assignment model \mathcal{M}_γ and conditional on $\mathcal{F}', \tilde{\mathbf{Z}}_\vee^{obs}, \tilde{\mathbf{Z}}_\wedge^{obs}$, the test that rejects $H_0^L : LB = l$ when

$$\bar{\tau}_\gamma - (l - K_0) \geq z_{1-\alpha} \sqrt{S^2(\gamma; K_0)} \quad (6)$$

is an asymptotically valid level- α test, where $z_{1-\alpha}$ is the $(1 - \alpha)$ -th quantile of the standard normal distribution. A valid one-sided, level- α confidence interval can then be constructed by inverting the hypothesis testing.

Remark 4. When $\gamma = 0$, \mathcal{M}_γ reduces to the randomization scheme studied in Section 5.1. In this case, $\Gamma_i = 1$ for all i , and $\hat{\tau}_{i,\Gamma_i}$ defined in (5) reduces to the usual treated-minus-control difference in the observed outcome in each pair. The test (6) and the associated confidence interval reduce to those studied in Section 5.1 under the randomization assumption.

Remark 5. By replacing K_0 with K_1 in Theorem 1, a valid test can be derived analogously for testing the null hypothesis $H_0^U : UB = u$. A valid level- α confidence interval of the partial identification bound $[LB, UB]$ may then be obtained by combining two one-sided, level- $\alpha/2$ confidence intervals of LB and UB .

The test derived in Theorem 1 also applies to testing the effect ratio estimand under \mathcal{M}_γ , as formalized in Proposition 3.

Proposition 3. Consider testing the null hypothesis $H_0^\lambda : \lambda = \lambda_0$ regarding the effect ratio under the biased IV assignment model \mathcal{M}_γ . Let $\hat{\tau}_i = \sum_{j=1}^2 (2Z_{ij} - 1)(R_{ij} - \lambda_0 D_{ij})$. Define $\hat{\tau}_{i,\Gamma_i}$, $\bar{\tau}_\gamma$, and $S^2(\gamma; \lambda_0)$ as in Theorem 1. Conditional on $\mathcal{F}', \tilde{\mathbf{Z}}_\vee^{obs}$, and $\tilde{\mathbf{Z}}_\wedge^{obs}$, the test that rejects H_0^λ when $\bar{\tau}_\gamma \geq z_{1-\alpha} \sqrt{S^2(\gamma; \lambda_0)}$ is an asymptotically valid level- α test.

6 Simulation studies

We have two goals in the simulation studies. In Section 6.1, we illustrate how strengthening an IV in the design stage helps improve the compliance rate and thus narrow the partial identification bounds and deliver more informative inferential targets. In Section 6.2, we generate synthetic data modeled after the real data from the case study and verify the level of the proposed tests.

6.1 Simulation study I: study design and its effect on the causal estimand

We generate potential outcomes data for each participant $n \in \{1, \dots, N\}$. We consider a 5-dimensional covariate as follows: $X_{n,1} \sim \mathcal{N}(0, 1)$, $X_{n,2} \sim \mathcal{N}(2, 5)$, $X_{n,3} \sim \text{Unif}[1, 3]$, $X_{n,4} \sim \text{Unif}[-2, 0]$ and $X_{n,5} \sim \text{Bernoulli}(0.5)$. Each participant is associated with a step function $D_n(Z = z)$ with a jump at a randomly sampled threshold $T_n \sim \text{Unif}[20, 30]$. The step function $D_n(Z = z)$ describes the potential treatment received for each participant as a function of the IV dose Z . According to this data-generating process, each participant has one's own incentive structure. Factor 1 specifies the distribution of the observed IV dose Z_n^{obs} for participant n :

Factor 1: We consider two scenarios for \tilde{Z}_n^{obs} : (1) $\tilde{Z}_n^{obs} \sim \text{Unif}[5, 50]$ is randomized; and (2)

$$\tilde{Z}_n^{obs} = 4X_{n,2} + 6X_{n,3} + \varphi_n \text{ is correlated with observed covariates, where } \varphi_n \sim \text{Unif}[0, 2].$$

The observed treatment received D_n^{obs} is then determined by $D_n^{obs} = D_n(\tilde{Z}_n^{obs}) = \mathbb{I}(\tilde{Z}_n^{obs} > T_n)$. Using the covariates and the observed IV dose \tilde{Z}_n^{obs} , we perform non-bipartite matching. Factor 2 specifies three matching algorithms under consideration:

Factor 2: $\tilde{\mathcal{M}}_1$, $\tilde{\mathcal{M}}_2$ and $\tilde{\mathcal{M}}_3$ refer to matching designs with no caliper, a small caliper of 7 minutes, and a large caliper of 15 minutes on the absolute difference between two within-matched-pair observed IV doses, respectively.

Each matching design yields $I = N/2$ matched pairs of participants, where each matched pair is indexed by $i \in [I]$ and each within-matched-pair participant indexed by $j \in \{1, 2\}$. The two observed IV doses within each matched pair, $\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}$ and $\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}$, are fixed in each matched design. We then determine participant ij 's compliance status S_{ij} as follows:

$$\text{If } D_{ij}(\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) = D_{ij}(\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}) = 0, \text{ then } S_{ij} = (0, 0);$$

$$\text{If } D_{ij}(\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) = 0 \text{ and } D_{ij}(\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}) = 1, \text{ then } S_{ij} = (1, 0);$$

$$\text{If } D_{ij}(\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) = D_{ij}(\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}) = 1, \text{ then } S_{ij} = (1, 1),$$

where $S_{ij} \in \{(0, 0), (1, 0), (1, 1)\}$ indicates that participant ij is a never-taker, complier or always-taker with respect to the two observed IV doses in matched pair i , respectively.

Finally, we generate the potential outcomes $r_{d=0,ij} \sim \mathcal{N}(0, 1)$. Factor 3 specifies the unit-level treatment effect and hence the data-generating process for $r_{d=1,ij}$:

Factor 3: We consider two scenarios for $r_{d=1,ij}$: (1) $r_{d=1,ij} = r_{d=0,ij} + \psi_{ij}$, where the unit-level treatment effect ψ_{ij} is independent of participant ij 's compliance status and follows $\psi_{ij} \sim \text{Unif}[4, 6]$; and (2) $r_{d=1,ij} = r_{d=0,ij} + \phi_{ij}$, where the unit-level treatment effect ϕ_{ij} depends on participant ij 's compliance status as follows: $\phi_{ij} \sim \text{Unif}[2, 5]$ for a complier, $\phi_{ij} \sim \text{Unif}[4, 6]$ for an always-taker, and $\phi_{ij} \sim \text{Unif}[1, 3]$ for a never-taker.

Participant ij 's potential outcomes $r_{T_{ij}}$ and $r_{C_{ij}}$ are then determined by the compliance status S_{ij} and the potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$ as follows: $(r_{T_{ij}}, r_{C_{ij}})$ equals $(r_{d=0,ij}, r_{d=0,ij})$ for never-takers, $(r_{d=1,ij}, r_{d=0,ij})$ for compliers, and $(r_{d=1,ij}, r_{d=1,ij})$ for always-takers. For each matched dataset, we calculate LB and UB as described in Section 4.3 with $(K_0, K_1) \in \{(4, 6), (1, 6)\}$ for Scenario 1 or 2 in Factor 3, respectively. We generate data for $N = 1,000$ participants and repeat the simulation 1,000 times under each data-generating process.

Table 2: Average widths of the partial identification bounds across 1,000 simulations. In the first column, F_{ij} refers to the j -th scenario in the i -th factor.

	$\widetilde{\mathcal{M}}_1$	$\widetilde{\mathcal{M}}_2$	$\widetilde{\mathcal{M}}_3$
$F_{11} \times F_{31}$	1.03	0.72	0.41
$F_{11} \times F_{32}$	2.57	1.80	1.02
$F_{12} \times F_{31}$	1.83	1.33	0.83
$F_{12} \times F_{32}$	4.58	3.34	2.07

Table 2 summarizes the empirical means of the widths of partial identification bounds, $\Delta = UB - LB$, across 1,000 simulations for each combination of the three factors. In the first column of Table 2, F_{ij} denotes the j -th scenario in the i -th factor; for instance, $F_{11} \times F_{32}$ denotes the simulation setting of randomized IVs \widetilde{Z}_k^{obs} and potential outcomes $r_{d=1,k}$ that depend on the compliance status. Across the four data-generating processes specified by Factors 1 and 3, the more we strengthen the continuous IV, the narrower the widths of the partial identification bounds, yielding more useful information on the SATE. This is in line with our expectation, as the width of a partial identification bound is proportional to the compliance rate, which increases with the IV dose caliper.

Table S3 in Supplemental Material D further summarizes within-matched-pair covariate balance under each data-generating process using the average absolute value of the standardized mean

difference (SMD) across 1,000 simulations. The average absolute value of the SMD increases with the IV dose caliper, with X_2 and X_3 exhibiting the largest increase when they are correlated with the IV dose as specified by Factor 1 Scenario 2. Nevertheless, SMDs are almost always less than 0.1, which usually indicates a good covariate balance in empirical studies (Silber et al., 2001).

6.2 Simulation study II: validity of the proposed tests

In this simulation study, we verify the validity of the proposed statistical tests under randomization inference (Proposition 1) and biased randomization inference (Theorem 1). For every unit j in matched pair i , we first generate potential outcomes data. Specifically, we sample two continuous IV doses $\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}$ and $\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}$ with replacement from the real NICU dataset. Unit ij 's compliance status $S_{ij}(\tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}, \tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}) \in \{(1, 0), (1, 1), (0, 0)\}$ is generated as follows:

$$\begin{aligned} P\{S_{ij} = (1, 0)\} &= C^{-1}; \\ P\{S_{ij} = (1, 1)\} &= C^{-1} \cdot \exp\{-0.2 \times (\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs} - \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs})\}; \\ P\{S_{ij} = (0, 0)\} &= C^{-1} \cdot \exp\{-\alpha_i(\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs})\}, \end{aligned}$$

where C is a normalizing constant, and ij 's compliance status depends on the two IV doses in each matched pair. The latent compliance category S_{ij} then determines (d_{Tij}, d_{Cij}) as defined in (1).

We consider two scenarios for each of the two types of potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$:

Continuous case: Scenario 1: $r_{d=0,ij} \sim \mathcal{N}(0, 1)$ and $r_{d=1,ij} = r_{d=0,ij}$; Scenario 2: $r_{d=0,ij} \sim \mathcal{N}(0, 1)$ and $r_{d=1,ij} = r_{d=0,ij} + \tau_{ij}$, where $\tau_{ij} \sim \text{Unif}[-1, 1]$.

Binary case: Scenario 1: $P(r_{d=0,ij} = 1) = \text{expit}(0.5)$, where $\text{expit}(x) = \exp(x)/(1 + \exp(x))$ is the inverse of the logit function, and $r_{d=1,ij} = r_{d=0,ij}$; Scenario 2: $P(r_{d=0,ij} = 1) = \text{expit}(0.5)$ and $P(r_{d=1,ij} = 1) = \text{expit}(0.5 + \tau_{ij})$, where $\tau_{ij} \sim \text{Unif}[-1, 1]$.

For both outcome types, Scenario 1 represents a sharp null hypothesis of no unit-level treatment effect, while Scenario 2 allows a heterogeneous treatment effect. Once we generate the potential outcomes data, for every matched pair i , we let the participant with the larger potential outcome under control, i.e., $r_{d=0,ij}$, be more likely to receive the treatment under a biased IV dose assignment mechanism π_i , which is introduced below. In this way, the IV doses are correlated with both the

treatment assignment and the potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$.

According to this data generating process, ij 's potential outcomes (r_{Tij}, r_{Cij}) are completely specified by the compliance category S_{ij} and potential outcomes $(r_{d=1,ij}, r_{d=0,ij})$. Finally, we generate the observed IV dose \tilde{Z}_{ij}^{obs} according to one of the following IV dose assignment mechanisms:

$$\begin{aligned} \pi_i &= P(\tilde{Z}_{i1} = \tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs}, \tilde{Z}_{i2} = \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs} \mid \mathcal{F}', \tilde{\mathbf{Z}}_{\vee}^{obs}, \tilde{\mathbf{Z}}_{\wedge}^{obs}) \\ &\sim \text{Unif} \left[\frac{1}{2}, \frac{\exp \left\{ \gamma (\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs} - \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) \right\}}{\exp \left\{ \gamma (\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs} - \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) \right\} + 1} \right] \quad (\textbf{Mechanism I}), \text{ or} \\ &= \frac{\exp \left\{ \gamma (\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs} - \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) \right\}}{\exp \left\{ \gamma (\tilde{Z}_{i1}^{obs} \vee \tilde{Z}_{i2}^{obs} - \tilde{Z}_{i1}^{obs} \wedge \tilde{Z}_{i2}^{obs}) \right\} + 1} \quad (\textbf{Mechanism II}). \end{aligned}$$

The observed data comprises the observed IV dose \tilde{Z}_{ij}^{obs} , treatment D_{ij} , and outcome R_{ij} , with the observed D_{ij} and R_{ij} completely determined by \tilde{Z}_{ij}^{obs} and the potential outcomes data. We vary the following factors in the simulation study:

Factor 1: Number of matched pairs I : 100, 500, 1000 and 2000.

Factor 2: IV dose assignment probability γ : 0, 0.025 and 0.05. If $\gamma = 0$, the two IV doses are randomly assigned within each pair and the randomization assumption holds in either mechanism. Otherwise, the IV dose assignment could be biased within each pair and the degree of bias depends on the difference between the two IV doses.

In **Scenario 1**, we have $(K_0, K_1) = (0, 0)$ regardless of whether the outcome is continuous or binary. In **Scenario 2**, $(K_0, K_1) = (-1, 1)$ for both the continuous and binary potential outcomes. In each setting, we repeat the simulation 1,000 times. For each simulated dataset, we calculate the ground truth $LB_0 = \frac{1}{N} \sum_{ij} (r_{Tij} - r_{Cij}) - K_0 \times \frac{1}{N} \sum_{ij} (d_{Tij} - d_{Cij}) + K_0$ and construct the 95% confidence interval for LB according to Proposition 1 and Theorem 1. We apply Proposition 1 and Theorem 1 to data generated under the biased IV dose assignment scheme, i.e., $\gamma \neq 0$, to illustrate that the 95% confidence intervals constructed according to Theorem 1 have the desired level while those constructed using Proposition 1 may not.

Table 3 considers the case where the potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$ are continuous and summarizes the coverage of 95% confidence intervals under Proposition 1 and Theorem 1 across

1,000 simulations in **Scenario 1** and **Scenario 2**. In the absence of a biased IV dose assignment, i.e., $\gamma = 0$, the two IV assignment mechanisms collapse to one, and the test statistic almost or fully achieves nominal coverage in both scenarios across a range of sample sizes.

As the degree of bias in the IV dose assignment increases in either scenario, the test exhibits exceedingly small or zero coverage under Proposition 1. In such cases, conducting randomization inference for LB overestimates LB and leads to under-coverage, even though the test tends to be conservative in the first place. By contrast, the test constructed according to Theorem 1 tends to achieve perfect coverage under **Mechanism I** and close to nominal coverage under **Mechanism II**, whereby the degree of coverage varies with unit-level treatment effect heterogeneity.

Two sources of conservativeness account for this trend. First, the test constructed according to Theorem 1 assumes a worst-case allocation of bias within each pair; hence, the test will tend to be more conservative for **Mechanism 1** compared to **Mechanism 2**. Second, even under the worst-case bias allocation in **Mechanism 2**, the variance estimator of the test statistic is a conservative estimator of the true variance in **Scenario 2**; therefore, the test still tends to be conservative with a coverage often exceeding its nominal level. We observe similar trends for the case where the potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$ are binary; see Supplemental Material D for details.

7 Revisiting the NICU study

7.1 Assessing the randomization assumption

As a first step towards a randomization-based outcome analysis for the design M1, we assessed the randomization assumption using the Classification Permutation Test (CPT) (Gagnon-Bartsch and Shem-Tov, 2019). Specifically, we tested the null hypothesis that the excess travel times of mothers within each matched pair are randomly assigned. When implementing the CPT, we fit a logistic regression model to predict which mother within each matched pair had a larger excess travel time based on the observed covariates and used in-sample classification accuracy rate as our test statistic. We then obtained the permutation-based null distribution of the test statistic based on 500 permutations of the IV doses. Finally, we computed an exact p-value by comparing the observed test statistic to the reference distribution. Figure 2a shows this null distribution with the observed test statistic superimposed. A large value of the test statistic indicates that the covariates,

Table 3: Simulation results when the potential outcomes $(r_{d=0,ij}, r_{d=1,ij})$ are continuous under two scenarios: causal null hypothesis (**Scenario 1**) and heterogeneous unit-level treatment effect (**Scenario 2**). We report the average coverage of 95% confidence intervals under Proposition 1 and Theorem 1 across 1,000 simulations.

even after matching, are still predictive of the IV dose magnitude within each matched pair and serves as evidence against the randomization assumption. Thus, the randomization assumption for the design M1 was rejected (p-value < 0.001).

To what extent was the randomization assumption violated? Towards understanding this question, we proceeded to test the following biased randomization assumption: $H_{0,\Gamma} : \frac{1}{1+\Gamma} \leq \pi_i \leq \frac{\Gamma}{1+\Gamma}$ for all i (Chen et al., 2023). The null hypothesis $H_{0,\Gamma}$ implies that the IV-dose-dependent odds ratio Γ_i for every matched pair i within M1 is uniformly bounded between $1/\Gamma$ and Γ and hence the IV assignment probability π_i is uniformly bounded between $1/(1+\Gamma)$ and $\Gamma/(1+\Gamma)$. Using Chen et al.’s (2023) sample-splitting CPT, we rejected the null hypothesis $H_{0,\Gamma}$ for Γ as large as 1.17; therefore, we have evidence that at least one matched pair exhibits bias in the IV dose assignment odds Γ_i at a magnitude larger than 1.17. This implies that the smallest γ in \mathcal{M}_γ not falsified by

Figure 2: Panel (a): Distribution of the in-sample classification accuracy rate under the null hypothesis for M1. The vertical bar denotes the observed test statistic. Panel (b): density plot of Γ_i 's with $\gamma = 0.0012$ in the design M1.

the observed data and the diagnostic test equals $\gamma = \log(1.17)/(\max_i \tilde{Z}_{i1}^{\text{obs}} \vee \tilde{Z}_{i2}^{\text{obs}} - \tilde{Z}_{i1}^{\text{obs}} \wedge \tilde{Z}_{i2}^{\text{obs}}) = \log(1.17)/129 = 0.0012$ for M1. Figure 2b displays the distribution of Γ_i 's across all matched pairs in M1 when $\gamma = 0.0012$. This value of γ and its associated sensitivity analysis model \mathcal{M}_γ served as the basis for our biased-randomization-based primary outcome analysis.

7.2 Primary analysis of the matched sample

We conducted a biased-randomization-based primary analysis for the matched sample M1 under \mathcal{M}_γ with $\gamma = 0.0012$. We considered two outcomes of interest. The primary outcome of interest was infant mortality rate. We also considered a composite outcome that combines infant mortality rate and length of stay in the intensive care unit (ICU) as an overall measurement of health care quality; such a composite outcome is referred to as a “placement of death” approach (Lin et al., 2017) and used in many clinical settings (see, e.g., Courtright et al. 2024). Specifically, this composite outcome equals the length of stay in the ICU (LOSI) if the baby survived and the top 1% quantile of survivor LOSI if the baby died. Table 4 summarizes the sample size, compliance rate, mortality, LOSI among survivors, and the composite outcome in the near group (mothers with the smaller excess travel time in each pair) and far group (mothers with the larger excess travel time in each pair).

We first made inference for the effect ratio estimand under \mathcal{M}_γ with $\gamma = 0.0012$ using Propo-

Table 4: Level of encouragement, proportion attending a high-level NICU, and mortality in the near (mothers with the smaller excess travel time in each pair) group and far (mothers with the larger excess travel time in each pair) group.

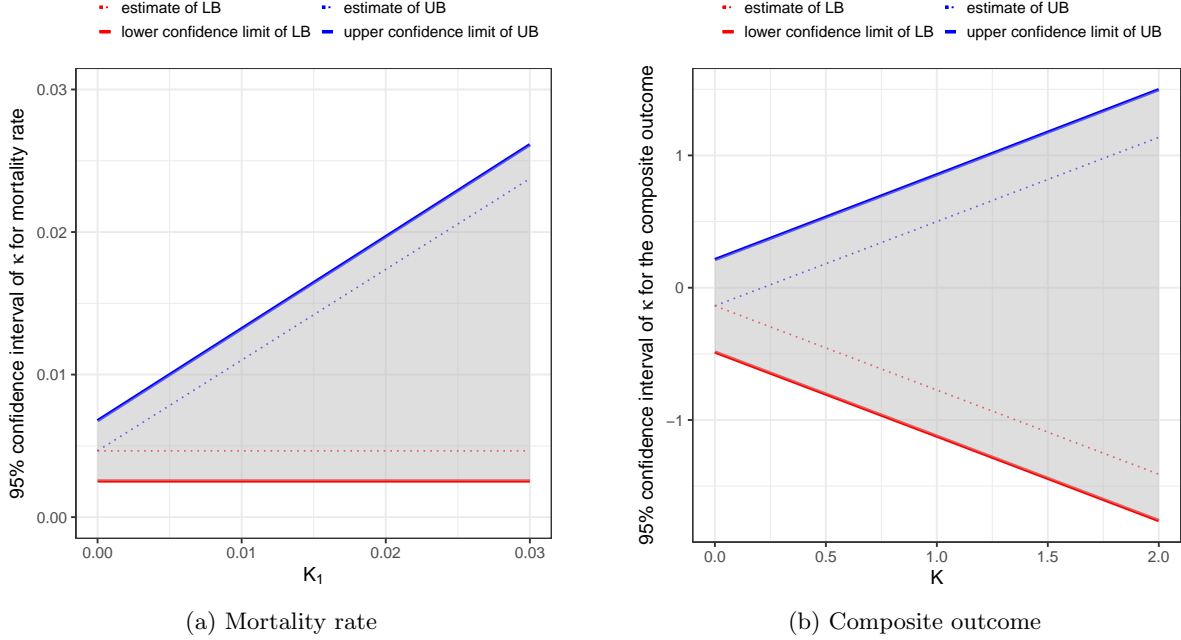

Figure 3: 95% confidence interval plot of κ for (a) the mortality rate with $K_0 = 0$ and $0 \leq K_1 \leq 0.03$ and (b) for the composite outcome with $0 \leq -K_0 = K_1 = K \leq 2$, under model \mathcal{M}_γ with $\gamma = 0.0012$. The dotted lines represent the point estimates while the solid lines represent the one-sided confidence limits of UB (in blue) and LB (in red), respectively.

sition 3. The effect ratio of the mortality outcome (low-level NICU vs. high-level NICU) was estimated to be 1.28% with a 95% confidence interval of [0.69%, 1.90%], providing evidence that delivering at a low-level NICU increased infants' mortality rate among the $71.9\% - 35.5\% = 36.4\%$ compliers in M1. Such an estimated treatment effect on compliers is substantial, almost half of the overall mortality rate in the entire study cohort. On the other hand, the effect on the composite outcome was estimated to be -0.38 among compliers with a 95% confidence interval of $[-1.34, 0.59]$, not providing evidence for an effect on the composite outcome.

We next considered inferring the sample average treatment effect for the entire matched cohort M1 under \mathcal{M}_γ with $\gamma = 0.0012$ based on Theorem 1. The left panel of Figure 3 plots the 95% confidence intervals of the mortality outcome for $81,766 \times 2 = 163,532$ participants in M1 against different hypothesized upper bound K_1 on the unidentified SATE among non-compliers. We assumed that compared to a low-level NICU, delivering at a high-level NICU would not hurt non-compliers so $K_0 = 0$. For instance, the 95% confidence interval for the SATE was estimated to be [0.25%, 1.32%] when $K_1 = 1\%$ and [0.25%, 1.97%] when $K_1 = 2\%$. Results in Figure 3 simul-

taneously account for the sampling variability, the bias in the instrumental variable (controlled by \mathcal{M}_γ), and the unidentifiability of the SATE among non-compliers (controlled by the sensitivity parameters K_0 and K_1). Finally, the right panel of Figure 3 summarizes the results for the composite outcome for some selected K_0 and K_1 values.

7.3 Subgroup analyses: Does the treatment effect vary by risk groups?

To further examine treatment effect heterogeneity, we perform an additional biased-randomization-based primary outcome analysis for the matched sample M1 under Proposition 3 and model \mathcal{M}_γ with $\gamma = 0.0012$ on four subgroups of mothers: (i) black mothers; (ii) non-black mothers who had reached 35 and whose gestational age were at most 30 weeks (non-black, high risk); (iii) non-black mothers who had not reached 35 and whose gestational age were at most 30 weeks (non-black, medium risk); and (iv) non-black mothers whose gestational age exceeded 30 weeks (non-black, low risk). Table 4 summarizes the information of sample size, compliance rate, and outcomes of interest in the near and far groups for these subgroups in the design M1.

For the subgroup of black mothers, the estimated effect ratio (low-level NICU vs. high-level NICU) is 1.62% with a 95% confidence interval of $[-1.16\%, 4.50\%]$. Thus, we did not find evidence for a treatment effect among the $82.96\% - 64.64\% = 18.32\%$ compliers in M1. Figure 4a further plots the 95% CIs for the sample average treatment effect among black mothers against different levels of K_1 . Because of the low compliance rate among black mothers (even after strengthening) and a smaller sample size, both the effect ratio estimate and the partial identification bounds estimates are less precise compared to the analysis based on the entire study cohort in the design M1. The results from our analysis acknowledge that excess travel time yields rather limited information regarding a potential treatment effect of delivering at a high-level NICU vs. low-level NICU for the black mothers in Pennsylvania, mostly as a consequence of the geography of the state.

Among the non-black mothers, the effect ratio (low-level NICU vs. high-level NICU) was estimated to be 3.10% with a 95% confidence interval of $[0.92\%, 5.42\%]$ among the non-black, high risk subgroup; 2.02% with a 95% confidence interval of $[0.85\%, 3.26\%]$ among the non-black, medium risk subgroup; and 0.35% with a 95% confidence interval of $[0.10\%, 0.61\%]$ among the non-black, low risk subgroup. Our analyses suggest that the clinical benefit of delivering at a high-level NICU appeared to be most pronounced among compliers in the high-risk subgroup, with a risk difference

estimate almost 10-fold that among compliers in the low-risk subgroup.

Figure 4 further plots the 95% CIs of the sample average treatment effect for each non-black subgroup against different values of K_1 . Comparing the partial identification bounds of three non-black risk groups, we have an impression that the low-risk subgroup appeared to minimally benefit from the high-level NICU; for instance, a 95% CI for the SATE equals $[0.05\%, 0.39\%]$ when $K_1 = 0.2\%$, $[0.05\%, 0.50\%]$ when $K_1 = 0.4\%$, and $[0.05\%, 0.61\%]$ when $K_1 = 0.6\%$. Interestingly, among the four subgroups, the partial identification bounds are the narrowest for the non-black, low-risk subgroup, as a consequence of the large sample size ($n = 29,155 \times 2 = 58,310$) and high compliance rate ($65.9\% - 17.7\% = 48.2\%$) in this subgroup.

Finally, we repeated the subgroup analysis for the composite outcome. We did not find any difference in the composite outcome among compliers in the black, high-risk non-black, and the medium-risk non-black subgroups; however, the effect ratio was estimated to be -0.24 with a 95% confidence interval of $[-0.42, -0.07]$ for low-risk non-black mothers, providing some additional evidence that the triage system may consider sending low-risk mothers to low-level NICUs, especially under a resource constraint for high-level NICUs. For a 95% confidence interval plot of the sample average treatment effect for each subgroup; see Supplemental Material C.

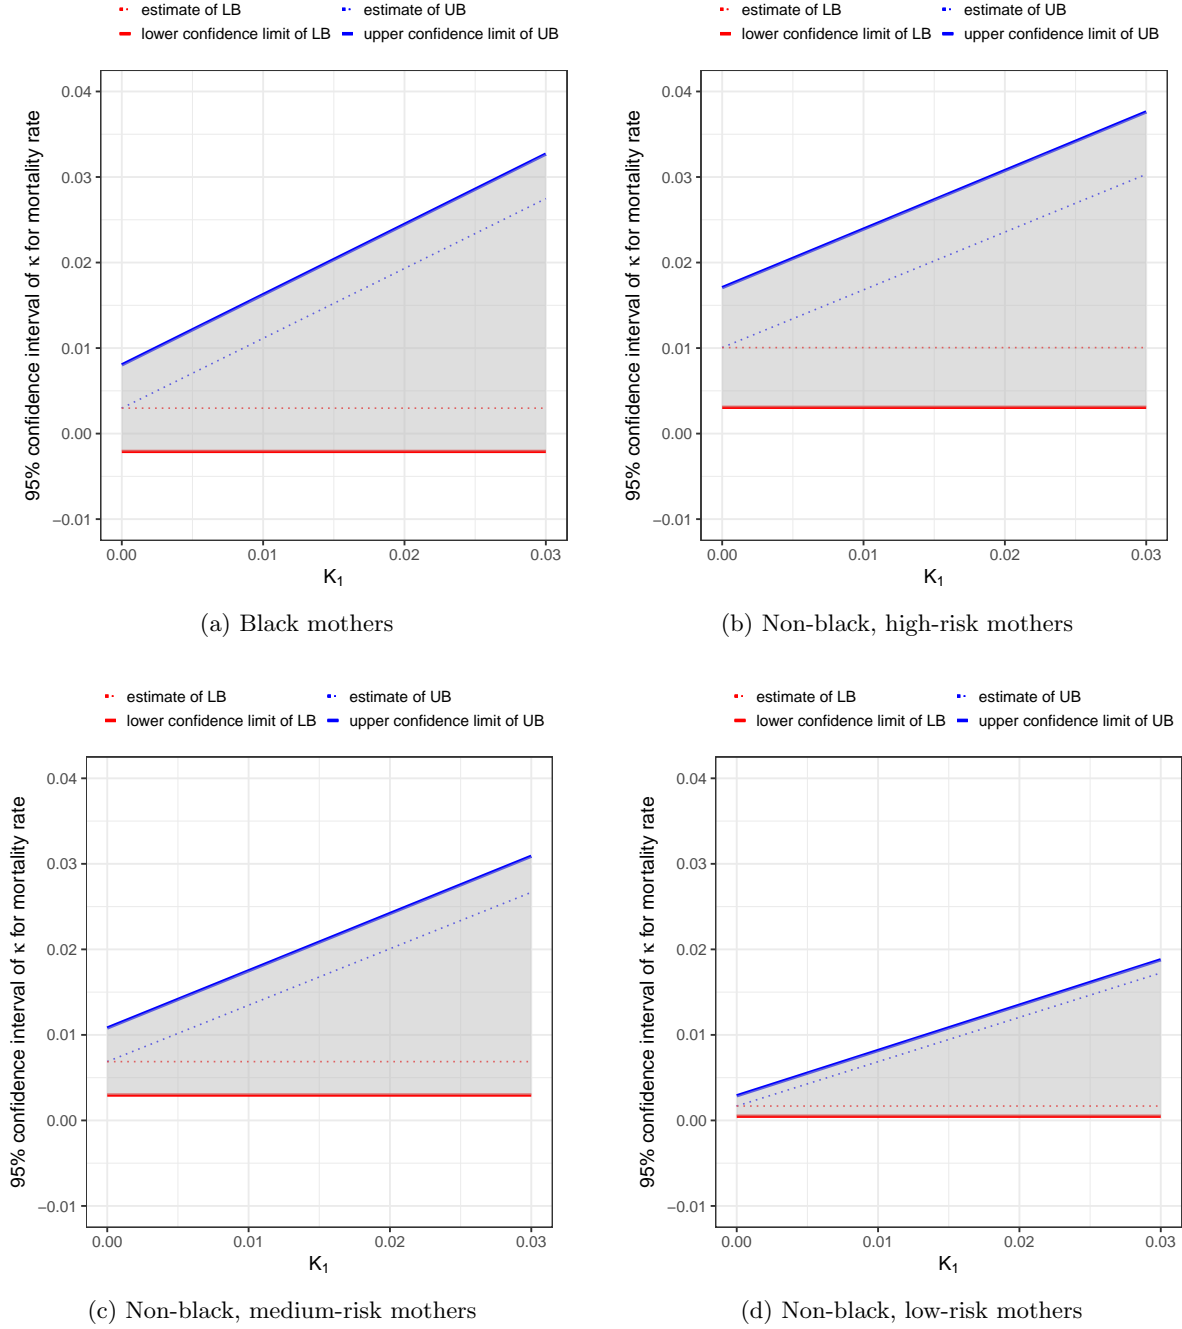

Figure 4: 95% confidence interval plot of κ for (a) the mortality rate with $K_0 = 0$ and $0 \leq K_1 \leq 0.03$ and (b) for the composite outcome with $0 \leq -K_0 = K_1 = K \leq 2$, under model \mathcal{M}_γ with $\gamma = 0.0012$. The dotted lines represent the point estimates while the solid lines represent the one-sided confidence limits of UB (in blue) and LB (in red), respectively.

8 Discussion

Strengthening an instrumental variable when designing an observational study is a novel and useful tool currently underused in empirical comparative effectiveness research. It also has profound consequences. In their discussion, Baiocchi et al. (2010, Section 5) discussed aspects that would change as one switch between an unstrengthened IV design and a strengthened IV design, or between two IV designs that strengthen an IV to different extent. This article builds upon the discussion in Baiocchi et al. (2010) and related critiques in Deaton (2009) and proposes strategies to better reconcile different strengthened IV designs. One promising strategy is to complement an effect ratio estimate with partial identification bounds on the sample average treatment effect. Unlike the effect ratio estimate that targets the SATE among compliers, a study-design-dependent estimand, the SATE on the entire matched cohort is agnostic about how one forms the matched pairs or matched sets. Just like strengthening an IV improves the precision of the effect ratio estimate, strengthening an IV also helps narrow the partial identification bounds by improving the compliance rate.

We studied the effect of delivering at a high-level NICU versus a low-level NICU using a comprehensive administrative database in Pennsylvania and a suite of tools developed in this article, including an improved non-bipartite matching algorithm that emulates a randomized encouragement trial, inferential methods for constructing a valid level- α confidence interval for partial identification bounds, and inferential methods that conducts valid inference under a more realistic and less conservative, IV-dependent biased randomization scheme. Our data analyses suggest that delivering at a high-level NICU decreased preterm infants' mortality rate. The effect was found to be heterogeneous, with a most pronounced effect for non-black, high-risk mothers but marginal for the non-black, low-risk mothers, providing some evidence that a triage system may not need to send mothers and their preterm babies to high-level NICUs. Interestingly, although black mothers were at elevated risk and could potentially benefit from delivering at a high-level NICU, our analysis did not find evidence for this, most likely because the excess travel time was a weak IV, even after strengthening, for black mothers in Pennsylvania.

In this study, we pre-specified several subgroups based on previous clinical findings (Hansen, 1986; Yang et al., 2014; Mathews et al., 2015). With a binary treatment and in the context of

testing Fisher’s sharp null hypothesis, data-dependent methods that identify promising subgroups have been developed and deployed in matched observational studies (Hsu et al., 2013, 2015; Lee et al., 2018). It is of great interest to develop methods that could identify subgroups most amenable to being strengthened and with promise for a large treatment effect.
