We perform a detailed dynamical system analysis for the behaviour of a Dirac-Born-Infeld (DBI) field in a spatially closed Friedmann-Lemaître-Robertson-Walker (FLRW) cosmology. The DBI field is characterised by a potential and brane tension. We study power-law or exponential functions for the potential and tension. We find that in a spatially closed FLRW cosmology, a DBI field in the ultra-relativistic limit allows for a broader range of initial conditions resulting in a bouncing universe than in the non-relativistic limit. We further note that the range of initial conditions allowing for a bounce is larger if we consider power-law functions for the potential and tension, compared to the exponential case. Our dynamical analysis shows that a DBI field does not exhibit stable cyclical behaviour, including the case in which a negative cosmological constant is present.

## I. INTRODUCTION

Scalar fields have been studied extensively in theories of particle physics and cosmology [1, 2]. In the standard model (SM), the Higgs boson is the only fundamental scalar field, but extensions of the SM, such as string theory, predict a plethora of new fundamental scalar fields [3, 4]. In cosmology, they play an important role in models for the early and late time universe [5, 6]. According to inflationary cosmology, at least one scalar field has driven a period of accelerated expansion in the very early universe and in dynamical models of dark energy the present accelerated expansion of the universe is usually driven by a scalar field.

One interesting class of scalar fields, so-called Dirac-Born-Infeld (DBI) fields, is suggested by string theory. These fields do not possess canonical kinetic terms. They describe the motion of D-branes in a higher-dimensional warped internal space and their origin is geometrical [7]. Since D-branes are described by DBI actions, it is not surprising that their kinetic term in the low-energy effective theory is non-canonical. The particular form of the DBI's kinetic term in the Lagrangian imposes a speed restriction analogous to the Lorentz factor in special relatively [8, 9].

DBI fields have mainly been studied in the context of inflationary cosmology as part of k-inflation, inflation driven by a scalar field with a non-canonical kinetic term [10-12]. Not surprisingly, because of the non-canonical kinetic term, the predictions of DBI inflationary models are different from standard slow-roll inflation. DBI's inherent speed limit allows for inflation to occur with steeper potentials compared to that of standard slow-roll inflation [13-18]. This allows for potentials motivated by other fields of study that were ruled out otherwise, such as "stringy" potentials. However, this relativistic feature in single-field inflation amplifies non–Gaussianities compared to the standard slow-roll inflationary model. This amplification provides a possible way to constrain such models with cosmological experiments and pin down the properties and origins of an inflationary field[19–24].

DBI fields have also been studied in the context of models for dark energy. The non-canonical kinetic term introduces interesting features in late-time cosmology, such as obtaining a cosmological constant behaviour without a false vacuum [25–28]. A dynamical system analysis indicates a scaling solution proven to be attractor [29–31]. However, it is found that the non-trivial solutions and critical points in the phase-space analysis are highly dependent on the Lorentz term,  $\gamma$ , being large.

In this paper we perform a detailed dynamical system analysis of DBI dark energy models and extend the work of the literature in several ways. Firstly, we allow for a non-zero spatial curvature. This is motivated by some works claiming that current observational data still marginally allows for a closed universe [32–34]. Even a small curvature at the present can have implications for the future evolution of the universe. Secondly, we study the impact of a negative cosmological constant on the dynamics of the DBI scalar field. There are some recent works studying dark energy in the presence of a negative cosmological constant [35–37]. From a theoretical perspective, either a non-zero curvature or a negative cosmological constant opens up the possibility of a bouncing cosmology, which could lead to a cyclic universe. Therefore, the aim of our study is to determine whether the dynamics of a DBI field naturally favours a universe with possible cyclic behaviour.

This paper is organised as follows: in section II, we present the model and the autonomous set of equations for a dynamical analysis. In section III, we analyse the stability of a model with a power-law potential and brane tension. We also analyse the stability of an exponential behaviour in section IV. We illustrate the stability of both the models in section V. We continue our analysis, examining bouncing scenarios in section VI and the effect of adding a negative cosmological constant in section VII. We summarise and conclude our paper in section VIII.

#### II. THE DBI MODEL

We consider the following action that in addition to Einstein gravity and matter, includes a DBI field,  $\phi$ :

$$S = \int d^4x \sqrt{-g} \left[ \frac{R}{2} - \frac{1}{f(\phi)} (\gamma^{-1} - 1) - V(\phi) + \mathcal{L}_m \right].$$
(1)

In this equation,  $\mathcal{L}_m$  is the Lagrangian that encodes the matter sector,  $f^{-1}(\phi)$  is the D3-brane tension, encoding geometrical properties of the bulk spacetime, and  $\gamma^{-1} = \sqrt{1+fX}$  where  $X = g^{\mu\nu}\partial_{\mu}\phi\partial_{\mu}\phi$  [8, 9]. We will assume throughout this work that V and f are strictly positive. Adopting the Friedmann-Lemaître-Robertson-Walker (FLRW) metric to describe an isotropic and homogeneous universe, and in which a(t) is the scale factor, t the cosmic time, and assuming a homogeneous field  $\phi$ , the kinetic term becomes  $X = -\dot{\phi}^2$  and therefore

$$\gamma^{-1} = \sqrt{1 - f\dot{\phi}^2},\tag{2}$$

which acts as a Lorentz factor, bounding  $\gamma \ge 1$  and  $f^{-1} \ge \dot{\phi}^2$ , thereby limiting the speed of the scalar field. The equation of motion for  $\phi$  is (as usual  $H = \dot{a}/a$ )

$$\ddot{\phi} + 3H\gamma^{-2}\dot{\phi} + \frac{1}{2}f_{\phi}f^{-2}(1 - 3\gamma^{-2} + 2\gamma^{-3}) + \gamma^{-3}V_{\phi} = 0,$$
(3)

and Einstein's equations lead to the Friedmann equation:

$$3H^2 = \frac{\gamma^2}{\gamma + 1}\dot{\phi}^2 + V + \rho_m - 3\frac{K}{a^2},\tag{4}$$

where  $\rho_m$  is the energy density of additional forms such as matter or radiation, and K encodes the spatial curvature. We will study the case of a closed universe in this paper and set K = 1 for the remainder of the work. It will also be useful to define the energy density and pressure of the DBI field:

$$\rho_{\phi} = \frac{\gamma^2 \dot{\phi}^2}{\gamma + 1} + V,$$

$$P_{\phi} = \frac{\gamma \dot{\phi}^2}{\gamma + 1} - V,$$
(5)

and  $\rho_m$  and  $\rho_r$  are the energy density of matter and radiation, respectively. In the limit where  $\dot{\phi}^2 \to f^{-1}, \gamma^{-1} \to 0$ . In this limit, which we will dub as *ultra-relativistic*, we see from eq. (3) that the acceleration of field is governed by the brane tension, which results in a deceleration in an expanding universe as explored by [8, 9], with the Friedmann equation, eq. (4) dominated by the velocity of the field. On the other hand, when  $\gamma \to 1$ , both eqs. (3) and (4) result in the equations of motion for a canonical scalar field.

To analyse the dynamics of the system, we define the variables:

$$x = \frac{\dot{\phi}}{\sqrt{3\bar{\gamma}(1+\bar{\gamma})}} \frac{1}{D}, \quad y = \frac{\sqrt{V}}{\sqrt{3}D}, \quad z = \frac{H}{D}, \quad \Omega_m = \frac{\rho_m}{3D^2} \tag{6}$$

where

$$D = \sqrt{H^2 + \frac{K}{a^2}}, \quad \bar{\gamma} = \gamma^{-1}.$$
(7)

Here, x encodes the kinetic energy of the system, y the potential energy, and  $\Omega_m$  is the matter density parameter, which has an equation of state parameter,  $w_m$ . To make the phase compact, we adopted the variable  $\bar{\gamma}$ , which is bounded between  $0 \leq \bar{\gamma} \leq 1$ . Furthermore, to ensure a compact phase space in a closed universe, we introduce another variable, z, such that the spatial curvature is encoded in the effective Hubble parameter, D. The Friedmann equation, Eq. (4), in terms of these variables is then  $x^2 + y^2 + \Omega_m = 1$ , which we will refer to as the Friedmann constraint. The energy density of the scalar field can be determined from the Friedmann constraint or Eq. (5), resulting in the energy density and equation of state,

$$\Omega_{\phi} = x^2 + y^2, \quad w_{\phi} = \frac{\bar{\gamma}x^2 - y^2}{x^2 + y^2},\tag{8}$$

respectively. We characterise the potential and brane tension by introducing new parameters,

$$\lambda = -\frac{V_{\phi}}{V}, \quad \mu = -\frac{f_{\phi}}{f}.$$
(9)

To ensure that the system remains closed, we introduce a new time variable,  $\tau$ , defined by  $\frac{d}{d\tau}$  =  $D^{-1}\frac{d}{dt}$ . We denote the derivative with respect to  $\tau$  with a prime. The equations of motion eqs. (3)

and (4) result in the following set of equations:

$$\bar{\gamma}' = \frac{\tilde{\gamma} \left(1 - \bar{\gamma}^2\right)}{\sqrt{1 + \tilde{\gamma}}} \left[ 3\sqrt{1 + \tilde{\gamma}}z + \frac{\sqrt{3\tilde{\gamma}}}{x} \left(\mu x^2 - \lambda y^2\right) \right],\tag{10}$$

$$x' = \frac{1}{2}\sqrt{3\tilde{\gamma}(1+\tilde{\gamma})}\lambda y^2 + \frac{3}{2}xz\left[-(1+\tilde{\gamma}) + (x^2+y^2)(1+w_{\phi}) + \Omega_m(1+w_m)\right],$$
 (11)

$$y' = -\frac{1}{2}\sqrt{3\tilde{\gamma}(1+\tilde{\gamma})}\lambda xy + \frac{3}{2}\left[\left(x^2 + y^2\right)(1+w) + \Omega_m(1+w_m)\right]yz,$$
(12)

$$z' = (1 - z^2) \left[ 1 - \frac{3}{2} (y^2 + x^2)(1 + w) - \frac{3}{2} \Omega_m (1 + w_m) \right],$$
(13)

and for completeness,

$$\Omega'_{m} = -3z(1+w_{m})\Omega_{m} + 3\Omega_{m} \left[ (1+w)(x^{2}+y^{2}) + (1+w_{m})\Omega_{m} \right],$$
(14)

as a consequence of the Friedmann constraint. Maintaining generality, we also include the rate of change of  $\lambda$  and  $\mu$ ,

$$\mu' = \left(1 - \frac{f_{\phi\phi}f}{f_{\phi}^2}\right) \mu^2 \sqrt{3\bar{\gamma}(1+\bar{\gamma})}x,\tag{15}$$

$$\lambda' = \left(1 - \frac{V_{\phi\phi}V}{V_{\phi}^2}\right)\lambda^2\sqrt{3\bar{\gamma}(1+\bar{\gamma})}x.$$
(16)

Utilising eqs. (15) and (16), we can note that the autonomous system can describe a wide range of potentials and brane tension functions. If we are to consider an exponential model, as often explored in quintessence models, we note that the  $\mu$  and  $\lambda$  become a constant, reducing the number of equations to be solved.

## III. MODEL WITH POWER LAW BEHAVIOUR

Following the work of [29], we consider a power law functions for both the potential  $V(\phi)$  and the brane tension  $f(\phi)$ , which are forced to be strictly positive,

$$V(\phi) = \sigma |\phi|^p, \qquad f(\phi) = \nu |\phi|^r. \tag{17}$$

where  $(\sigma, \nu) > 0$ , and p and r are power-law parameters to be set.

#### A. Autonomous system

When considering the power law functions, we re-parameterise the potential and brane tension such that,

$$\Lambda = -\frac{V_{\phi}}{f^q V^{q+1}}, \qquad M = -\frac{f_{\phi}}{f^{q+1} V^q}, \tag{18}$$

where q = -1/(p+r). For the power-law case we are studying here, both  $\Lambda$  and M are constant, which allows us to reduce the number of equations for the system. We note that the case q = 0

identifies a specific behaviour that reduces to the exponential scenario explored later in section IV. The variables  $\Lambda$  and M are related to  $\lambda$  and  $\mu$  by

$$\lambda = \left[\frac{(1-\bar{\gamma})y^2}{\bar{\gamma}(1+\bar{\gamma})x^2}\right]^q \Lambda, \qquad \mu = \left[\frac{(1-\bar{\gamma})y^2}{\bar{\gamma}(1+\bar{\gamma})x^2}\right]^q M.$$
(19)

As  $\mu$  and  $\lambda$  can be written in terms of x, y, z we can utilise Eq. (18) with the need only to solve for x', y', z'. Equations (10)–(13) becomes:

$$\bar{\gamma}' = \frac{\bar{\gamma}\left(1-\bar{\gamma}^2\right)}{\sqrt{\bar{\gamma}+1}} \left[\frac{\bar{\gamma}^{\frac{1}{2}-q}\sqrt{3}}{x} \left(\frac{(1-\bar{\gamma})y^2}{(\bar{\gamma}+1)x^2}\right)^q \left(Mx^2 - \Lambda y^2\right) + 3\sqrt{\bar{\gamma}+1}z\right],\tag{20}$$

$$x' = \frac{\sqrt{3}}{2} \left[\bar{\gamma}(\bar{\gamma}+1)\right]^{\frac{1}{2}-q} \left[\frac{(1-\bar{\gamma})y^2}{x^2}\right]^q \Lambda y^2 + \frac{3xz}{2} \left[(\bar{\gamma}+1)(x^2-1) + \Omega_m(1+w_m)\right], \quad (21)$$

$$y' = -\frac{\sqrt{3}}{2} \left[\bar{\gamma}(\bar{\gamma}+1)\right]^{\frac{1}{2}-q} \left[\frac{(1-\bar{\gamma})y^2}{x^2}\right]^q \Lambda xy + \frac{3}{2}yz \left[x^2(1+\bar{\gamma}) + \Omega_m(1+w_m)\right],$$
(22)

$$z' = \left(1 - z^2\right) \left[1 - \frac{3}{2}x^2\left(\bar{\gamma} + 1\right) - \frac{3}{2}\Omega_m(1 + w_m)\right].$$
(23)

## B. Stability analysis

The equations (20) to (22) potentially contains a singular fixed point due to  $\bar{\gamma}^{-1}$  and  $x^{-1}$  terms. Therefore, in order to examine the fixed points, we determine the fixed points for  $\bar{\gamma}$ ,

$$\begin{split} \bar{\gamma} &= 0, \\ \bar{\gamma} &= 1, \\ \frac{\bar{\gamma}^{\frac{1}{2}-q}\sqrt{3}}{x} \left(\frac{(1-\bar{\gamma})y^2}{(\bar{\gamma}+1)x^2}\right)^q \left(Mx^2 - \Lambda y^2\right) + 3\sqrt{\bar{\gamma}+1}z = 0. \end{split}$$

We also restrict ourselves to examining unambiguous fixed points (solutions that do not result in 0/0) at the background level. We then examine the range of fixed points for x, y, z for each case, summarised in table I.

## Case I: $\bar{\gamma} = 0$

The fixed point  $\bar{\gamma} = 0$  corresponds to an ultra-relativistic field, with  $\gamma \to \infty$ . Therefore, the fixed point is an asymptotic solution instead of a truly physical one. In the ultra-relativistic scenario, we find a condition on  $q, q \leq 1/2$ , such that Eqs. (20)–(22) remains physical, thus constraining the potentials and warp functions. The resulting set of equations becomes

$$x' = \frac{3xz}{2} \left[ (x^2 - 1) + \Omega_m (1 + w_m) \right], \tag{24}$$

$$y' = \frac{3}{2}yz \left[x^2 + \Omega_m (1 + w_m)\right],$$
(25)

$$z' = \left(1 - z^2\right) \left[1 - \frac{3}{2}x^2 - \frac{3}{2}\Omega_m(1 + w_m)\right].$$
(26)

In this case, the equations are now void of the parameter q, where the condition  $q \leq 1/2$  has to be satisfied so that the system remains physical. We also note, given this condition, the equations are independent of the variable M and  $\Lambda$ , and thus on the specific choice of V and f.

Fig. 1, panels P1–P5, describes the stability of the ultra-relativistic case for fixed points indicating expansion, contraction and at the bounce. Panels P1 and P3 shows the stability of the fixed points describing contraction, i.e. z = -1. When considering ultra-stiff matter,  $w_m = 1$ , and  $\Omega_m > 0.5$  we find the stability of these fixed points to be a saddle. When  $w_m = 1/3$ , radiation filled, and  $\Omega < 0.7$ , we see that the stability for P1 is stable and P3 is unstable.

Panels P2 and P4 shows the stability of the fixed points describing expansion, i.e. z = 1. During expansion, we see that the stability of P2 is a swap of the stability of P1 and the stability of P4 is a swap of the stability of P3 for the matter cases considered.

Panel P5 describes the stability at the bounce, i.e. z = 0. We see that when  $w_m = 1/3$ , radiation filled, with  $\Omega_m < 0.5$  the bounce has a saddle stability. Pressureless matter,  $w_m = 0$ , with  $\Omega < 0.65$ , shares the same stability. When considering ultra-stiff matter,  $w_m = 1$ , and  $\Omega_m > 0.3$ , no real fixed points exist.

## Case II: $\bar{\gamma} = 1$

In this scenario, provided  $q \neq 0$ , the dependence on  $\gamma$  is removed. In the case where q = 0, the system of equations reduces back to Eqs. (10)–(13). The q = 0 scenario, is further explored in section IV with the resulting fixed points given in table II. Many fixed points will result in an ambiguity, i.e terms that contain 0/0, such as  $x \to 0$ . These are treated with care, and the non-divergent solutions are listed in table I. The autonomous system is, for  $q \neq 0$ ,

$$x' = \frac{3xz}{2} \left[ 2(x^2 - 1) + \Omega_m (1 + w_m) \right], \tag{27}$$

$$y' = \frac{3}{2}yz \left[2x^2 + \Omega_m (1+w_m)\right],$$
(28)

$$z' = (1 - z^2) \left[ 1 - 3x^2 - \frac{3}{2}\Omega_m (1 + w_m) \right].$$
<sup>(29)</sup>

It is worth noting that for  $\bar{\gamma} = 1$  the DBI field behaves identically to the usual canonical scalar field. Interpreting z > 0 as a strictly expanding universe, the fixed points are  $x = 1, y = 0, w_m = -1$ , corresponding to the power-law inflationary fixed points [38]. Therefore, in later sections, we will compare the effects of including  $\bar{\gamma} \neq 1$  against a canonical scalar field,  $\bar{\gamma} = 1$ .

We find that the ultra-relativistic and the canonical scalar have very similar resulting equations of motion, and as such similar behaving fixed points. For instance, in regards to z', the fixed point is determined by the kinetic energy, the value of  $x^2$  as seen from eq. (23). From table I, we see that when the relative kinetic energy of our scalar field is not dominating,  $x^2 \to 0$ , we find the dynamics result in a quasi-de-sitter expansion. An expected result from a slow-rolling scalar field. However, with a fast-rolling scalar field,  $x^2 \to 1$ , the dynamics result in a singular collapse, identified as the "Big Crunch".

Fig. 1 P6, shows the stability at the bounce, z = 0, for the specific case q = 1/2. The stability at the bounce is the same as in the ultra-relativistic case,  $\bar{\gamma} = 0$ , at the bounce.

Case III: 
$$0 < \gamma < 1$$

Here we further identify fixed points using  $\frac{\bar{\gamma}^{\frac{1}{2}-q}\sqrt{3}}{x} \left(\frac{(1-\bar{\gamma})y^2}{(\bar{\gamma}+1)x^2}\right)^q \left(Mx^2 - \Lambda y^2\right) + 3\sqrt{\bar{\gamma}+1}z = 0$  where  $\bar{\gamma}$  remains a constant between 0 and 1. Assuming that  $q \neq 0$ , we use the fixed point to remove the dependence on the *q*-parameter by setting

$$\sqrt{3} \left[\bar{\gamma}(\bar{\gamma}+1)\right]^{\frac{1}{2}-q} \left[\frac{(1-\bar{\gamma})y^2}{x^2}\right]^q = \frac{3xz\sqrt{\bar{\gamma}+1}}{(\Lambda y^2 - Mx^2)}.$$
(30)

This allows us to remove the q dependency in Eqs. (21) and (22):

$$x' = \frac{3}{2} \left[ \frac{\sqrt{\bar{\gamma} + 1}}{(\Lambda y^2 - Mx^2)} \Lambda y^2 + (\bar{\gamma} + 1)(x^2 - 1) + \Omega_m (1 + w_m) \right] xz, \tag{31}$$

$$y' = \frac{3}{2} \left[ -\frac{\sqrt{\bar{\gamma} + 1}}{(\Lambda y^2 - Mx^2)} \Lambda x^2 + (1 + \bar{\gamma})x^2 + \Omega_m (1 + w_m) \right] yz, \tag{32}$$

with z' remaining unchanged. Upon analysing the set of equations (23), (31) and (32), we find that there are no stable fixed points for  $0 < \bar{\gamma} < 1$ , as identified in table I. Regarding the resulting behaviour of the system, we utilise the relationship between z' and  $x^2$ . If the kinetic energy is dominating in eq. (23) such that  $x^2(\bar{\gamma}+1) > \frac{2}{3} - \Omega_m(1+w_m)$  this drives z to negative values. On the other hand, if the kinetic energy is not dominating,  $x^2(\bar{\gamma}+1) < \frac{2}{3} - \Omega_m(1+w_m)$ , then z will be driven to positive values.

Furthermore, if we allow  $\bar{\gamma}$  to evolve from eq. (10), we can see that the resulting negative (positive) z, which is a product of large (small) values of  $x^2$  drives  $\bar{\gamma}$  towards zero (one) and consequently to the fixed points determined for  $\bar{\gamma} = 0$  or  $\bar{\gamma} = 1$ . We interpret this result as the system being highly unstable in the regime of  $0 < \bar{\gamma} < 1$ , with the resulting stable fixed point highly dependent on the initial conditions given.

#### IV. MODEL WITH AN EXPONENTIAL POTENTIAL

Now we consider the case in which both the potential and brane tension depend exponentially on the scalar field,

$$V(\phi) = \sigma e^{-\lambda\phi}, \qquad f(\phi) = \nu e^{-\mu\phi}, \qquad (33)$$

where  $\sigma$ ,  $\nu$ ,  $\mu$  and  $\lambda$  are constants. This implies that eqs. (15) and (16) are automatically set to zero. The power-law case in section III can be related to an exponential function with  $\phi$  in the limit  $(p, r) \to \infty$ . This reduces the following parameters to  $q \to 0$  and  $\Lambda \to \lambda$ ,  $M \to \mu$ . The resulting autonomous equations are given by Eqs. (10)–(13). In the limit q = 0, the autonomous system is described by Eqs. (20)–(23).

$\gamma$	x	<i>y</i>	z	]	Stability	
0	$\pm\sqrt{\frac{2-3\Omega_m(1+w_m)}{3}}$	$\sqrt{\frac{1}{3} + \Omega_m w_m}$	0	$q \le 1/2 \ \Omega_m (1+w_m) \le 3/2$		saddle

TABLE I: Each of the physical fixed points with corresponding stability and conditions for existence, for the power-law potential case.

# A. Stability analysis

Performing the same fixed point analysis as in section III, we begin by determining the fixed points of Eq. (10), which has three roots:

$$\begin{split} \bar{\gamma} &= 0,\\ \bar{\gamma} &= 1,\\ \bar{\gamma} &= \frac{3x^2z^2}{(\mu x^2 - \lambda y^2)^2 - 3x^2z^2}. \end{split}$$

FIG. 1: Stability of fixed points for the power-law potential case, with  $q = \frac{1}{2}$ , as referenced in Table I. The purple regions in P5 and P6 correspond to a pair of parameter values that result in an imaginary fixed point.

# Case I: $\bar{\gamma} = 0$

Setting q = 0 for  $\bar{\gamma} = 0$  results in the same set of autonomous equations as Eqs. (24)–(26). Therefore, the fixed points and their stability are the same in this case as given in table I.

Case II: 
$$\bar{\gamma} = 1$$

Re-emphasising, as in section III,  $\bar{\gamma} = 1$  represents a canonical scalar field. For the case q = 0, the result is an exponential potential similar to that found in dark energy models [39]. The autonomous

system reads,

$$x' = \frac{3}{2}xz \left[2(x^2 - 1) + \Omega_m(1 + w_m)\right] + \sqrt{\frac{3}{2}\lambda y^2},$$
(34)

$$y' = \frac{3yz}{2} \left[ 2x^2 + \Omega_m (1 + w_m) \right] - \sqrt{\frac{3}{2}} \lambda xy,$$
(35)

$$z' = (1 - z^2) \left[ 1 - 3x^2 - \frac{3}{2} \Omega_m (1 + w_m) \right].$$
(36)

The fixed points' outcomes and characteristics are presented in table II. The table shows that the fixed points exhibit behaviour analogous to the power law's description. Specifically, when the potential is zero (y = 0), the only stable fixed point corresponds to a collapse leading to a singular "Big Crunch." However, including a non-zero potential (y > 0) results in the general behaviour of the Universe, which tends toward a quasi-de-Sitter solution. This finding aligns with prior research in the field [39–41]. It tells us that the universe will eventually collapse without a scalar field i.e. no dark energy or a zero potential. However, it is important to acknowledge that these scenarios are physically unrealistic, as dictated by the inherent nature of exponential decay where V > 0, implying  $y \neq 0$ . The solution resembles standard quintessence with a non-zero potential, with dark energy dominating the dynamics.

Case III: 
$$\bar{\gamma} = \frac{3x^2z^2}{-3x^2z^2 + (\mu x^2 - \lambda y^2)^2}$$

The resulting fixed points specifying  $\bar{\gamma} = \frac{3x^2z^2}{-3x^2z^2+(\mu x^2-\lambda y^2)^2}$  result in either x = 0 or z = 0. Therefore,  $\bar{\gamma} = 0$ , resulting in a repeated fixed point. Thus, the q = 0 case results in no new fixed points.

## V. NUMERICAL ANALYSIS

We numerically analyse the system's behaviour for the case q = 1/2 to indicate the behaviour of the commonly cited scenario of  $V \propto \phi^2$  and  $f \propto \phi^{-4}$ . We have numerically explored other values of q, with little difference in the overall dynamical behaviour. We also note that the behaviour of the potential, y, is not included in figs. 2 and 3 as this provides little insight and is constrained by the Friedmann equation.

The fixed points resulting in  $\bar{\gamma} = 0$  and  $\bar{\gamma} = 1$  have similar behaviours, as illustrated in Fig. 2. We see the emergence of the stable solutions, identified in table I, for y, z = 0, -1 and x, z = 0, 1, which correspond to an accelerated collapse or accelerated expansion, respectively. The saddle solution at z = 0 is also clearly depicted in Fig. 2, for  $\bar{\gamma} = 0$  and  $\bar{\gamma} = 1$ , corresponding to the saddle found in table I.

Although, there seems to be a resemblance of an almost unstable cyclic behaviour at z = 0,  $\bar{\gamma} = 1/2$ , this is an artefact of the transition between z < 0 flowing towards  $\bar{\gamma} \to 0$  and z > 0 flowing towards  $\bar{\gamma} \to 1$ . There is an unstable point at z = 0 while  $0 < \bar{\gamma} < 1$  in table I, but it is not well-defined given the choice of parameters in Fig. 2. Expanding the cross-section to examine further values of  $\bar{\gamma}$  between 0 and 1, result in the same behaviour as seen for  $\bar{\gamma} = 1/2$ . We conclude that the dynamics in the regime  $1 > \bar{\gamma} > 0$  quickly result in an ultra-relativistic  $\bar{\gamma} = 0$  or standard

$\bar{\gamma}$	x	y	z	$\Omega_m$	Existence	Stability
1	-1	0	-1	0	$0 \le w_m < 1$ and $0 \le \lambda \le \frac{6}{\sqrt{6}}$	stable
					$0 \le w_m \le 1 \text{ and } \lambda > \frac{6}{\sqrt{6}}$	saddle
1	-1	0	1	0	$0 \le w_m \le 1 \text{ and } \lambda > 0$	unstable

					$w_m = 1 \text{ and } \lambda \in \mathbb{R}$	unstable
1	1	0	-1	0	$0 \le w_m \le 1 \text{ and } \lambda \in \mathbb{R}$	stable
1	1	0	1	0	$0 \le w_m \le 1$ and $0 \le \lambda < \frac{6}{\sqrt{6}}$	unstable
1	$-\frac{1}{\sqrt{3}}$	$\sqrt{\frac{2}{3}}$	$-\frac{\lambda}{\sqrt{2}}$	0	$0 \le w_m \le 1$ and $\sqrt{\frac{6}{3}} < \lambda \le \sqrt{\frac{8}{3}}$	unstable
					$0 \le w_m \le 1 \text{ and } 0 < \lambda < \sqrt{2}$	saddle
					$0 \le w_m \le 1 \text{ and } \lambda > \sqrt{\frac{8}{3}}$	unstable spiral
1	$\frac{1}{\sqrt{3}}$	$\sqrt{\frac{2}{3}}$	$\frac{\lambda}{\sqrt{2}}$	0	$0 \le w_m \le 1$ and $\sqrt{2} < \lambda \le \sqrt{\frac{8}{3}}$	stable
					$0 \le w_m \le 1 \text{ and } 0 < \lambda < \sqrt{2}$	saddle
					$0 \le w_m \le 1 \text{ and } \lambda > \sqrt{\frac{8}{3}}$	unstable spiral

TABLE II: Additional fixed points for q = 0, an exponential potential and brane tension.

quintessence  $\bar{\gamma} = 1$  scenario. Thus, the dynamics always result in a quasi-de-Sitter Universe,  $z \to \pm 1$ , as specified by stable solutions in table I.

We also study the initial conditions and the time taken for the Universe to end up in the final solution of  $z \to \pm 1$  as shown in Fig. 3, where the colours of the individual trajectories denote the initial value for the variable x. As it can be seen, trajectories in phase space are highly dependent on the initial conditions, which is similar to what happens in many models that include bouncing cosmologies. A universe is generally more likely to end up in an expanding Universe if it has a dominant kinetic energy and more likely to result in a collapse if the kinetic energy is subdominant. This effect can be seen in Fig. 3, where the initial conditions of the kinetic term vary in values of  $\bar{\gamma}$ . In addition, there are unstable spiral solutions that exhibit a cyclic solution which quickly tend towards and singular collapse or quasi-de-Sitter Universe. However, these are not included in Fig. 3, due to the resolution and the exhaustive numerical analysis required to study these particular solutions.

An interesting result from our analysis is the enhancement of the phase space of a resulting bounce scenario  $(z < 0 \rightarrow z > 0)$  in ultra-relativistic scenarios compared to a canonical scalar field scenario. This feature is explored further in the next section.

### VI. BOUNCING COSMOLOGIES WITH A DBI FIELD

We have concluded that stable, generic cyclic models are not exhibited in a DBI model. However, it was found that the "deceleration" mechanisms of the scalar field provide a more extensive range of initial conditions that lead to a bounce. This can be seen in figures fig. 2 and fig. 5 for the ultra-relativistic case ( $\bar{\gamma} = 0$ ), compared to the standard quintessence case ( $\bar{\gamma} = 1$ ).

We investigate this aspect further in the following. Provided a range of initial conditions for  $z_i$ ,

FIG. 2: A phase plot showing the behaviour of the system with q = 1/2,  $\Omega_m = 0.2$ ,  $w_m = 1/3$  and  $M = \Lambda = 10^{-4}$ .

 $x_i$ , with the dependence on  $y_i$  determined by the Friedmann constraint, we numerically integrate the system as before for fig. 3. This results in a relationship between the initial conditions and the dynamics, resulting in a bounce. This is shown in fig. 4, in which the area under each graph shows the initial conditions that will result in a bounce.

In the case of an exponential form for potential and brane tension, for which the results are shown in Fig. 4, we find an increase of 69% in initial conditions for the ultra-relativistic case,  $\bar{\gamma} = 0$ , will lead to a bounce, whereas  $\bar{\gamma} = 0.5$  leads to a 36% increase in initial conditions resulting in a bounce. For the power-law case with q = 0.5, we find that for the ultra-relativistic case, there is a 77% increase in the initial conditions that result in a bounce. This drops to a 41% increase at

FIG. 3: Phase plots analysing the role of initial conditions for the power law model with q = 1/2. The other model parameter are set to  $M = \Lambda = 10^{-4}$  and  $\Omega_m = 0$ . The colours of the trajectories indicate the initial value of x, as shown in the legend. It can be seen that trajectories with larger initial values of x end up at z = -1, whereas trajectories with smaller initial values of x end up at z = 1.

 $\bar{\gamma} = 0.5.$ 

Note that smaller  $z_i$  values correspond to a slower contraction of the Universe, which results in more time for the spatial curvature to dominate and a larger range of  $x_i$  values that result in a bounce. We can see from Fig. 4, that including the DBI model with the condition  $\bar{\gamma} < 1$ , the range of initial conditions that lead to a bounce increases as the initial value of  $\bar{\gamma}$  grows towards an ultra-relativistic state,  $\bar{\gamma} = 0$ .

FIG. 4: Lines identify the maximum initial condition that results in an expanding universe, z > 0, with each colour identified as the initial value of  $\bar{\gamma}$ ,  $\bar{\gamma}_i$ . Therefore, the area under the line for each case of  $\bar{\gamma}_i$  encodes the initial conditions that result in a bouncing scenario.

### VII. ADDING A NEGATIVE COSMOLOGICAL CONSTANT

As we have seen in the last section, after the bounce the dynamics results in a quasi-de-Sitter expansion,  $z \to +1$ . In the following we include a negative cosmological constant to arrange for this system to re-collapse. The aim of this analysis is to see whether universe would as a result, settle into a cyclic behaviour.

We include a cosmological constant denoted by an energy density  $\rho_C$  (the equation of state is -1). The Friedmann equation becomes,

$$3H^2 = \frac{\gamma^2 \dot{\phi}^2}{\gamma + 1} + V - 3\frac{K}{a^2} - \rho_C.$$
(37)

In the following we define the quantity  $\tilde{D}^2 = H^2 + \frac{K}{a^2} + \frac{\rho_C}{3}$  in order to compactify the K > 0 state space. In addition, we define a new dimensionless variable  $\Omega_C \equiv \frac{\rho_C}{3\tilde{D}^2}$ . The only change to the equations of motion Eqs. (20)–(23) is

$$z' = (1 - z^2) \left[ 1 - \frac{3}{2} x^2 (1 + \bar{\gamma}) \right] - \Omega_C,$$
(38)

where  $' \equiv \tilde{D}^{-1} \frac{d}{dt}$  as before, and the Friedmann contraint remains  $x^2 + y^2 + \Omega_m = 1$ . The same analysis can be performed by setting  $w_m = -1$ , which will remove  $\Omega_m$  from Eqs. (20)–(23), giving the same results. We choose the equations above, as it provides an explicit dependence on  $\Omega_C$ . We furthermore consider the power law case with q = 1/2.

$\bar{\gamma}$	x	y	2	Existence	Stability
0	0	$\pm\sqrt{1-\Omega_m}$	$-\sqrt{\frac{2(\Omega_C-1)+3\Omega_m(1+w)}{-2+3(1+w_m)}}$	$\Omega_m(1+w_m) \ge \frac{2}{3}$	stable
0	0	$\pm\sqrt{1-\Omega_m}$	$\sqrt{\frac{2(\Omega_C - 1) + 3\Omega_m (1 + w_m)}{-2 + 3(1 + w_m)}}$	$\Omega_m(1+w_m) \ge \frac{2}{3}$	unstable
0	$\pm\sqrt{\frac{2(1-\Omega_C)-3\Omega_m(1+w_m)}{3}}$	$\sqrt{\frac{1+2\Omega_C+3\Omega_m w_m}{3}}$	0	$\Omega_m(1+w_m) \le \frac{2}{3}(1-\Omega_C)$	saddle
1	0	$\pm\sqrt{1-\Omega_m}$	$\boxed{-\sqrt{\frac{2(\Omega_C-1)+3\Omega_m(1+w_m)}{-2+3(1+w_m)}}}$	$\Omega_m(1+w_m) \ge \frac{2}{3}$	stable
1	0	$\pm\sqrt{1-\Omega_m}$	$\sqrt{\frac{2(\Omega_C - 1) + 3\Omega_m (1 + w_m)}{-2 + 3(1 + w_m)}}$	$\Omega_m(1+w_m) \ge \frac{2}{3}$	unstable
1	$\pm\sqrt{\frac{2(1-\Omega_C)-\Omega_m(1+w_m)}{6}}$	$\sqrt{\frac{4+2\Omega_C+3\Omega_m(w_m-1)}{6}}$	0	$\Omega_m(1+w_m) \le 2(1-\Omega_C)$	saddle
$\boxed{\frac{1+w_m\Omega_m}{3(\Omega_m-1)}}$	$\pm \sqrt{\frac{2(1-\Omega_C)-3\Omega_m(1+w_m)}{2-3\Omega_m(1+w_m)}}$	$\sqrt{\frac{2(1-\Omega_m)\Omega_C}{2-3\Omega_m(1+w_m)}}$	0	$w_m < 0, \ \Omega_m > \frac{1}{3}, \\ \frac{2}{3} > \Omega_m (1 + w_m)$	unstable

TABLE III: A table categorising the stability of fixed points found by including a negavive cosmological constant. We assume  $0 < \Omega_C < 1$ , disregarding any fixed results that set  $\Omega_C = 0$  as this reduces back to table I.

As shown in Fig. 5, the introduction of a negative cosmological constant leads to a noteworthy outcome — namely, an expansion in the range of larger 'x' values that lead to a collapse, as compared to the scenario presented in Fig. 2. This expansion is attributed to the downward shift of the saddle point at  $\bar{\gamma} = 0, 1$  concerning its 'x' position, a change documented in table I. Notably, the fixed points associated with  $\bar{\gamma} = 0$  and  $\bar{\gamma} = 1$  no longer display asymptotic quasi-de-Sitter solutions at z = -1 and z = 1, as shown in Fig. 5 and in table I. However, this shift of the saddle point towards lower 'x' values reduces the available parameter space conducive to a successful bounce scenario compared to the scenario discussed in section III.

Our analysis results shows that additional features or advantages emerge from including a negative cosmological constant. But we conclude that including a negative cosmological constant to the DBI model does not exhibit any further enhancement towards a cyclic model.

### VIII. CONCLUSION

DBI models have generated significant interest due to their non-canonical kinetic term introduced by the brane, which results in a unique deceleration mechanism. This mechanism imposes a Lorentz factor that effectively sets a "speed limit" for the DBI scalar field, determined by the brane tension. This deceleration mechanism has led to many attractive inflationary models with unique potentials and non-trivial results. More recently, DBI models have been studied in the context of dark energy with interesting and future detectable features.

The authors of [29] conducted an in-depth dynamical analysis of a DBI field regarding dark energy and inflation, analysing both exponential and power-law potentials and brane tensions. We have extended their analysis to include a closed universe, allowing us to explore the stability of additional fixed points, most interestingly around z = 0. Motivated by string theory phenomenology, we focused our numerical analysis on the power-law scenario,  $V \propto \phi^2$  and  $f \propto \phi^{-4}$ .

From our analysis, we find the system is unstable in the regime  $0 < \bar{\gamma} < 1$  and is driven to either the ultra-relativistic case,  $\bar{\gamma} = 0$ , or the conformal scalar field case,  $\bar{\gamma} = 1$ . This behaviour is depicted in Fig. 2, where the regime  $0 < \bar{\gamma} < 1$  drives the system to settle at the fixed points  $\bar{\gamma} = 0$ or  $\bar{\gamma} = 1$ . The fixed point around z = 0 is a saddle in both the ultra-relativistic and conformal

FIG. 5: Phase plots for the power-law model (q = 1/2) with a negative cosmological constant, set  $\Omega_C = 0.3$ . All other parameters are the same used to generate fig. 2

regimes. Although the system still accounts for a bouncing scenario, dependent on initial conditions, it lacks a generic cyclic behaviour. We also find that including a DBI field increases the number of initial conditions that result in a bouncing universe, which reaches a maximum when  $\bar{\gamma} = 0$ . This result is depicted in Fig. 4, where we see that given an ultra-relativistic case, the system has an increased number of initial conditions leading to a bounce compared to a conformally kinetic field.

Motivated by an increase in the initial conditions that allow for a successful bounce, we include an additional degree of freedom to induce a cyclic behaviour. In section VII, we investigate the effects of incorporating a negative cosmological constant into the analysis. While introducing a negative cosmological constant expands the range of points leading to collapse, the initial conditions that result in the bounce are constrained by the saddle point. Given a negative cosmological constant, it

reduces the x value of the saddle fixed point. Therefore, in interest to this work, including a negative cosmological constant only reduces the initial conditions that lead to a bounce. Consequently, while a DBI field does lead to an increase of the initial conditions leading to a bounce, a more exotic degree of freedom is required to achieve a generic cyclic behaviour.
